Reference to the diagram in the entry on **Skeletal System** will reveal the general structure of the spine, with the cervical vertebrae at the top of the spine and, progressing downward, the thoracic vertebrae and the lumbar vertebrae. The vertebral column, with 33 vertebrae, in a male of average height is about 28 inches (71 centimeters) long. Although the vertebrae differ in shape and size, they have a similar structure. The joints between the bodies of the vertebrae are somewhat movable and those between the arches are freely movable. *Disks* of fibrocartilage located between the vertebrae connect the bodies of the vertebrae and function essentially as shock absorbers. Because 31 nerves are associated with the spine, diseases and injuries of the spine and its vertebrae may seriously involve a few or several of these nerves. For example, in the cervical region, there are 8 pairs of nerves; in the thoracic region, 12 pairs; in the lumbar region, 5 pairs; in the sacral region, 5 pairs; and in the coccygeal region, 1 pair. The disks are subject to damage from trauma (injury) or degenerative changes. These factors may cause nerve root compression.

Cervical Disk Disease. In this ailment, a lateral protrusion or herniation, which most commonly occurs at the C5-6 or C6-7 vertebral spaces, may happen spontaneously, or as the result of trauma. A C5-6 disk rupture causes neck pain which is noted across the shoulders and down the arm, and may involve the thumb. Muscular weakness in the biceps may be noted. A C6-7 disk rupture causes pain and muscular weakness of the mid-arm (triceps brachii) and reduction of reflex that may extend to the index and middle fingers. Coughing, sneezing, etc., will usually accentuate these symptoms. Relief is usually provided by wearing a cervical collar adjusted to stretch the neck. The next step in therapy, if needed, is cervical traction, which normally does not require a hospital environment. In a minority of patients, surgical correction may be indicated.

Lumbar Disk Disease. Here the usual sites of disk protrusion are between the L4 and L5 and between the L5 and S1 interspaces. Lumbar herniation produces low back pain, which radiates and involves the thigh and calf. Such pain is accentuated by movement of the back, coughing, etc. The physician will differentiate this condition from peripheral nerve disease through a series of limb motion tests. Therapy commences with absolute bed rest in a hospital environment. Lying in a flat position is usually mandatory. Supportive measures, such as application of heat, use of analgesics to control pain, and the administration of muscle relaxants, such as diazepam, are immediately instituted. In most cases marked

improvement can be expected within about three weeks. In non-responsive cases, surgical correction is indicated.

Myeloma. The stimulus for malignant conversion of the plasma cells (*myeloma*) in humans is not known. Plasma cells reside in bone marrow. Replacement of normal marrow elements may become so extensive that plasmoblasts appear in the peripheral blood, causing plasma cell leukemia. Erosion of bone may be diffusive or take the form of tumors (*plasma cytomas*). Myeloma ultimately may involve many bones of the body and migrate to other organs, such as nerves and kidneys (*multiple myeloma*), or the myeloma may be confined to one bone for long periods. There may be involvement of the axial skeleton that leads to fractures and vertebral collapse. Where bone destruction is extensive, this may be evidenced by hypercalcemia (abnormally high calcium in blood), the symptoms of which include nausea, vomiting, and somnolence. The diagnosis of multiple myeloma is complex, involving hematologic, blood chemical, urinary, and radiologic studies. Ultimate therapy and prognosis is affected by the site of the plasmocytoma. Initially, the diagnosis of multiple myeloma may be suggested by the presence of high serum proteins. Radiation and chemotherapy are important elements in current procedures for the treatment of this disease. Myeloma confined to one site may progress slowly; multiple myeloma usually takes a rather rapid course, measured in terms of months or a few years.

During the last quarter-century, very little progress has been made in the treatment of multiple myeloma, during which period pessimism prevailed in terms of finding a possible cure for the disease. Essentially standard procedures during this period have included the melphalan-prednisone regimen introduced during the mid-1970s. A few other therapies have been introduced, but with indeterminate effectiveness in at least 50% of cases. In late 1991, G. Gahrton (see reference) of the Huddinge Hospital and Karolinska Institute, Huddinge, Sweden, and a large number of coresearchers reported on the allogeneic bone marrow transplantation in multiple myeloma. The report of the research and trials led to the conclusion, "Allogeneic bone marrow transplantation with the use of HLA-matched sibling donors appears to be a promising method of treatment for some patients with multiple myeloma." See also **Immune System and Immunology**.

Bone Marrow Transplantation

Although bone marrow transplantations have been made for a number of years, the procedure experienced much public attention as the result of the ionizing radiation injuries resulting from the Chernobyl (Russia) nuclear disaster of 1986.

Transplantation of bone marrow is a recognized modality for the treatment of aplastic anemia. Its principal current use is in the management of malignant disorders, particularly the acute leukemias and chronic myeloid leukemia.

Bone marrow is transplanted to restore to the bone marrow of the patient the functions of normally proliferating stem cells, which function in the formation of blood cells (*hematopoiesis*). The donor can be the patient (for autologous transplantation), the patient's identical twin (for isogenic, or syngenic, transplantation), or a histocompatible donor (for allogeneic transplantation), usually a sibling. Determination of histocompatibility involves clinical testing and matching of the donor and recipient. Statistics show that the usual patient will have a 30–40% chance of having a histocompatible sib donor. This, however, does not lead to a perfect transplantation match. In the procedure, the donor (under anesthesia) will yield about 750 ml of marrow suspension taken from the posterior and anterior iliac crests. After the marrow particles are passed through a sterile stainless steel screen to break them up, the suspension is infused intravenously into the recipient. After the stem cells circulate through the peripheral blood, they reach the marrow cavity. In allogeneic transplantation, the host's immune responses must be altered to avoid rejection of the infused cells. Cyclophosphamide is normally administered for this purpose. The marrow cells are infused 36 to 48 hours after the last dose of immunosuppressive drug. A complex clinical course follows. The effects of the procedure on the patient usually appear after 2 to 4 weeks, first noted by a rise in circulating granulocytes and later by an increase in the platelet count. In allogeneic transplantation, the engrafted cells may attack the host in a situation known as graft-versus-host disease (GVHD). This occurs in about half the cases. GVHD ranges in severity.

BONE CONDUCTION. The process by which sound is conducted to the inner ear through the cranial bones.

BONNER DURCHMUSTERUNG. The name applied to the monumental catalogue of over 324,000 stars observed by that tireless observer, F.W.A. Argelander. Accompanying the catalogue is an atlas of the heavens upon which each of the catalogued stars is shown by a dot, the size of the dot being proportional to the apparent brightness of the star. The catalogue contains practically every star brighter than the tenth magnitude north of declination -2°. The catalogue is commonly referred to as the B.D., and in many astronomical writings, a particular star is referred to by its B.D. number (i.e., by the number assigned to it in the Bonner Durchmusterung).

The catalogue was continued by Schonfeld down to declination -23°, and Thome, at Cordoba, has extended it still further to -61°. It is hoped that the plan will be continued to the South Pole.

In each of the catalogues, stars are numbered in order of increasing right ascension within a particular zone of declination. Hence, a star known as CDM -48 1116 is the 1116th star in the Cordoba extension of the B.D. catalogue between declination -48° and -49°.

BONNET, CHARLES (1720–1793). The only son of an aristocratic family, Bonnet was born in Geneva, and was educated by a tutor. He entered the Calvinist Academy (college) to study classics in 1735. His passion for natural history was awakened in 1736, by the reading of N. A. Pluche's *Spectacle of Nature*. This best-seller reported many rough experiments and ethological observations, aiming at glorifying God through Nature. As Bonnet himself started reproducing many entomological observations, he studied philosophy and physics (1737), before receiving a degree in law. Reading A.-F. Réaumur's *History of Insects* determined him to start corresponding with this famous French academician in the spring of 1738. Two years later, he repeated an experiment on the asexual reproduction of aphids, which Réaumur had not managed to achieve. Bonnet improved Réaumur's procedure with better isolation conditions and feeding of the aphids, and discovered the parthenogenesis on one generation in May 1740. The discovery was read by Réaumur before the Academy of Sciences, who immediately named Bonnet their correspondent –a prelude to 15 other prestigious distinctions. Following Abraham Trembley's suggestion, he then pushed his investigation of asexual reproduction up to nine generations of aphids and added to this the discovery of their cycle of oviparity and viviparity (1745). See also **Trembley, Abraham (1710–1784)**.

The year 1744 marked a turning point in Bonnet's life because of increasing eye pain which he attributed to a too frequent use of the microscope. Half-blind, he gave up insects to publish on plant physiology (1754) before focusing on the body–soul problem (1754, 1760). Here he formulated a psychophysiological but qualitative law of the correspondence between impressions and sensations. His peaceful marriage to the wealthy Jeanne-Marie de la Rive in 1756 was disturbed by both bad health and an accident during her pregnancy which eliminated any hope of children. Assisted in reading and writing by a secretary, Bonnet elaborated a general philosophy of nature in two books (1762, 1764) which synthesize the main naturalistic, physiological and ethological knowledge of his time. Written partly against J. T. Needham and G. Buffon's spontaneous generation theories, the *Contemplation of Nature* –"contemplation" meaning "observation" in the eighteenth century –can be considered the first handbook of biology published before the generalization of the Linnaean nomenclature occurring between 1770 and 1800. Bonnet defended a preformationist theory, i.e. all parts of the body are coexistent in the germ. But the emphasis on his preformationism and metaphysical ideas by historians has obscured his leading activity in the diffusion and advancement of the experimental method. For instance Bonnet corresponded with Lazzaro Spallanzani from 1765, asking him to perform many experiments, especially on the generation of infusoria, artificial fecundation and hybridization. See also **Buffon, Georges Louis (1707–1788)**; **Needham, John Turberville (1713–1781)**; and **Spallanzani, Lazzaro (1729–1799)**.

M. J. RATCLIFF, Wellcome Institute for the History of Medicine, London, UK

BONY-TAIL *(Osteichthyes)*. A fish (*Gila elegans*) of the Colorado and Gila rivers, related to the minnows and chubs.

BONY TONGUES *(Osteichthyes)*. Of the order *Isospondyli*, family *Osteoglossidae*, the bony tongues are fresh water fishes, apparently found only in the streams, rivers, and lakes of South America, Malaysia, Australia, and Africa. A bony plate covers the head, the eyes are large, and the body is covered with heavy scales. The *Arapaima gigas* (giant arapaima of the Amazon) is the largest of the species and, in fact, may be the largest of fresh water fishes. Records indicate attainment of lengths up to 15 feet (4.5 meters), but the average is considered to be less than 8 feet (2.4 meters). It is a favorite for aquariums. The scales are olive-green. The arapaima is well regarded as a food fish in South America, with the exception of Guyana, where it is not esteemed. The *Clupisudis niloticus*, found in African waters, is similar to the South American arapaima, but is much smaller, rarely attaining a length in excess of 3 feet (1 meter). Both of these species are nest builders. These nests are built in the sandy bottoms of shallow areas, the fish using the fins for digging. A typical nest will have a diameter of about 20 inches (51 centimeters). The *Osteoglossum bicirrhosum* (South American arawana) grows to about 2 feet (0.6 meter) in length and appears much as the arapaimas. See Fig. 1. It is suspected that it is a mouth breeder. Other species of bony tongues include: *formosus* (Borneo, Malay region, Sumatra); and *S. leichardtii* (Australia and New Guinea).

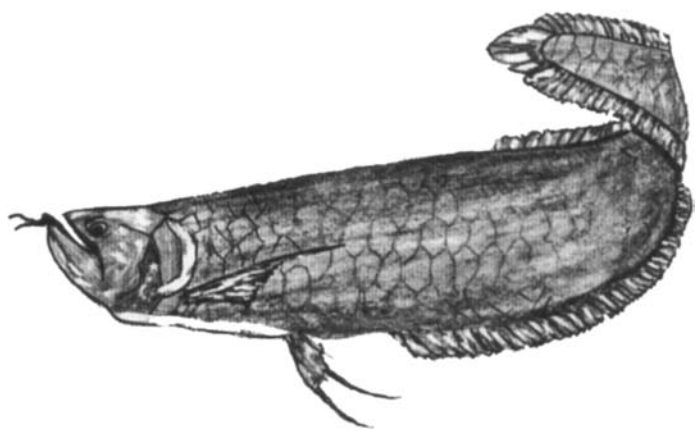

Fig. 1. Bony tongue. Arawana (*Osteoglossum bicirrhosum*).

BOOK LOUSE *(Insecta, Corrodentia)*. A small insect found in old papers, books and rubbish and in collections of biological specimens. The order to which they belong is a small one containing winged species found on bark and lichens, and wingless species to which this name is applied.

Book lice must be very numerous to do appreciable damage, and since they frequent damp situations, heating and drying rooms where they are found is usually a simple method of destroying them. Severe infestations can be checked by fumigation. See also **Corrodentia**.

BOOLEAN ALGEBRA. A distributive lattice that has universal bounds and has complements. (A lattice is distributive if $a(b+c) = ab + ac$ and $a \times bc = (a \times b)(a \times c)$, has universal bounds if it contains elements 0 and I with $0 \leqq a \leqq I$ for all a, and has complements if for every a there exists an a' such that $aa' = 0$ and $a + a' = I$.) Boolean algebra can be characterized in many other, equivalent ways. The subsets $a, b, \ldots$ of a set of objects S form a Boolean algebra if ab denotes the *intersection* and $a + b$ the *union* of a and b. The algebra of statements $a, b, c \ldots$ with connectives "and," "or," "not" form a Boolean algebra if $a + b$ means a or b (including the possibility of both), while ab means a and b. The simplest Boolean algebra is the one whose elements are the empty set θ, and the set of one point I.

In practical terms of computer technology, Boolean algebra, first proposed by George Boole (1815–1864) provides a mathematical procedure for manipulating logical relations in symbolic form. Boolean variables are confined to two possible states or values. The pairs of values possible are YES and NO, ON and OFF, TRUE and FALSE. In engineering practice, it is common to employ 1 and 0 as the symbols for the Boolean variables. Inasmuch as a digital computer generally will use signals which have only two possible states or values, Boolean algebra makes it possible for designers of computers to combine these variables mathematically and to manipulate the variables in a way to obtain that minimum design which provides a desired logical function. Some of the logical operations defined in Boolean algebra and their symbols are given in Table 1.

TABLE 1. LOGICAL OPERATIONS IN BOOLEAN ALGEBRA

Symbol	Definition	Logical Operation
$\cdot$	$A \cdot A = A, A \cdot 0 = 0, A \cdot 1 = 1, A \cdot \overline{A} = 0$	AND
$+$	$A + A = A, A + 0 = A, A + 1 = 1, A + \overline{A} = 1$	OR
$-$	$A\overline{A} = 0, A + A = 1$	NOT
$\oplus$	$A \oplus B = \overline{A}B + A\overline{B} = \overline{A \odot B}$	EXCLUSIVE OR
$\odot$	$A \odot B = \overline{A}\overline{B} + AB = \overline{A \oplus B}$	COINCIDENCE
/	$A/B = \overline{A} + \overline{B} = \overline{AB}$	NAND (OR SHEFFER STROKE)
/	$A/B = \overline{AB} = \overline{A + B}$	NOR (OR PEIRCE)

BOOLE'S INEQUALITY. An inequality concerning the frequencies in logical classes or equivalently of probabilities. For example, if $A_1, A_2, \ldots A_k$ are compatible events (any or all can occur at any particular trial) the probability that *at least* one occurs cannot exceed the sum of the probabilities that each occurs independently of the others.

BOOM. A boom is a movable inclined arm of wood or steel used on some types of cranes or derricks to support the hoisting lines that carry the loads. The loads cause direct compression in the boom due to the manner in which the hoisting lines are connected to the member.

The word boom also describes a floating chain of logs, which is anchored in such a position in a body of water as to deflect or intercept saw logs, or to prevent floating debris from approaching water intakes to pipe lines and penstocks. Nautically, a boom is a spar holding the foot of a fore and aft sail.

BOOSTER (Electrical). An electrical booster is inserted in series in an electric circuit, and increases the voltage of that circuit. There are several uses to which the booster can be put. It may be employed to compensate for a line voltage drop, or it may be employed to vary voltage in such a way that constant current is maintained. The boosting of dc circuits is accomplished by rotating equipment called booster generators. If this booster is driven by an electric motor the set is called a motor-booster. The booster generator can be used to raise the line voltage at a feeder point on an electric traction system.

The booster transformer is sometimes used in alternating current circuits. On a simple single-phase circuit it boosts the line voltage by connecting the primary of the transformer across the line, and the secondary in series. There are some disadvantages to this connection, however, since blowing of a fuse, or otherwise open-circuiting the primary, leaves the transformer connected as an open-circuited series transformer, and the open-circuit voltage on the primary winding may be excessive. The induction regulator is a form of booster transformer whose effect is varied by rotating one winding with respect to the other.

BOOTES (the herdsman). Although not in the zodiac, Bootes is one of the earliest recorded constellations. It is readily recognized in the early summer skies from the kite-shaped configuration of stars, with the bright star Arcturus at the position of the tail of the kite. Many of the other bright stars in Bootes are double stars, several of them forming interesting objects of study with relatively small instruments. (See map accompanying entry on **Constellations**.)

BOOTSTRAP. 1. Referring to a self-generating or self-sustaining process; specifically, the operation of liquid-propellant rocket engines in which, during main-stage operation, the gas generator is fed by the main propellants pumped by the turbopump, and the turbopump in turn is driven by hot gases from the gas generator system. Such a system must be started in its operation by outside power or propellants. When its operation is no longer dependent on outside power or propellant the system is said to be in bootstrap operation.

2. In computer operations, the coded instructions at the beginning of an input tape which together with manually inserted instructions, initiate a routine.

BORA. See **Winds and Air Movement**.

BORACITE. This mineral is a magnesium borate containing some chlorine, $Mg_3B_7O_{13}Cl$. It appears to be isometric but probably becomes so only at 265 °C, below which temperature it is believed to be ortho-rhombic. Its hardness is 7; specific gravity, 2.9; luster, vitreous; color, white to gray, sometimes yellow or green; translucent to subtransparent. It occurs in beds with gypsum and salt in Germany, particularly at Stassfurt in Saxony.

BORA FOG. See **Fog and Fog Clearing**.

BORANE. One of a series of boron hydrides (compounds of boron and hydrogen). The simplest of these, BH_3, is unstable at atmospheric pressure and becomes diborane [CAS: 19287-45-7] (B_2H_6) as gas at normal pressures. This is converted to higher boranes, i.e., penta-, deca-, etc., by condensation. This series progresses through a number of well-characterized crystalline compounds. Hydrides up to $B_{20}H_{26}$ exist. Most are not very stable and readily react with water to yield hydrogen. Many react violently with air. As a rule, they are highly toxic. Their properties have suggested investigation for rocket propulsion, but they have not proved satisfactory for this purpose. There are also a number of organoboranes used as reducing agents in electroless nickel-plating of metals and plastics. Some of the compounds used are di- and triethylamine borane and pyridine borane. See also **Carborane**; and **Organoborane**.

BORAX. [CAS 1303-96-4] This hydrated sodium borate mineral, $Na_2B_4O_7 \cdot 10H_2O$, is a product of evaporation from shallow lakes and plays. Borax crystallizes in the monoclinic system, usually in short prismatic crystals. Its color grades from colorless through gray, blue to greenish. Vitreous to resinous luster of translucent to opaque character. Hardness of 2–2.5, and specific gravity of 1.715.

Borax from the salt lakes of Kashmir and Tibet has been known since early history. India, the former U.S.S.R., and Persia possess small deposits. Extensive deposits are known in the United States, notably in Lake, San Bernardino, Inyo, and Kern Counties in California, and Esmeralda and Dona Ana Counties in New Mexico.

It is used in antiseptics and medicines, as a flux in smelting, soldering and welding operations, as a deoxidizer in nonferrous metals, as a neutron absorber for atomic energy shields, in rocket fuels, and as extremely hard abrasive boron carbide (harder than corundum). See also **Boron**.

BORDET, JULES JEAN BAPTISTE VINCENT (1870–1961). Bordet was born at Soignies, Belgium and at age 16 entered the University of Brussels, graduating Doctor of Medicine in 1892. By 1890, he was enhancing the virulence of *Vibrio metschnikovii* by passage in immunized animals. He received a travel grant in 1894 and served as preparator in Metchnikoff's laboratory at the Institut Pasteur in Paris from 1894 to 1901. In 1897 he traveled to the Transvaal to investigate rinderpest. He left the Institut Pasteur in 1901 to take up a post as Director of the Rabies and Bacteriology Institute of Brabant in Belgium. He received Madame Marie Pasteur's permission to rename the facility the Institut Pasteur de Bruxelles in 1903. In 1907, he was appointed Professor of Bacteriology in the Faculty

of Medicine of the Free University of Brussels. See also **Metchnikoff, Elie (Ilya) (1845–1916)**.

In addition to his discovery of *Bordetella pertussis*, the causative agent of whooping cough, Bordet also described the mycoplasma of bovine pleuropneumonia, bacteriophage lysogeny. He discovered the spirochete of syphilis but did not publish this finding. These are in addition to his legion of discoveries in immunology that include specific agglutination (1895), conglutination (1909), the antigenicity of antibodies and complement and, most importantly, his investigations of complement reactions. Noting the similarity of specific lysis of cholera vibrios by Richard Pfeiffer to the phenomenon of hemolysis described by Hans Buchner, Bordet decided to use the red blood cell system to illustrate complement activity rather than lysis of pathogenic bacteria as a model system. He investigated both bacterial lysis and the lysis of red blood cells. The lytic action of serum was sensitive to heat but could be restored by the addition of unheated normal serum. Bordet's experiment showed complement to be nonspecific and able to function only when target cells were sensitized with "substance sensibilisatrice." He showed the similarities of bacterial lysis and hemolysis. In 1900, Bordet showed further the nonspecific nature of complement by using the same source for both hemolysis and bacterial lysis. He demonstrated that complement, specifically C1, is fixed by bacteria that resist lysis, providing the foundation for the highly sensitive complement fixation test to detect specific antibodies in serum. Wassermann applied the complement fixation technique to the diagnosis of syphilis, a test that was used worldwide for many years. See also **Syphilis**.

Bordet debated with Paul Ehrlich concerning the latter's complex explanations of immune reactions. For example, Bordet believed toxin to be neutralized by antitoxin through absorption similar to a fabric interacting with a dye. He considered antitoxic sera to contain "substance sensibilisatrice," i.e. antibody, which sensitized red blood cells or bacteria to the action of "alexine," his term for complement. He postulated that this acts as a mordant does for a dyestuff. Thus, he disputed with Ehrlich about the nature and mechanism of action of antibodies and complement. This led to the publication in 1909–1910 of competing volumes entitled *Studies on Immunity*, one by the "Bordet school" and the other by Ehrlich and his colleagues. He received the Nobel Prize in Medicine or Physiology in 1919 for his studies on complement and its reactions. During his long and productive career, Bordet authored a popular text entitled *Trait de l'Immunité dans les Maladies Infectieuses* and trained a number of gifted investigators, including the prominent American bacteriologist/immunologist, F. P. Gay. The Bordet Institute in Brussels is named for him. See also **Ehrlich, Paul (1854–1915)**; and **Immunology (The History)**.

J. M. CRUSE and R. E. LEWIS, University of Mississippi Medical Center, Jackson, MS

BORDONI PEAK. A maximum in the internal friction spectrum at low temperatures found in all face-centered cubic lattices. It may be characterized by the fact that it only occurs in deformed poly- or single crystals. There are two peaks. The processes contributing to the peaks are thermally activated ones, and the peaks are removed only by annealing above the recrystallization temperature. The processes contributing to these peaks are believed to involve intrinsic dislocation loss mechanisms.

BORELLI, GIOVANNI ALFONSO (1608–1679). Giovanni Borelli's life and scholarly career were inextricably intertwined with political turmoil on the Italian peninsula. The son of an Italian woman and a Spanish soldier garrisoned near Naples, he numbered among his early friends the radical scholar Tommaso Campanella, who fled Italy after being implicated in plots against Spanish rule in the south. Borelli was likewise accused of anti-Spanish activities late in his life, and he spent his last years exiled in Rome with patronage from Queen Christina of Sweden, herself an exile following her conversion to Catholicism.

Borelli first visited Rome as a youth and studied there with a former pupil of Galileo shortly after the latter's trial for heresy in 1633. His mathematical abilities subsequently led to an appointment as Professor of Mathematics at Messina University in 1639 and then at Pisa in 1656. Although rapidly eclipsed by Isaac Newton's work, his 1666 treatise on celestial mechanics propounded a new physics for the heavens even while carefully skirting the ban on Copernican teachings by focusing on the orbits of Jupiter's moons rather than on planetary orbits around the sun. Borelli also pursued interests in anatomy and medicine during this time and corresponded frequently with his anatomist contemporary Marcello Malpighi, for whom he helped secure a faculty position at Messina. See also **Malpighi, Marcello (1628–1694)**.

Borelli's final work was a two-volume treatise *On the Movement of Animals*, dedicated to Christina and published posthumously in 1680–1681. It built on his previous writings concerning the physics of solids and fluids and was one of the earliest works to examine animal motion and physiology according to principles of mechanics. Critical of contemporaries including Malpighi who sometimes invoked chemical principles to explain the activities of living bodies, Borelli believed that a more thoroughly mechanical and corpuscular philosophy could bring anatomy into the fold of mathematical subjects such as physics and astronomy.

BORER *(Insecta)*. This term usually refers to the larval form of a beetle or moth, that is, a *grub*. The grubs of most species are voracious eaters of plants, with a wide range of targets, such as vegetables, fruits, nuts, grasses, grains, weeds, trees, etc. Some of the borers, such as the European corn borer, inflict many millions of dollars worth of damage to crops. Some of the borers of interest to food production and agriculture include the following:

Bronze birch borer (*Agrilus anxius* of the family *Buprestidae*, order *Coleoptera*). Attacks white or paper birches. Native to North America.

Clover root borer (*Hylastinus obscurus*, Marsham of the family *Scolytidae*, order *Coleoptera*). Prefers red and mammoth clover. Of lesser importance to white and sweet clover, alfalfa, pea, and vetch.

Currant borer (*Ramosia* or *Synanthedon tipuliformis*, Clerck of the family *Aegeriidae*, order *Lepidoptera*). Widely distributed in North America, but of European origin. Attacks currant, as well as black elder, gooseberry, and sumac. More injurious to black than to the red currant. The yellowish borers or larva ($\frac{1}{2}$-inch; 12 millimeters long) are found inside the canes just above groundlevel. Insect cannot be reached by contact insecticides.

European corn borer (*Pyrausta nubilalis*, Hübner of the family *Pyralididae*, order *Lepidoptera*). Although the insect feeds on a variety of herbaceous plants, it prefers corn (maize) whenever available. See Fig. 1. A native of Europe, this borer is widely distributed in Europe and Asia and was imported into North America in about 1917, believed to have been contained in a shipment of broomcorn from Italy or Hungary. As of the early 1950s, the insect had spread into all major corn-producing areas of the United States. Annual damage reported has been hundreds of millions of dollars on the corn crop. The insect winters as a fully developed worm or caterpillar in a burrow which it has made in the stem of a food plant. The worm ranges from $\frac{3}{4}$- to 1 inch (18 to 25 millimeters) in length and is flesh-colored, with rather small, round, brown spots on its back. The worm can be found in any part of the stem or ear, but during winter, the worm's most common location is in the cornstalk just above groundlevel. As the weather begins to warm, the caterpillar prepares a rather flimsy cocoon in the burrow and there transforms into a smooth, brown pupal stage. Adult moths emerge in late spring at which time they may migrate considerable distances. Their movement is mainly at night. When young corn plants are in abundance, the female moth (pale yellow-brown) deposits from 500 to 600 eggs on the underside of leaves of the target plant, corn (maize) when available. Until about half-grown, the young larva feeds in tight spaces

Fig. 1. European corn borer. (*USDA diagram.*)

between leaves, husks, or ear and stalk. After they are half-grown, they commence feeding on the stalk, the ear, and all thicker portions of the plants. To do this, they commence boring. This feeding operation continues until the larva is fully developed. Researchers have counted nearly 200 borers on a single plant and over 40 borers have been found in a single ear.

Chemical controls can be effective, but preventive measures are also very important. These include removal and burning of infested debris. Late-planting has been found of value in some areas. Planting of resistant varieties is extremely important. Rotations also are effective. Parasites have been introduced as natural enemies of the corn borer, a number of which have been established. These include *Lydella stabulans grisescens* and *Macrocentrus gifuensis*. Certain fungi, such as *Beauveria bassiana* and *Perezia pyraustae* (protozoan), also are effective.

Flatheaded apple tree borer (*Chrysobothris femorata*, Oliver, family *Buprestidae*, order *Coleoptera*). A very severe economic pest of deciduous fruit trees, as well as numerous decorative shrubs and trees. The insect is particularly damaging to young trees, during the first 2 to 3 years after planting. They are more active during dry periods. The insect mines the main trunk as well as large branches, just under the bark and penetration into the wood may be as much as 1 or 2 inches (2.5 to 5 centimeters). Such injuries are found most frequently on the sunny side of the tree. The burrows are packed with wood debris (sawdust) or excelsior fibers. All fruit-producing areas of the United States and Canada are affected. A close relative, the Pacific flatheaded borer (*Chrysobothris mali*, Horn), occurs throughout western North America and is found as far south as Arizona and Texas. The insect winters in the form of the grub (borer) stage. Length may range from $\frac{1}{2}$- to 1-inch (12 to 25 millimeters). As the borer develops, it penetrates more deeply into the wood. When mature, the grub is yellowish-white, legless, with a characteristic enlargement just in back of the head. The beetle usually lies with part of its body curled to one side. The adult beetle has a very blunt head, is about $\frac{1}{2}$-inch (12 millimeters) long and about $\frac{1}{5}$-inch (5 millimeters) wide. They are a dark-green-brown color with a metallic cast and distinctly love sunlight.

Peach tree borer (*Sanninoidea* or *Conopia esitiosa*, Say, family *Aegeriidae*, order *Lepidoptera*). This is the most severe economic pest of peach. The pest also attacks apricot, cherry, nectarine, plum, and prune. The insect winters in the larval form and ranges widely in length up to about $\frac{1}{2}$-inch (12 millimeters). Some varieties may be as short as $\frac{1}{8}$-inch (3 millimeters). Size variation results from differing spans of time allowed for the worms to develop. Shortly after the soil has had opportunity to warm in the spring, the worms become active. At this time, the worms, about 1 inch (2.5 centimeters) in length, congregate under the bark of the tree and close to the ground. The worm is a dirty-white color with a dark, brownish head and has a noticeable plate behind its head. Very shortly, they convert into a cocoon to the brown pupal stage and will be found on the surface of the burrows they have made, or immediately under the soil. The range is from about 2 to 3 inches (5 to 7.5 centimeters) below ground level to about 1 foot (0.3 meter) above the ground. In observing an infected tree, one may see considerable bark debris at the base of the tree. The adults emerge in mid-summer, but this process may continue until late September. The moth has clear hind wings, is of a blue-black coloration with an orange crossband on the abdomen. See Fig. 2. They are somewhat wasp-like in appearance and flight pattern.

Unless eradicated, the moths usually kill a tree within a season or two. The insect is prolific, the female laying from 200 to 800 eggs on the tree trunks or in separations in the soil very close to the trunk. Certain chemical controls have proven relatively effective. Treatment is similar to that for peach twig borer, described next in this list. The peach tree borer is distributed throughout the United States and Canada. A related species is the western peach tree borer (*S. exitiosa graefi*). The lesser peach tree borer (*Synanthedon pictipes*, Grote and Robinson) is similar in its habits and destruction to deciduous trees.

Peach Twig Borer (*Anarsia lineatella* Zeller, family *Gelechiidae*, order *Lepidoptera*). The insect attacks almond, apricot, peach, and plum. The insect winters as a partially grown caterpillar. The caterpillar is brown with a black head, very small, ranging from $\frac{1}{16}$- to $\frac{1}{8}$-inch (1.5 to 3 millimeters) in length. It hides in a cocoon that is closely fixed to the tree bark, either on trunk or branches. The larva leaves the cocoon at same time the tree is leafing out, and commences to feed on the tender new growth, causing wilting and destruction of twigs. The worms become about $\frac{1}{2}$-inch (12 millimeters) long and then again spin cocoons on the larger tree branches, or even the tree trunk. They become small, grey moths, with a wingspread of only about $\frac{1}{2}$-inch (12 millimeters). The female moth lays her eggs on twigs and the cycle is repeated. As many as four generations can occur per year.

Young borers can be cut from the tree with a knife. However, care must be taken not to cut away more wood than necessary. Older borers can be killed by probing the wood with a wire with a hooked tip. The wound should be painted over to reduce damage from other insects and diseases.

Pear tree borer (*Agrilus sinuatus*, Oliver, family *Buprestidae*, order *Coleoptera*). This insect affects pear as well as some timber and shade trees. A native of Europe, the insect has been known in North America since the mid-1890s, particularly in the northeastern states. The life cycle of the insect is typical of moths. Both adult beetle and larva cause damage, the grubs burrowing into the bark and the beetles feeding on foliage.

Potato stalk borer (*Trichobaris trinotata*, Say, family *Curculionidae*, order, *Coleoptera*). An occasional pest in potato fields. The beetle larva eats out the interior of the plant stalks, usually causing the plant to die. The insect is most injurious to early potatoes. Other plants attacked include eggplant and several weeds.

Shot-hole borer (*Scolytus rugulosus*, Ratzeburg, family *Scolytidae*, order *Coleoptera*). There are numerous species of this insect. The larva is a white to yellowish-white or brown grub from 1 to $1\frac{1}{2}$ inches (2.5 to 4 centimeters) in length. See Fig. 3. The insect is very similar in habit to the bark beetle, attacking both trunk and branches of apple, cherry, peach, and plum trees. Serious attacks of this insect are usually limited to unhealthy and injured trees.

Squash vine borer (*Melittia cucurbitae*, Harris, family *Aegeriidae*, order *Lepidoptera*).

Strawberry crown borer (*Tyloderma fragariae*, Riley, family *Curculionidae*, order *Coleoptera*). Essentially, a pest of the midwestern United States and notably damaging in bluegrass regions of Kentucky and Tennessee. The insect winters as snout beetles about $\frac{1}{6}$-inch (4 millimeters) long among debris in strawberry patches. Damage is caused by thick-bodied, white grubs (about $\frac{1}{5}$-inch; 5 millimeters long) that tunnel through the strawberry crowns, not always killing the plants, but greatly reducing yields. Cultural practices are the best prevention.

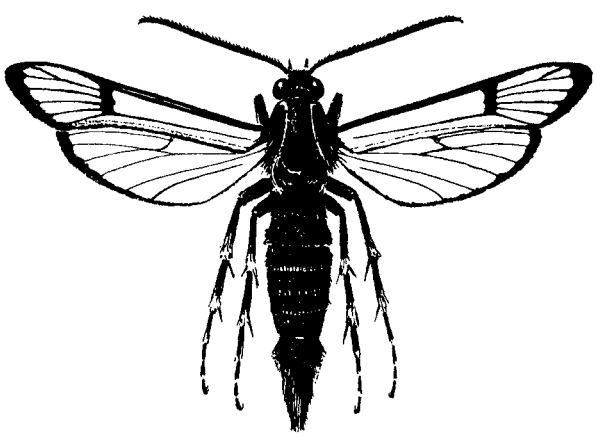

Fig. 2. Adult peach tree borer. (*USDA diagram.*)

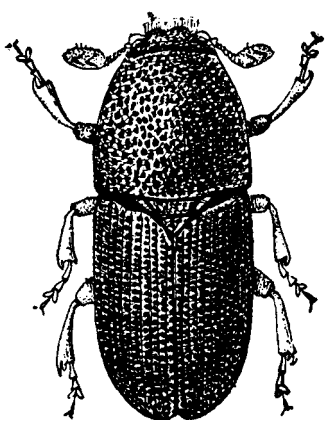

Fig. 3. Shot-hole borer. (*USDA diagram.*)

BORE (Tidal). A large, turbulent, wall-like wave of water with a high abrupt front, caused by the meeting of two tides or by a very rapid rise or rush of the tide up a long, shallow, and narrowing estuary, bay, or tidal river where the tidal range is appreciable; it can be 3–5 meters high and moves rapidly (10–15 knots) upstream with and faster than the rising tide. (*Glossary of Geology*, American Geologic Institute.) See also **Estuary**.

An interesting example of a tidal bore can be seen in North America at Moncton, New Brunswick, Canada. The effects of very large tidal changes in the Bay of Fundy are transmitted to the Petitcodiac River, on which Moncton is located, by way of Chignecto Bay and Shepody Bay. At Moncton, the tidal bore ranges several feet (meters) in height. This can be observed from a special bridge constructed for visitors.

BORIC ACID. See **Boron**.

BORING (Soil). Through site investigations of a geological and structural nature should be conducted prior to the construction of any major work that requires an excellent foundation. This practice should and often does extend to residences that are to be built on a hillside, beach, and other locations that may have a prior history of instability. Site investigations are best made prior to procurement of a site, but certainly before the commencement of construction. Test pits provide visual examination of soil in place and make it possible to manually procure an undisturbed sample of soil. Pit digging costs, however, increase with depth. Thus other methods frequently are used except for relatively shallow depths.

In *wash boring*, a hole is formed in the ground for soil sampling or rock drilling. The equipment consists of a hollow pipe called a jet pipe and a larger hollow pipe called a casing. Water under pressure is forced down the jet pipe. This water washes disintegrated material up through the space between the jet pipe and casing to the surface where it may be retained for future examination. As the material at the bottom of the casing is washed away, the casing is slowly forced downward. Information also is obtained on subsoil characteristics by noting the resistance of the casing to driving. Generally, this method is relatively unsatisfactory because the jetting disturbs the soil and the wash water leaves coarse particles behind.

Where the precise character and formation of subsurface rock formations must be known, as in the case of foundations for important dams, core boring (sometimes called core drilling) is usually a necessity. A core drill consists of a hollow cylindrical bit with its cutting edge set with hard cutting particles (such as commercial diamond particles) connected to a hollow cylindrical drill shank. The whole is rotated by mechanical power and thus cuts out a vertical, or inclined, cylinder of the rock. These cores are periodically removed and when reassembled constitute a clear and visible section of the rock structures pierced.

BORN APPROXIMATION. A method of computing approximately the wave-functions and cross-section in the quantum mechanics of collision processes, chiefly applicable when the interaction energy between the colliding particles is small compared with their kinetic energy. Thus the first Born approximation corresponds to keeping terms of first order in the interaction energy, which is treated as a perturbation to the Hamiltonian of the system.

BORNITE. Named for the German mineralogist of the eighteenth century, Ignatius von Born, this mineral is a sulfide of copper and iron corresponding to the formula Cu_5FeS_4. It is isometric with a cubic habit, although crystals are rare, usually occurring as granular or compact masses. Its fracture is conchoidal to uneven; brittle; hardness, 3; specific gravity, 5.079; color, copper-red to reddish-brown (hence the name horseflesh ore) when freshly fractured; it soon assumes an iridescent tarnish (hence the name peacock ore); luster, metallic; streak, grayish-black; opaque.

Bornite as a primary mineral has been observed in pegmatite veins and in igneous rocks and is also a common secondary mineral.

Bornite crystals have been obtained in Austria and England. As an ore it is important in Tasmania, Chile, Peru and in Montana. In the United States, bornite also has been found in Connecticut, and in Canada, in the Province of Quebec.

Bornite also is known as *peacock ore* and *horseflesh ore*.

BORN, MAX (1882–1970). A German-born British physicist, Max Born studied mathematics and physics and in 1904 became David Hilbert is private assistant for. While at the University of Breslau, he won a competition on the stability of elastic wires and it became the dissertation for his Ph.D. After graduate school, he studied special relativity for a while, then became interested in the physics of crystals. In 1912, he published the Born-Karman theory of specific heats and his work on crystals is a cornerstone of solid-state theory.

Born coined the term "Quantum mechanics" and in 1925 devised a system called matrix mechanics, which accounted mathematically for the position and momentum of the electron in the atom. He devised a technique called the Born approximation in scattering theory for computing the behavior of subatomic particles which is used in high-energy physics. Also, interpretation of the wave function for Schrodinger's wave mechanics was solved by Born who suggested that the square of the wave function could be understood as the probability of finding a particle at some point in space. For this work in quantum mechanics, Max Born received the Nobel Prize in Physics in 1954.

See also **Born Approximation**.

J. M. I.

BORN-OPPENHEIMER APPROXIMATION. An argument for calculating the force constants between atoms in a molecule or solid, based on the observation that the motion of the electrons is so rapid compared with that of the heavier nuclei that it can be assumed that the electrons follow the motion of the nuclei adiabatically. That is, one calculates the eigenvalues of energy for the electrons with the nuclei in fixed positions; the variation of this electronic energy with the configuration of the nuclei may then be treated as a contribution to the potential energy of the interatomic forces.

BORON. [CAS:7440-42-8] Chemical element, symbol B, at. no. 5, at. wt. 10.81, periodic table group 13, mp 2079 °C, sublimes at approximately 2550 °C, density 2.35 g/cm^3 (amorphous form). There are four principal crystal modifications of boron: (1) α-rhombohedral, (2) β-rhombohedral, (3) I-tetragonal, and (4) II-tetragonal. There are two natural isotopes, ^{10}B and ^{11}B. In 1807, Davy first produced elemental boron in amorphous form by electrolyzing boric acid. A year later, Gay-Lussac and Thénard produced elemental boron by reducing boric acid with potassium. However, it was not until 1892 that boron with a purity of over 90% was produced by Moissan, who reduced the element from B_2O_3. Moissan observed that the produced substances earlier claimed to be elemental boron were in effect compounds of boron. First ionization potential 8.296 eV; second 23.98 eV; third 37.75 eV. Oxidation potential $B + 3H_2O \rightarrow H_3BO_3 + 3H^+ + 3e^-$, 0.73V; $B + 4OH^- \rightarrow H_2BO_3^- + H_2O + 3e^-$, 2.5 V. Other important physical properties of boron are given under **Chemical Elements**.

Boron is (1) a yellowish-brown crystalline solid and (2) an amorphous greenish-brown powder. Both forms are unaffected by air at ordinary temperatures but when heated to high temperatures in air form oxide and nitride. Crystalline boron is unattacked by HCl or HNO_3, or by NaOH solution, but with fused NaOH forms sodium borate and hydrogen; reacts with magnesium but not with sodium.

Boron occurs as rasorite or kernite (sodium tetraborate tetrahydrate, $Na_2B_4O_7 \cdot 4H_2O$) and colemanite (calcium borate, $Ca_2B_6O_{11} \cdot 5H_2O$) in California, as sassolite (boric acid, H_3BO_3) in Tuscany, Italy, and also locally in Chile, Turkey, and Tibet. See also **Colemanite**; **Kernite**; and **Ulexite**.

Production: Commercial boron is produced in several ways. (1) Reduction with metals from the abundant B_2O_3, using lithium, sodium, potassium, magnesium, beryllium, calcium, or aluminum. The reaction is exothermic. Magnesium is the most effective reductant. With magnesium, a brown powder of approximately 90–95% purity is produced. (2) By reduction with compounds, such as calcium carbide or tungsten carbide, or with hydrogen in an electric arc furnace. The starting boron source may be B_2O_3 or BCl_3. (3) Reduction of gaseous compounds with hydrogen. In an atmosphere of a boron halide, metallic filaments or bars at a surface temperature of about 1200 °C will receive depositions of boron upon admission of hydrogen to the process atmosphere. Although the deposition rate is low, boron of high purity can be obtained because careful control over the purity of the starting ingredients is possible. (4) Thermal decomposition of boron compounds, such as the boranes (very poisonous). Boranes in combination with oxygen or H_2O are very reactive. In this process, boron halides, boron sulfide, some borides, boron phosphide, sodium borate and potassium borate also can be decomposed thermally. (5) Electrochemical reduction of boron compounds where the smeltings of metallic fluoroborates or metallic borates are electrolytically decomposed. Boron oxide alkali metal oxide–alkali chloride compounds also can be decomposed in this manner.

Both chemical methods and float zoning are used to purify the boron product from the foregoing processes. In the latter method, a boron of 99.99% purity can be obtained.

Although the chemistry of boron is extremely interesting, there is no substantial market for elemental boron. Some boron compounds are high-tonnage products. Elemental boron has found limited use to date in semiconductor applications, although it does possess current-voltage characteristics that make it suitable for use as an electrical switching device. In a limited way, boron also is used as a dopant (*p*-type) for $p-n$junctions in silicon. The principal problem deterring the larger use of boron as a semiconductor is the high-lattice defect concentration in the crystals currently available.

Uses of Boron. As early as 1959, boron filaments were introduced as the first of a family of high-strength, high-modulus, low-density reinforcements developed for advanced aerospace applications. A process was engineered by Avco Specialty Materials (Lowell, Massachusetts) and the U.S. Air Force to manufacture boron filaments that had high strength and high stiffness, but low density and, hence, low weight. During the interim, advanced boron fibers have been used as a reinforcement in resin-matrix composites. Boron aluminum has been used for tube-shaped truss members, for reinforcing space vehicle structures, and has also been considered as a fan blade material for turbofan jet engines. However, boron's rapid reaction with molten metals, such as aluminum, and the degradation of its mechanical properties when diffusion-bonded at temperatures above 480 °C have been difficult to surmount. These shortcomings led to the development of silicon-carbide (SiC) fibers for some applications.

The principal use of boron filaments is in the form of continuous boron-epoxy pre-impregnated tape, commonly known as *prepreg*. The boron filaments are unidirectionally arranged and occupy about 50% of the composite volume. Typically, there are about 200 filaments/inch (8/cm). Usually, the resin content is about 30–35% (weight). Boron composites have been used in military aircraft, including helicopters. In addition to aircraft, boron-epoxy composites have been used in tennis, racquetball, squash, and badminton rackets, fishing rods, skis, and golf club shafts, for improving strength and stiffness.

Boron, which is extremely hard (3300–3500 on the Knoop scale; 9.5 on the Mohs scale), has been used in cutting and grinding tools. Boron is 30–40% harder than silicon carbide and almost twice as hard as tungsten carbide. Boron also has interesting microwave polarization properties. Research (Southern Illinois University) has shown that a single ply of boron epoxy will transmit 98.5% and reflect 0.6% of the incident microwave power when the angle between the grain and the E-field is 90°. This property has been useful in the design of spacecraft antennas and radomes.

As described by Buck, a chemical vapor deposition (CVD) process is used to form boron fibers. A small-diameter substrate wire is run through a glass reactor tube and suitable gases are introduced. The substrate is heated by electrical resistance, causing the gases to react and allowing boron to deposit on the heated wire, thus forming the filament. In the process, elemental boron is obtained through the reaction of boron trichloride and hydrogen gases.

Various boron compounds have been used as rocket fuels, diamond substitutes, and additives to aluminum alloys to improve electrical and thermal conductivity, as well as for grain refining. Boron hydrides are sensitive to shock and can detonate easily. Boron halides are corrosive and toxic.

Biological Functions: Although boron is required by plants, there is little solid evidence to date that it is required for the nutrition of livestock or humans. Boron deficiency may alter the levels of vitamins or sugars in plants owing to the effect of boron upon the synthesis and translocation of these compounds within the plant. The addition of boron to some boron-deficient soils has increased the carotene or provitaminA concentration in carrots and alfalfa.

Like several of the other trace elements, while concentrations of very low levels are desirable, high levels of boron are toxic to plants. Different plant species vary widely in their requirement for this element and in their tolerance for high levels. Application of boron-containing fertilizer can be carefully adjusted for different crops. An application of boron-containing fertilizer to improve the yields of alfalfa or beets may be toxic to such boron-sensitive crops as tomatoes and grapes. In the southwestern United States, serious boron toxicity to plants has resulted from using irrigation waters that are high in boron.

Boric Acid: [CAS: 1303-86-2] Boric oxide, B_2O_3, is acidic. It exists in two forms, a glassy form obtained by high temperature dehydration of boric acid, and crystalline form obtained by slow heating of metaboric acid.

The oxyacids of boron are of two types: (A) the boric acids, based upon boric oxide, and (B) the lower oxyacids based upon boron-to-boron structural linkages.

The really acidic boric acids consist essentially of metaboric acid (HBO_2), a polymer, and boric or orthoboric acid, H_3BO_3($pK_a = 9.24$). There is no compound corresponding to the formula for tetraboric acid, $H_2B_4O_7$, although there are a number of salts that may be based upon this composition. Sometimes called *boracic acid*, [CAS: 10043-35-3] H_3BO_3, is a high-tonnage material, the main uses being in the medical and pharmaceutical fields. A saturated solution of H_3BO_3 contains about 2% of the compound at 0 °C, increasing to about 39% at 100 °C. The compound also is soluble in alcohol. In preparations, solutions of boric acid are nonirritating and slightly astringent with antiseptic properties. Although no longer used as a preservative for meats, boric acid finds extensive use in mouthwashes, nasal sprays, and eye-hygiene formulations. Boric acid (sometimes with borax) is used as a fire-retardant. A commercial preparation of this type (*Minalith*) consists of diammonium phosphate, ammonium sulfate, sodium tetraborate, and boric acid. The tanning industry uses boric acid in the deliming of skins where calcium borates, soluble in H_2O, are formed. As sold commercially, boric acid is $B_3O_3 \cdot 3H_2O$, prepared by adding HCl or H_2SO_4 to a solution of borax.

Borates. Sodium tetraborate [CAS: 1330-43-4], $Na_2B_4O_7 \cdot 10H_2O$, is a very-high-tonnage material. Natural borax has a hardness of 2–2.5, mp 75 °C, sp gr 1.75. An aqueous solution of borax is mildly alkaline and antiseptic. The compound finds many uses, including: (1) cleaning compounds of numerous types; (2) important ingredient of glass and ceramics, notably for heat-resistant glass where as much as 40 pounds of borax may be required per 100 pounds of finished glass; (3) source of elemental boron and other boron compounds; (4) flux for soldering and welding; (5) constituent of fertilizers; (6) filler in paper and paints; and (7) corrosion inhibitor in antifreeze formulations. Borax also is used in fire retardants.

Chemistry of Boron and Other Boron Compounds. In 1901, the German chemist Alfred Stock stated, "It was evident that boron, the close neighbor of carbon in the periodic system, might be expected to form a much greater variety of interesting compounds than merely boric acid and the borates, which were almost the only ones known." In 30 years of research that followed that statement, Stock synthesized almost all of the important *boranes* (hydrogen and boron). Some of these compounds now find use in glass, ceramics, synthetic lubricants, and as ingredients of high-energy rocket fuels and jet-engine and automotive fuels. Further pioneering of borohydride chemistry was carried on by Schlesinger and Burg of the University of Chicago in the late 1940s. Boron carbide, B_4C, is used as neutron-absorbing material in nuclear reactors. Sodium borohydride, $NaBH_4$, is applied as a reducing agent in the manufacture of certain synthetics. Although not ultimately selected, because of the greater volatility of uranium hexafluoride, UF_6, both uranium borohydride, $U(BH_4)_4$, and its methyl derivative, $U(CH_3BH_3)_4$, were considered for use in separating the isotopes of uranium during the Manhattan Project. ^{10}B is used in brain tumor research. When injected intravenously, borax concentrates in the areas of tumors and its presence can be detected by radiation techniques. With further research, the tendency of boron to link with itself may comprise the foundation of future inorganic polymeric materials. Although they have poor mechanical strength, boron-phosphorus polymers, prepared by reacting diborane with phosphone derivatives, do exhibit excellent heat-resistance.

X-ray diffraction studies show five general types of structures in solid borates:

1. Discrete anions containing individual BO_3^{3-} groups, or a limited number of other groups combined by sharing oxygen atoms. (The simplest is $B_2O_5^{4-}$, which is called pyroborate.)
2. Extended anions in which individual BO_3 groups are linked into rings or chains, such as $B_3O_6^{3-}$ or $B_2O_4^{2-}$ (metaborate).
3. Sheet structures in which all the oxygen atoms are shared between borate groups, as in $B_5O_{10}^{5-}$ (pentaborate).
4. Structures containing the tetrahedral $B(OH)_4^-$ ion, which is the principal ion found in alkaline aqueous solutions.

5. Extended anions containing tetrahedral BO_4 units, usually linked with triangular BO_3 groups.

The lower oxyacids of boron may be derived from the various boron hydrides, whence their boron-boron linkages result. These compounds include the hypoborates, which may be produced by reactions of tetraborane with strong alkali, and which may be formulated from the structure $H_2[H_6B_2O_2]$; the subborates, derived from $H_4[B_2O_4]$, which is called subboric acid; and the borohydrates, which are derived from acids of various compositions, such as $H_2[B_4O_2]$, $H_2[B_2O_2]$ and $H_2[H_4B_2O_2]$. The last of these compounds contains a double-bonded boron-boron linkage, and exhibits *cis-trans* isomerism.

The borides are binary compounds of boron with metals or electropositive elements in general. Except in isolated cases their compositions depart from the stoichiometry of trivalent boron compounds and are determined more by the requirements of metal and boron lattices than by valencies. On the basis of composition, they may be classified into types based respectively upon zigzag chains (MB) represented by CoB; isolated boron atoms (M_2B) represented by Co_2B; double chains (M_3B_4) represented by Mo_3B_4; hexagonal layers (MB_2) represented by CoB_2; three-dimensional frameworks (MB_6 or MB_{12}) represented by SiB_6 or UB_{12}. It is apparent that these borides are interstitial compounds existing primarily with the metals of main groups, II, III, IV, V, and VI.

There are at least six definitely characterized boron hydrides, as follows: diborane(6), B_2H_6; tetraborane(10), B_4H_{10}; pentaborane(9) (stable), B_5H_9; pentaborane(11) (unstable), B_5H_{11}; hexaborane(10), B_6H_{10}; and decaborane(14), $B_{10}H_{14}$. In these names, note that the prefix denotes the number of boron atoms, while the figure in parentheses denotes the number of hydrogen atoms. In addition to these compounds, which are all gases or volatile liquids except decaborane(14), decomposition of the lower boron hydrides yields colorless or yellow solid boron hydrides, ranging in composition from $(BH_{1.5})_x$ to $(BH)_x$. This readiness to polymerize is evidence of the reactivity of these borane compounds, which readily form additional products with ammonia, with the amalgams of the active metals, and with many organic compounds, as well as with CO.

In addition to BH_4^- there exist a number of hydroborate anions, which may be derived from real or hypothetical boron hydrides by addition of hydride ion. These include $B_2H_7^-$, formed by the reaction of B_2H_6 and BH_4^- in organic solvents, and the extremely stable ions $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ unaffected by either acidic or alkaline aqueous solutions or by atmospheric oxygen. Free halogens merely cause substitution of halogen for hydrogen. The structure of $B_{10}H_{10}^{2-}$ is based on the square antiprism, while that of $B_{12}H_{12}^{2-}$ is a regular icosahedron.

In 1976, the Nobel Prize for Chemistry was awarded to William Nunn Lipscomb, Jr., of Harvard University, for original research on the structure and bonding of boron hydrides and their derivatives. As pointed out by Grimes (1976), the insight into electron-deficient borane structures originally provided by Lipscomb carries over not only to the carboranes, but also to their organic cousins, the so-called "nonclassical" carbonium ions. The three-center bond descriptions given by Lipscomb to B_5H_9 and B_6H_{10} can as easily be applied to their hydrocarbon analogs, the pyramidal ions $C_5H_5^+$ and $C_6H_6^{2+}$, both presently known as alkyl derivatives. Also, molecules usually not so considered, such as metallocenes, organometallics, such as $(C_4H_4)Fe(CO)_3$ or $[(CO)_3Fe]_5C$, metal clusters and others, can be considered from the perspective of borane analogs. The boranes, once considered peculiar, over the years have provided insight to many cluster-type molecules, for which classical Lewis bond descriptions do not fit. Lipscomb's lecture given in Stockholm on December 11, 1976 provides an excellent overview of the boranes and their relatives.

In 1979, the Nobel Prize for Chemistry was received by Herbert C. Brown (shared with Georg Witting for research in another field) of Purdue University for the discovery of the *hydroboration reaction*. This reaction, depicted below, has made the organoboranes readily available as chemical intermediates. The boron atom adds to the less substituted carbon atom. As pointed out by Brewster and Negishi (1980), depending upon steric factors, mono-, di-, or trialkylboranes may be formed. These products comprise synthetically useful reactions whereby the boron atom is replaced, but the mono- and dialkylboranes are also useful as reducing or hydroborating agents.

$$RCH{=}CH_2 + B_2H_6 \longrightarrow (RCH_2CH_2{-})_3B \qquad (1)$$

$$CH_3{-}C{=}CHCH_3 + B_2H_6 \longrightarrow (CH_3{-}CH{-}CH{-})_2BH \qquad (2)$$

(CH$_3$ on the left; CH$_3$ CH$_3$ on the right)

$$CH_3{-}C{=}C{-}CH_3 + B_2H_6 \longrightarrow CH_3{-}CH{-}C(CH_3){-}BH_2 \qquad (3)$$

(CH$_3$ CH$_3$ on the left; CH$_3$ CH$_3$ on the right)

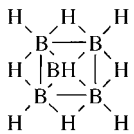
Among the other inorganic compounds of boron are the following:

Borides: Carbon boride, CB_6, and silicon borides SiB_3 and SiB_6 are hard, crystalline solids, produced in the electric furnace; magnesium boride, Mg_3B_2, brown solid, by reaction of boron oxide and magnesium powder ignited, forms boron hydrides with HCl; calcium boride, Ca_3B_2, forms boron hydrides and hydrogen gas with HCl.

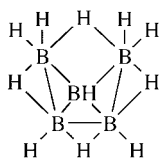
Nitride: Boron nitride, BN, white solid, insoluble, reacts with steam to form NH_3 and boric acid, formed by heating anhydrous sodium borate with ammonium chloride, or by burning boron in air.

Sulfide: Boron sulfide, B_2S_3, white solid, unpleasant odor, irritating to the eyes, reactive with water to form boric acid and hydrogen sulfide, formed by reaction of boron oxide plus carbon heated in a current of CS_2 at red heat.

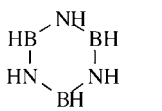
The great number of compounds of boron is due to the readiness with which boron atoms form, to some extent, chain structures with other boron atoms, and, to a far greater extent, cyclic compounds, both with other boron atoms, and with atoms of carbon, oxygen, nitrogen, phosphorus, arsenic, the halogens, and many other elements. Examples of them are shown below, beginning with the two pentaboranes B_5H_9 and B_5H_{11}:



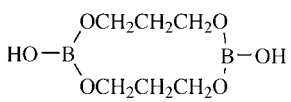
B_5H_9 Pentaborane (9)



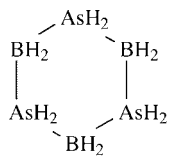
B_5H_{11} Pentaboranze (11)



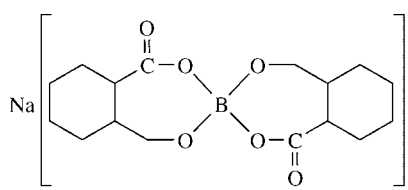
hexahydro-*s*-triazatriborine
(also called *borazine*)



2,8-dihydroxy-1,3,7,9-tetroxa-
2,8-diboracyclododecane



dodecahydro-*s*-triarsatriborine
(also called *s*-triphosphatri-
borane or *borarsane*)

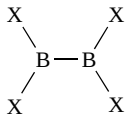


sodium dis(salicylato-*O*,*O*′)borate (1–)

Halides: Since simple boron compounds have only three electron pairs in the valence shell of boron, they tend to be electron acceptors. Its simple molecules are formed by sp^2 hybrid sigma bonds lying in a plane. Its strong tendency to form an octet is shown by the tetrahedral boron compounds

involving sp^3 hybridization. Boron halides include the trifluoride, BF_3, the trichloride, BCl_3, the tribromide, BBr_3 and the triiodide, BI_3, which range in mp from −127 to +43 °C. Typical methods of forming the boron halides are: treatment of boron oxide with hot concentrated H_2SO_4 in a reaction mixture with calcium fluoride to produce BF_3, and by heating boron, or boron oxide plus carbon with chlorine to produce the chloride.

In addition to the simple halides, boron forms fluorine complexes containing the fluoroborate ion (BF_4^-) Subhalides of boron are known (B_2X_4) of the structure:



and B_4X_4 of the structure

BOSE, SATYENDRA NATH (1894–1974). Bose was a theoretical physicist from India. He is chiefly known for the development of Bose-Einstein statistics. In 1924, he wrote his famous paper, "Planck's Law and the Hypothesis of Light Quanta." When Einstein reviewed the paper, he was so impressed he translated it into German and had it published. Bose derived Planck's formula for black body radiation in purely quantum terms requiring thinking of the radiation as a collection of photons. Einstein applied Bose's technique to a collection of particles and the result is known as Bose-Einstein statistics.

Bose promoted the intellectual side of Indian life and had a distinguished career. His later interests were in unified field theory and the theory of numbers.

See also **Emission Coefficients (Einstein)**.

J. M. I.

BOSONS. Those elementary particles for which there is symmetry under intra-pair production. They obey Bose-Einstein statistics. Included are photons, pi mesons, and nuclei with an even number of particles. (Those particles for which there is antisymmetry are *fermions*.) See **Mesons**; **Particles (Subatomic)**; and **Photon**.

Recent progress toward a complete theory of the weak interactions has led to sharper predictions for the properties of the hypothetical weak-force particles known as *intermediate bosons*.

BOSS. The term boss or stock is used to indicate a cross-cutting mass of igneous rock which has ascended into the crust of the earth and may or may not represent the roots of volcanic conduits. Bosses are roughly circular or elliptical in ground plan and usually of greater cross-sectional area than a volcanic neck, and lack pyroclastic materials. Most probably bosses are the irregular upward extensions of batholiths the main parts of which are as yet unexposed.

Boss also designates a circular projection on a casting, usually serving as the seat for a bolt head or nut.

BOSTONITE. A rather rare rock type, dense, with an occasional feldspar phenocryst and grayish in color. It is composed almost wholly of alkaline feldspar, being analogous to aplites. The type locality is Salem Neck, Massachusetts, close to Boston, for which it was named.

BOSWELLIA TREE. Of the family *Burseraceae* (torchwood family), the boswellia tree is native to the island of Socotra near Saudi Arabia. The tree is small, not attaining a height of over 12 to 20 feet (3.6 to 6 meters). The fruit is a berry about the size of an olive. The branches are short, twisted, and harsh in appearance, rising from low on the trunk. The leaves curl and are sparse. The flowers are few and appear like a red geranium blossom, but are quite fragrant. The tree was known at the time of Christ and was the source of frankincense mentioned in the Bible. The bark of the tree is filled with an amber-green resin, the source of frankincense.

BOTANY. Botany is the science that deals with plants. It is divided into many sections, each dealing with a specific part of the subject. One section, which describes plants and arranges them in classes, is called taxonomy; another section, morphology, considers the form of the various parts of a plant, while its subsections include anatomy and histology, the study of the internal structure of plants, and cytology, the study of the cell and its parts. A third, physiology, deals with the functions of the parts and the activities of the plant. In addition, one may study plant geography, or the distribution of plants on the earth; ecology, the relations of plants to each other and to their environment; phytopathology, or the diseases of plants; paleobotany, the science of fossil plants; and economic botany, which considers the uses man has found for plants and plant products.

The science of botany is very old. Since the welfare of man is closely connected with plants, it is natural that they should receive attention early. Undoubtedly plants were known and observed by men long before the period of Greek supremacy. Various recorded observations suggest that such is true. But only with the intellectual curiosity of the Greek mind did plants receive close attention. Aristotle (384–322 B.C.) studied them attentively and cultivated many species from widely separated regions. His disciple Theophrastus (371–287 B.C.) carried on the work and wrote about them in his "Equiry into Plants," in which he describes some 500 species and gives extensive and keen observations concerning them. In Rome another naturalist, Pliny the Elder (23–79 A.D.), writes extensively on Natural History, setting forth information on some thousand species of plants. His facts are largely drawn from sources other than the plants themselves and are often grossly exaggerated. His Natural History was of immense importance, however, and largely controlled the thought of botanists for many centuries. Another ancient naturalist, Dioscorides, also studied plants. He was mainly interested in them because of the important place they held in the medical practice of that time. Indeed, the study of plants was for a long period of time considered the province of physicians and doctors, whose main interest was in plants as remedies or supposed remedies for various ills. After this, centuries followed in which little attention was given to plants; all knowledge thereof was drawn directly from the works of the ancient writers.

Beginning with the sixteenth century, however, interest in plants was revived. Men began observing the native plants around them and recording these observations, often accompanied by illustrations, in herb books or herbals. Such observations led to attempts to arrange and classify the various plants. Among the first herbals were those of Brunfels (1530)

and Fuchs (1542), both of them containing excellent illustrations, but relying for their descriptions largely on the ancient writers of Greece and Rome. Hieronymus Bock (1498–1554) was another herbalist, who gave in his book extensive first-hand descriptions of the plants which he treats. William Turner and John Gerard published herbals treating of English plants. Valerius Cordus (1515–1544) gave even more complete and accurate descriptions of the plants in his books than Bock.

As a result of the work of these men and many others, came a need for a better understanding of plants and the necessity for arranging them in some sort of system other than that of size or of the alphabet. John Ray (1628–1705) advanced the problem considerably by introducing an exact concept of species, which he held to come from a single parent and to continue to produce like organisms, although he does allow some variation to occur. Ray separated flowerless plants from flowering, and divided the latter into Dicotyledons, with two seed leaves, and Monocotyledons, with only one. See also **Angiosperms**; and **Dicotyledons**.

The number of plants described was constantly increasing, rendering even more necessary a system of arranging them in order. Many systems were proposed, some having great merit. As early as 1583 Casalpino had eliminated any classification based on such variable organs as roots, stems or leaves, and had concluded that the flowers and fruit offered the only real basis. It remained for Carolus Linnaeus (1707–1778) to bring order to the situation. He invented the binomial system of nomenclature, by which each plant (and animal also) should be known by a name designating the genus and a qualifying adjective limiting the species named. His system of classification was purely artificial, being based on the number of stamens and pistils (see **Flower**), but did make it easy to refer to a description and so verify an identification. He also grouped plants and animals in larger divisions, the classes and orders. The present-day names of plants date from the time of Linnaeus. It has long been recognized that there seemed to be a natural grouping of plants; John Ray apparently understood some of the larger groups of plants. With the work of the French taxonomist A.L. de Jussieu came a definite knowledge of the natural relations of plants, which he grouped into 15 classes with about 100 orders.

While classification and description occupied a large place in the development of botany, other branches of the science were not neglected, although of necessity many of them waited on advancement in taxonomy. The anatomy of plants was studied by Nehemiah Grew (1641–1712) in England, and Marcello Malpighi (1628–1684) in Italy, while casual observations, of the internal structures of some plant substances, were made by Robert Hook. The finely illustrated writings of these men established the foundations for an understanding of the internal structure of plants. Subsequent workers in this field showed the similarities existent in the internal structures of plants, and the changes that have occurred during the evolution of plants. Out of this have come the later studies of cytology and histology.

Any knowledge of the way in which the plant lives and the functions of its various parts was slow to develop. The lack of definite organs connected with such functions as digestion, circulation, respiration, etc., made the problem even more difficult. Occasional observations had been made from time to time, often leading to erroneous conclusions. With Stephen Hales (1677–1761) plant physiology became established. He first used instruments to measure various physiological activities that he studied. His observations, recorded in his "Vegetable Staticks," published in 1727, show how attentively he studied the problem of nutrition in plants and the movements of liquids within the plant. Ingen-Housz (1730–1799) gained more exact knowledge of the problem of nutrition in plants, definitely showing that the carbon in plants came from the carbon dioxide of the atmosphere. He had an accurate knowledge of the role of gases in the life of the plant. Another worker, Andrew Knight (1758–1838), studied an entirely different field, being largely interested in the problem of direction of growth of root and stem. To him is due the use of a rapidly revolving wheel to which seedlings were attached. From this experiment he determined that roots grew away from the center of the revolving wheel and stems toward the center. Out of his studies came the study of tropisms in general.

However, other branches of the science of botany have not been overlooked. The study of the distribution of plants has been pursued with great vigor, bringing to light many interesting problems, at times difficult to explain. Why should certain similar groups of plants appear in widely separated regions? At present this and many other questions are subjects for speculation and cause for further study. See **Plant Breeding**.

Another branch of botany that occupies an important position today is that of plant pathology, which treats of the diseases of plants. When a single disease such as wheat rust, attacking a single crop, causes the loss of millions of dollars in reduced harvests, and with so many crops subject to numerous diseases, this must be recognized as a study of vital importance to man. Comprehensive and exact knowledge of the disease-producing organism is necessary. Often it is obtained only after prolonged, painstaking study. Then follows the problem of treatment leading to elimination of the disease, a study in itself. Sometimes this is impracticable; it is quicker to attack the problem in another way — to attempt to develop strains of plants resistant or immune to the disease. In this field new problems are constantly arising, or assuming greater importance — for example, the outbreak of the Dutch Elm disease in recent years, or of the Oak Wilt disease which threatens the oak forests of America. See **Elm Trees**; and **Oak Trees**.

These and many other problems show how close is the welfare of mankind tied up with the study of botany and the knowledge of the many sides of that science.

Not including specific trees, plants, and plant families, the botany-related entries in this book are:

BOT FLY *(Insecta, Diptera).* The maggots of several species of the bot fly seriously damage cattle, sheep, horses, and other farm and domestic animals. Distribution of these pests is essentially throughout the United States. The larvae live as internal parasites in mammals. The adult bot flies have, as a rule, vestigial mouth parts and attack the host only to deposit their eggs. Horses are attacked by three species of bot flies of the genus *Gasterophilus*. The *lip* or *nose bot fly* (*Gasterophilus haemorrhoidalis*, Linne) deposits its eggs on the lips, whence the larvae reach the throat or stomach. The species, *G. inermis* (Brauer), attaches the larvae to the hairs of the forelegs, where they die unless the horse takes the larvae into its mouth by licking or biting the legs. The larvae develop in the alimentary tract and pass out when mature with the feces. The sheep bot fly is described in the entry on **Nose Fly**.

In cattle, the larvae of the species of bot fly known as *Hypoderma lineatum* (De Villiers) is referred to generally as the common *cattle grub*, and the adult, as the *heel fly*. The larvae of the species of fly known as the bomb fly, species *Hypoderma bovis* (De Geer), is commonly referred to as the *northern cattle grub*. All species of cattle grub produce a condition sometimes called *ox warbles* because of the tumerous swellings or "warbles" produced. The adult fly may be as large as a honeybee and continues to chase and bother an animal until it finds opportunity to lay its eggs, often along the animal's back. Maggots from the eggs migrate through the animal's skin and usually ultimately find a permanent location along the back, causing a tumor, inside of which is a fat, well-nourished maggot. It is evident that hides are severely damaged from this procedure. The general health of the animal is also affected and, if a dairy cow, milk production is reduced.

The heel fly is most abundant, ranging throughout the United States. The bomb fly is most commonly found in the Northeastern states and is not a pest in the Southern states. However, the total range of the bomb fly is from the east to west coasts of North America, both north and south of the Canadian border.

The cattle grubs overwinter as maggots, usually in the backs of animals. After residing in the animals for about 6 months, usually in early winter, the larvae drop to the ground and pupate in the soil. The adult flies appear in the spring and commence egg laying.

Numerous chemical formulations and methods are available for treating the animals once an infestation has occurred, but the procedures followed are complex and detailed and beyond the scope of this volume.

BOTTOM WATER. 1. The water mass at the deepest part of the water column. It is the densest water that is permitted to occupy that position by the regional topography. In the case of a basin, bottom water may be formed locally, or it may represent the densest water that has existed at sill depth in the recent past.

2. Water masses found at the bottom of ocean basins. The most important bottom waters of the World Ocean are Antarctic Bottom Water and Arctic Bottom Water. Baffin Bay Bottom Water has a salinity of 34.49 and a temperature of $-0.4\,^{\circ}$C (31.3 $^{\circ}$F) and is found in Baffin Bay below a depth of 1,800 meters (5,906 feet); its low oxygen content of 3.6 ml l^{-1} indicates slow water renewal. Japan Sea Bottom Water has a salinity of 34.1 and a temperature of 0.04 $^{\circ}$C (32.1 $^{\circ}$F) ; it is formed by winter convection in the northern Japan Sea and occupies the Japan Sea basins at depths below 2,000 meters (6,562 feet).

AMS

BOTULISM. See **Foodborne Diseases**; and **Bacterial Diseases**.

BOUGAINVILLEA. Genus of the family *Nyctaginaceae* (four-o'clock family). This is a relatively small genus of plants, natives of South America, which are frequently cultivated in the tropics and to some extent as greenhouse plants outside the tropics. However, some species do very well in subtropical areas, as in Florida, the Gulf Coast, and southern California. The flowers of the plants are small and inconspicuous, but are surrounded by showy bracts of various colors, notably pink, purple, and orange. The plants are generally cultivated in gardens and in landscaping for these brilliantly colored bracts. *Bougainvillea spectabilis*, a heavily thorned and climbing vine, is frequently cultivated.

BOUGUER AND LAMBERT LAW. In homogeneous materials, such as glass or clear liquids, the fractional part of intensity or radiant energy absorbed is proportional to the thickness of the absorbing substance. Summing over a series of thin layers or integration over a finite thickness gives the relation

$$\log I_0/I = k_1 b$$

where I_0 is the intensity or radiant power incident on a sample b centimeters thick and I is the intensity of the transmitted beam. The constant k_1 depends on the wavelength of the incident radiation, the nature of the absorbing material and other experimental conditions. Verification of the law fails unless appropriate corrections are made for reflection, convergence of the light beam and spectral slit width, as well as possible scattering, fluorescence, chemical reaction, nonhomogeneity, and anisotropy of the sample. Formerly, the constant k_1 was called the absorption coefficient. It is now preferable to avoid this term and to call the ratio I/I_0 the transmittance. The law was first expressed by Bouguer in 1729 but it is often attributed to Lambert, who restated it in 1768.

BOULANGERITE. A mineral compound of lead-antimony sulfide, $Pb_5Sb_4S_{11}$. Crystallizes in the monoclinic system; hardness, 2.5–3; specific gravity, 6.23; color, lead gray.

BOULBIE. See **Winds and Air Movement**.

BOULDER. A large fragment of rock, usually rounded, which has been moved from its place of origin by a natural agency or has been formed in situ by weathering processes. Rather arbitrarily, 8 inches (20 centimeters) has been set as the minimum diameter for a boulder.

BOUNDARY CONDITIONS. A set of mathematical conditions to be satisfied, in the solution of a differential equation, at the edges or physical boundaries (including fluid boundaries) of the region in which the solution is sought.

The nature of these conditions is usually determined by the physical nature of the problem, and is a necessary part of the problem's complete formulation. Common boundary conditions for the atmosphere are that the velocity component normal to the earth's surface vanish, and that the individual derivative of pressure vanish at the upper surface. The term is also used in the context of the time evolution of an "open" dynamical system that interacts with other "external" systems. The state of the external systems must be specified as a boundary condition to infer the evolution of the dynamical system under consideration. For example, the evolution of the earth's atmospheric state requires the specification of sea surface temperature as a boundary condition.

See also **Dynamic Boundary Condition**; and **Kinematic Boundary Condition**.

AMS

BOUNDARY CURRENTS. See **Ocean Currents**.

BOUNDARY LAYER. The layer of fluid in the immediate vicinity of a bounding surface; in fluid mechanics, the layer affected by viscosity of the fluid, referring ambiguously to the laminar boundary layer, turbulent boundary layer, planetary boundary layer, or surface boundary layer.

In aerodynamics the boundary-layer thickness is measured from the surface to an arbitrarily chosen point, e.g., where the velocity is 99% of the stream velocity. Thus, in aerodynamics, boundary layer by selection of the

reference point, can include only the laminar boundary layer or the laminar boundary layer plus all, or a portion of, the turbulent boundary layer.

BOUNDARY LAYER RADAR. A type of wind profiler specially designed to study the lower part of the troposphere. Because clear-air reflectivities in the boundary layer are usually orders of magnitude higher than in the upper troposphere, these profilers can be smaller, lower powered, and less expensive than those profilers designed to cover higher regions of the atmosphere. See also **MST Radar**. Boundary layer radars are generally characterized by short pulse lengths (less than 100 meters (328 feet) and the ability to make measurements starting at 100–200 meters (328–656 feet) above the radar and extending to at least 2–4 kilometers (1.2–2.5 miles) under typical atmospheric conditions. To satisfy these requirements, boundary layer radars usually operate in the UHF radar band.

BOUNDARY LAYER SEPARATION. A condition that occurs at sufficiently high Reynolds numbers in which the surface streamlines break away from the surface. See also **Reynolds Number**.

Separation is due to the presence of a solid boundary, at which the no-slip condition — that is, the velocity of the fluid particles in contact with the surface is the velocity of that surface — is satisfied and vorticity is generated. Separation of a steady boundary layer at a plane or rounded rigid wall occurs whenever the velocity of the fluid just outside of the boundary layer decreases in the mean flow direction sufficiently rapidly and by a sufficient amount. This can be accomplished by the imposition of an opposing pressure gradient in the direction of flow.

BOUNDARY-VALUE PROBLEM. A physical problem completely specified by a differential equation in an unknown, valid in a certain region of space, and certain information (boundary condition) about the unknown, given on the boundaries of that region. The information required to determine the solution depends completely and uniquely on the particular problem.

BOURDON TUBE. Patented by Eugene Bourdon in 1852, the bourdon tube continues to find wide application in instruments, notably for pressure and force measurement, and for performing mechanical work in response to pressure. Filled-system thermometers also utilize bourdon tubes. Although made in various forms, the principal configurations are: (1) the "C" shape tube, (2) the helical tube, and (3) the spiral tube.

"C" Shape Bourdon Tube. This is the most common form of bourdon tube. Its use in a dial-type pressure gage is shown in Fig. 1. Pressure is applied at the fixed end, causing movement of the free end as the result of deformation of the cross section of the tube. The designer usually is concerned with the total tip travel and/or the force available at the tip.

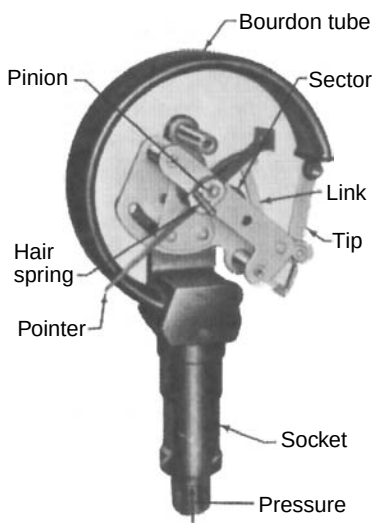

Fig. 1. Use of "C" shape bourdon tube in dial-type pressure gage.

The tip travel that may be obtained for bourdon tubes of different coiling radii is plotted in Fig. 2. The values shown are typical of what is in common use. Particularly in the low- and medium-pressure ranges, the curves do not represent the maximums that can be obtained. The tip force is determined by applying full-scale pressure and then finding the force

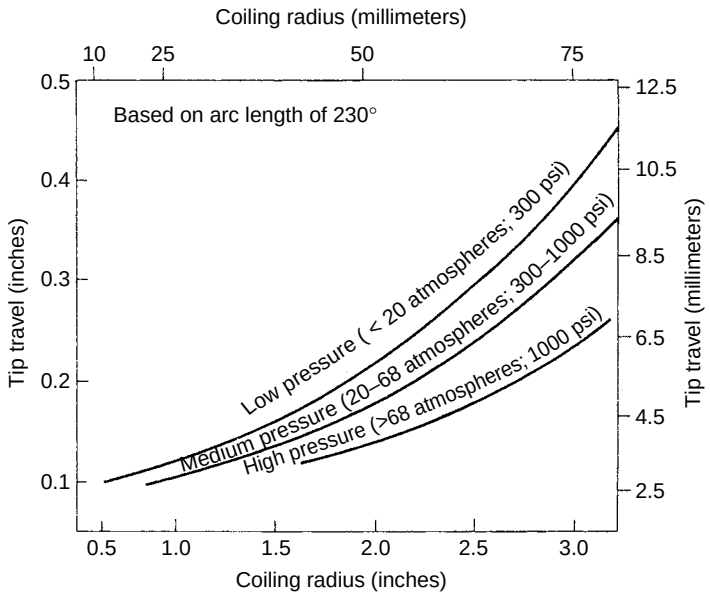

Fig. 2. Tip travel versus coiling radius (typical values).

necessary to return the tip to its original position. It can be noted that the direction of the force necessary to return the bourdon tube tip to its original position is not along the same path as the path of motion of the tip. This fact must be considered when using bourdons in a force-balance system and accounts for the difficulty in utilizing opposing bourdon tubes as a means to measure differential pressure.

Helical Bourdon Tubes. These are used most often for high-pressure gages — principally to permit obtaining a large tip travel without creating a high stress per unit length of tube. The direction of the motion will be an arc whose center is the center about which the helix is coiled. It must be kept in mind that the helix form introduces another axis of compliance so that all of the tip force will not be available unless the tip of the bourdon is constrained to move about its center.

Spiral Bourdon Tubes. Spirals often are used in liquid-filled systems, such as mercury or liquid temperature indicators. These are volumetric devices — as opposed to pressure devices — and the bourdon tube moves because the cross section must change to accommodate the volume change of the filling media due to temperature variation. The tube may be designed of relatively thin-walled tubing of a very flat cross section which permits winding into a compact spiral form. Spiral bourdon tubes having large tip travels also are used where it is desirable to eliminate multiplication linkages and gears. Little data are available on spiral bourdons with respect to travel and force available — hence their use generally requires cut-and-try methods.

PHILIP W. HARLAND, U.S. Gauge Division, Ametek, Inc.,
Feasterville, PA

BOURNONITE. An antimony-copper-lead sulfide corresponding to the formula $PbCuSbS_3$. It is orthorhombic, and repeated twinning often produces crosses or wheel-shaped crystals. It is brittle; fracture, subconchoidal; hardness, 2.5–3; specific gravity, 5.83; luster, metallic; color and streak, dark gray to black; opaque.

Bournonite is found with galena, chalcopyrite, and sphalerite. There are many European localities; it was first found in Cornwall, England, by Count Bournon, for whom it was later named. Bournonite occurs in Bolivia and Peru and in the United States in Arizona, Montana, Nevada and Utah. Bournonite is also known as *wheel ore*.

BOUSSINESQ APPROXIMATION. An approximation to the dynamical equations of motion whereby density is assumed to be constant except in the buoyancy term, $-g'$, of the vertical velocity equation, where g is the gravitational acceleration and $'$ is the density deviation.

The approximation is reasonable if the vertical extent of the dynamics being considered is much smaller than the density scale height — the height over which the density changes by a factor e. It is generally applicable to most oceanographic circumstances. If a system does not satisfy the Boussinesq approximation it is said to be non-Boussinesq.

BOUSSINGAULT, JEAN BAPTISTE (1802–1887). Jean Baptiste Boussingault was a French chemist and a pioneer in nutritional research.

Boussingault, the son of a Parisian tobacconist, was born and raised in a period of turmoil. At school his teachers thought him a blockhead and he left at 14, so losing the opportunity to go on to a university. But he attended public lectures on chemistry and, at 16, was admitted to a technical school for the training of mine managers where the syllabus included chemistry and geology. In his second year he was selected to be a student-demonstrator with permission to work freely in the laboratory, where he studied the fermentation of starches. After a year as a mine manager in Alsace, he moved, at the age of 20, to take up an academic position in the newly independent republic of Colombia, with the encouragement of Alexander von Humboldt. He spent the next ten years in South America, and had 50 papers published in France in this period, detailing his geological findings, meteorological observations and his treatment of goitre with iodine compounds. See also **Humboldt, Alexander von (1769–1859)**.

From 1835 on, after marrying into a farming family in Alsace, and then gaining a university teaching position in Paris, he began collaboration with J. B. Dumas on the chemical composition of organic materials, and animal metabolism. In 1839 he was elected to the prestigious Académie des Sciences.

On the farm he fed both a cow and a horse on rations that kept them at constant weight and analyzed both their feed and their excreta. He found that the nitrogen in the feed eaten was actually greater than that recovered in the excreta. He concluded therefore that, even though animal tissues may contain a higher proportion of protein (and thus of nitrogen) than does the feed eaten, there was no reason to think that animals need or have the power to utilize atmospheric nitrogen. This nitrogen balance trial formed the pattern for much future work all over the world with both humans and animals. In studies with plants he was able to show that legumes, but not wheat, could utilize atmospheric nitrogen. See also **Nitrogen (Nitrogen Fixation)**.

Following a controversy with Justus von Liebig over the generalization by Dumas that only the plant kingdom could engage in major organic synthesis, whilst animals were merely capable of oxidizing and degrading these products, Boussingault did another pioneering trial with pigs. The project was to determine whether or not animals could synthesize fat from carbohydrates. This involved taking a group of similar animals, killing a proportion at the beginning of the trial and analyzing their carcasses, then feeding the remainder for several weeks before killing and analyzing them also. This was tedious work but the final result in 1845 was, to his surprise, that the fat laid down was significantly greater than the fat ingested in the feed. Synthesis from carbohydrate must therefore have been occurring and the generalization had to be abandoned. See also **Carbohydrates**; and **Nutritional Science (The History)**.

Following the political upheavals in France in 1848, Boussingault was elected to represent Alsace in the National Assembly and then selected to be a State Councilor for three years. After this break his work was concerned with plant nutrition and photosynthesis, though in 1860 he did assist a relative who was running a steel plant by improving some of the analytic methods used in metallurgy. See also **Photosynthesis**.

K. J. CARPENTER, University of California, Berkeley, CA

BOVET, DANIEL (1907–1992). Daniel Bovet was a Swiss-born Italian physiologist and pharmacologist who discovered the antihistamine drugs. See also **Antihistamine**; and **Histamine**.

Bovet was born in Neuchatel, Switzerland, and died in Rome. He studied natural science at the University of Geneva, where he gained the degree DSc in 1929 with a thesis on zoology and comparative anatomy. At the same university he qualified as a professor in pharmaceutical chemistry in 1949. In 1940 he became director of the therapeutic chemistry laboratory at the Pasteur Institute in Paris.

It was the Pasteur Institute, that Bovet made two fundamental discoveries in chemotherapy. In 1935, Bovet, Federico Nitti and Jacques and Thérèse Trefouel proved that the antimicrobial action of Prontosil (Sulfamidochrysoidine), could be obtained by using only the sulfamide part of it. Then, in 1937, Bovet and Albert Staub described for the first time the antihistamine action of thymoxidiethylamine, a substance that had been synthesized in 1910. Thymoxidiethylamine was too toxic to be used clinically, but virtually every antihistamine that is used today in counteracting allergic reactions is derived from it. For this discovery Bovet was awarded the Nobel Prize for Physiology or Medicine in 1957. See also **Drug Discovery (The History)**; and **Sulfonamides (The History)**.

In 1947 Bovet left Paris to go to Rome, accepting the invitation of the Istituto Superiore di Sanità (Superior Institute of Health) to organize a laboratory of therapeutic chemistry. Here Bovet took up Italian citizenship in 1948 and married Filomena Nitti, sister of Federico, the bacteriologist, with whom he had a long and close collaboration.

In 1964 he became Professor of Pharmacology at the University of Sassari, in Sardinia. Continuing his studies on antihistamine he discovered their hypnotic effects. This led Bovet towards neuropharmacological research. In this field Bovet carried out important researches on the pharmacology of the sympathetic nervous system, on curare and curare-like drugs and the use of curare as an adjuvant to anesthesia (we owe to Bovet's research the general muscle relaxants in use today), on various drugs used in the treatment of Parkinsonism, and on strychnine and tranquillizers. In 1969 he founded the Laboratory of Psychobiology and Psychopharmacology of the Consiglio Nazionale delle Ricerche (National Research Council) in Rome. He directed this organization until 1976. From 1971 to 1982, when he retired, Bovet held the chair in psychobiology at the University of Rome. See also **Neurochemistry (The History)**.

BOVINES. Ungulates are the hooved animals. This subclass is divided into orders *Perissodactyla* (odd-toed) and *Artiodactyla* (even-toed). The former includes horses, tapirs, and rhinoceros, while the latter includes camels, pigs, deer, musk deer, chevrotains, giraffes, cattle, antelopes, sheep, and goats. *Bovidae* is the most important family in *Artiodactyla*, having about 128 species in about 45 genera. It includes many domesticated forms (cattle, sheep, and goats). The tribe *Bovini* or cattle, has 3 genera and 12 species. See Table 1. The term cattle derives from the Middle English and Old Northern French *catel*. Systematics authorities used herein were Nowak and Paradise (1983) and Graves (1981).

TABLE 1. LIVING MEMBERS OF TRIBE *BOVINI*

Genus	Species	Chromosome[1] Number	Common Names
Bos	Taurus	60	Cattle, aurochs, zebu
	Frontalis	58	Gaur, mithan, gayal
	Javanicus	60	Banteng, Bali cattle
	Sauveli	60	Kouprey
	Grunniens	60	Yak
	Bison	60	American bison, buffalo
	Bonasus[2]	60	European bison, wisent
Bubalus	Bubalis	48 or 50	Water, swamp, or river buffalo
	Mindorensis	Unknown	Tomaraw, tamarao, Tamarau
	Depressicornis	48	Lowland anoa
	Quarlesi	46	Mountain anoa
Syncerus	Caffer	52 or 54	African, Cape, Forest, or Congo buffalo

[1]See Groves, C.P. 1981.
[2]Some taxonomists would pool *B. bison* and *B. bonasus* into a single species, *B. bison*.

Urus was the Latin name for the wild cattle of Europe; in German they were aurochs. These became extinct when the last aurochs cow was killed in Poland in 1627. Aurochs (*Bos taurus*) gave rise to what is commonly called cattle. B. taurus originated in Asia, from whence it spread over its range during the Pleistocene Period, beginning about 600,000 years ago (Epstein and Manson 1984).

Taxonomically, domestic cattle were separated into *Bos indicus* and *Bos taurus* by Linnaeus. There is, however, no compelling biological

reason for maintaining this separation, as they are one species (Groves 1981). At best, the two types may have been domesticated from different races of *B. taurus*. They have similar karyotypes, differing slightly in Y chromosome morphology. Taxonomic rules dictate that the first published name given to a taxonomic group has priority. Naming problems arise among species that have been domesticated. For example, Linnaeus identified common cattle as *Bos taurus* in 1758. Later written accounts, skins, horns, skulls, and other historical evidence were used to raise aurochs to the new species designation *B. primigenius*. Still later, consensus was reached that aurochs were simply the ancestral form of common cattle. Since *B. taurus* was first used for the species, the name *B. primigenius* is invalid. For similar reasons, the author has used *Bubalus bubalis*, rather than *B. arnee*, *Bos frontalis* rather than *B. gaurus*, and *Bos grunniens* rather than *B. mutus*.

Aurochs was a grazer of temperate grasslands and open forests in Europe and Asia, north of the Tropic of Cancer (23.5° north) and south of the Arctic Circle (66°33′ north) (Reed 1984). Southwest Asia was apparently the site of domestication, as the earliest (c. 6000–5000 B.C.) known bones of domesticated *Bos taurus* occur in present day Iran, Iraq, Turkey, and Syria (Harris 1967). The center of domestication was at about 35° north and 40° east. This is not at all precise, as early bone occurs from southeast Hungary (c. 47° north, 20° east) to Afghanistan (c. 37° north, 70° east); these are at least 4500 kilometers apart. Zebu cattle have been reared in Azerbaijan, a former republic of the USSR just north of Iran and west of the Caspian (c. 40° north, 45° east), for at least 4500 years (Verdiev 1989). Zebu types probably originated in present-day India and Pakistan (Nowak and Paradiso 1983). To put these latitudes in more familiar terms, consider that new Orleans (or Cairo), Indianapolis (or Madrid), Calgary (or Frankfurt), and Anchorage (or Helsinki) are at 30°, 40°, 50°, and 60° north, respectively. Havana (or Aswan) is at the Tropic of Cancer (c. 23.5° north). Clearly, cattle were domesticated from aurochs populations that existed far from the tropics. Zebu are better adapted to tropical areas than European types, but Herre (1958) concluded that their adaptation was acquired after domestication.

Banteng, *Bos javanicus*, occur in Southeast Asia, from Burma to Indonesia. For thousands of years it has been domesticated in Bali and Sumbawa, where it is known as the Bali cow. They are used for both draught and meat production. Mature, intact males are black with white markings. This sex-influenced color characteristic also occurs in kouprey, but not in other species of *Bos*. A recent National Academy of Science report singled out the Bali cow as a candidate for beef production in the hot-humid tropics. Compared to zebu, Bali cattle have a much higher reproductive rate and greater resistance to parasites.

Yak, *Bos grunniens*, occur wild only in remote areas of Tibet. It has a dense haircoat and is adapted to high-altitude steppe and desert. Domestic yak are kept in mountainous areas of Central Asia, where they produce meat and milk. In some places they are used as pack animals, especially by nomadic peoples. Unique in *Bos* is that yak are seasonally polyestrus, with estrus expressed from June to October.

Gaur, *Bos frontalis*, are large wild oxen of India, Burma, Kampuchea, and the Malay Peninsula. the mithan, a domestic bovine, occurs in hills and mountains surrounding the Brahmaputra valley in India, Bhutan, and Burma (Simmons 1968). Mithan are found at elevations between 2000 and 9000 feet, and thus overlaps the ranges of both Yak and common cattle. Mithan today are more or less intermediate between *Bos taurus* and *Bos frontalis*, taking its inheritance from both, but favoring the gaur phenotype.

The rarest of the genus is the kouprey, *Bos sauveli*, which occurs mainly in Kampuchea, although small herds may exist in Laos and Vietnam. Owing to war and human population pressure, this most primitive species of living cattle is nearly extinct. Kouprey may have been domesticated during the Khmer culture, 1200–1600 A.D. Some have speculated that kouprey are domestic in remote parts of Indochina today, but this seems unlikely.

Bos taurus is the most successful species in the genus; it exists on all continents except Antarctica. There are about 1.5 billion domestic cattle in the world. Cunningham and Syrstad (1987) discuss the present distribution of European and Zebu breeds, pointing out that the former predominate north of the Tropic of Cancer and south of the Tropic of Capricorn, while the latter predominate between the tropics. There are about 1 million Bali cattle, nearly all are in Indonesia. Domestic gaur, mithan, probably number less than 100,000. Domestic yak numbers are estimated at 1 million.

African buffalo, *Syncerus caffer*, have never been domesticated. Two types occur. The Cape buffalo has 52 chromosomes and is larger than the Forest or Congo buffalo, which has 54 chromosomes.

The Asian buffalo, *Bubalus bubalis*, has many domestic breeds. Domestic buffalo number at least 130 million, and they are important milk, draught, and meat animals in Asia, Eastern Europe, and Egypt. There are two types — the river buffalo and the swamp buffalo. Swamp buffalo are generally found in Southeast Asia, whereas river buffalo are more often found in India and to the west. Swamp buffalo have 48 chromosomes; river buffalo have 50. They are interfertile, "but will interbreed only when artificially persuaded through association from calfhood to maturity" (Wurster and Benirschke 1968). Buffalo were probably domesticated in the area of India and Pakistan over 5000 years ago. They have existed in Transcaucasia since the first millennium B.C., and they reached Italy with pilgrims and crusaders returning from the Holy Land during the Middle Ages. Today buffalo are widely dispersed, being found between 40° north and 30° south. Buffalo tolerate foot and mouth disease better than cattle and are resistant to anthrax and brucellosis (Verdiev and Turabov 1989).

Three additional species of *Bubalus* occur in Southeast Asia. *B. mindorensis*, tamaraw, is found on the island of Mindoro in the Philippines. *B. depressicornis*, lowland anoa, is confined to the island of Sulawesi in Indonesia. *B. quarlesi*, mountain anoa, inhabit highlands on the island of Sulawesi. None have been domesticated. Small isolates of wild *B. bubalis* occur in India. These remnant populations are threatened by genetic "swamping" by domestic and feral buffalo and by inbreeding. Currently, efforts are underway to protect these populations.

The two bison species are completely interfertile. *Bos bonasus*, European bison or wisent, is a success story in species conservation. It existed in the same habitat as aurochs and persisted in the wild until about 1920. Animals taken from zoos were used to restock forests in Poland and Russia, where they are now plentiful. *B. bison* of our western plains was also near extinction; it too is now plentiful. Whether *B. bonasus* is a valid species or not is purely a matter of convenience (Groves 1981).

Interspecific hybrids rarely occur in nature, but there is a long history of hybrid breeding among captive populations. Gray (1972) summarized hybridization work in Bovini. Excluding Bos sauveli, calves have been produced from all crosses among the species of Bos, except between *Bos bison* (or *B. bonasus*) and *Bos javanicus*. Generally, Haldane's (1922) rule (wording modernized), "In interspecific hybrids, if only one sex is absent, rare or sterile, that sex is the heterogametic sex," is supported by crosses among the species in Bos. Nearly always, crosses among *Bos* yield fertile females and sterile males.

There are no reliable reports of conception in matings of Bos species to *Bubalus bubalis*, although matings sometimes occur. Groves (1981) phylogeny (Fig. 1) (based on cladistic analysis of mostly skull characters) is consistent with the hybridization results. Also, chromosome numbers (Table 1) suggest that fertility would be extremely unlikely in crosses between Bos and buffalo.

Yak x cattle crossbreds are used for production purposes in Nepal and elsewhere in the Himalayas at elevations where cattle do not thrive; higher up, the pure Yak must be used. The mithan (Simmons 1968) is semi-domesticated in the remote hills and mountains of the Indo-Burman border. A stable cross of cattle and banteng occurs on the island of Madura in Indonesia. Invading Indians brought zebu cattle, which interbred with the Bali ox some 15 centuries ago.

BOVINE SPONGIFORM ENCEPHALOPATHY (BSE). Bovine spongiform encephalopathy (BSE), widely referred to as "mad cow disease," is a chronic degenerative disease affecting the central nervous system of cattle that results from infection by an unconventional transmissible agent. The disease was first diagnosed in 1986 in the United Kingdom.

Cattle affected by BSE experience progressive degeneration of the nervous system. Affected animals may display changes in temperament, such as nervousness or aggression, abnormal posture, incoordination and difficulty in rising, decreased milk production, or loss of body weight despite continued appetite. Affected cattle die. The causative agent of the disease is not completely characterized and there is neither any treatment nor a vaccine to prevent the disease.

The incubation period (the time from when an animal becomes infected until it first shows disease signs) is from two to eight years. Following the onset of clinical signs, the animals condition deteriorates until it either dies or is destroyed. This process usually takes from two weeks to six months. Most cases in the UK have occurred in dairy cows between three and six years of age.

Currently, there is no test to detect the disease in a live animal; veterinary pathologists confirm BSE by postmortem microscopic examination of brain tissue or by the detection of the abnormal form of the prion protein. See also **Bacteria**. BSE is so named because of the spongy appearance of the brain tissue of infected cattle when sections are examined under a microscope.

Since 1996, evidence has been increasing for a causal relationship between ongoing outbreaks in Europe of a disease in cattle, called BSE, and a disease in humans, called new variant Creutzfeldt-Jakob disease (nvCJD). New variant Creutzfeldt-Jakob disease is described more fully later in this entry. Both disorders are invariably fatal brain diseases with unusually long incubation periods measured in years.

As of November 2000, more than 177,500 cases of BSE were confirmed in the United Kingdom alone in more than 35,000 herds. Regularly updated numbers of reported cases, by country, are available on the website of the Office International Des Epizooties at: *http://www.oie.int/eng/info/en_esb.htm.*

Bovine spongiform encephalopathy appears to have originated from scrapie, an endemic spongiform encephalopathy of sheep and goats that has been recognized in Europe since the mid-18th century (Brown and Bradley). It has since spread to most sheep-breeding countries and is widespread in the United Kingdom, where until 1988 the rendered carcasses of livestock (including sheep) were fed to ruminants and other animals as a protein-rich nutritional supplement.

During rendering, carcasses from which all consumable parts had been removed were milled and then decomposed in large vats by boiling at atmospheric or higher pressures, producing an aqueous slurry of protein under a layer of fat (tallow). After the fat was removed, the slurry was dessicated into a meat and bone meal product that was packaged by the animal food industry and distributed to owners of livestock and other captive animals (e.g., zoo and laboratory animals, breeding species, pets).

Although, certain elements are still disputed (including its origin from scrapie, rather than from unrecognized endemic BSE), it appears likely that changes in the rendering process that had taken place around 1980 allowed the etiologic agent in infected carcasses to survive, contaminate the protein supplement, and infect cattle. Cattle carcasses and carcass wastes were then recycled through the rendering plants, increasing the levels of the now cattle-adapted pathogen in the protein supplement and eventually causing a full-scale BSE epidemic (Wells et al., Collee and Bradley, and Brown).

Recognition of this source of infection has led to a series of countermeasures taken by the UK and other countries to break the cycle of cattle reinfection, restrict the geographic spread of disease, and eliminate potential sources of new infections. (See Fig. 1 and Table 1). Probably the single most important measure in the UK was the imposition in 1988 of a ruminant protein feed ban that by 1992 began to bring the epidemic under control. However, the loss of nearly 200,000 diseased cattle, followed by pre-emptive slaughter and destruction of nearly four and a half million asymptomatic cattle >30 months of age, has crippled the British livestock industry and also affected the tallow, gelatin, and pharmaceutical industries, all of which make bovine-derived products.

BSE is not restricted to the UK. Cases have occurred in many other countries as a result of imported live animals or livestock food supplements (see Table 2). In some countries, including the UK, the incidence of new cases is decreasing, but in other countries, France, Portugal, Germany, Spain, and the Republic of Ireland, the incidence appears to be increasing, or initial cases have only recently appeared. The explanation for this phenomenon is most probably improved case ascertainment (supported by active surveillance and immunologic methods), but new infections from contaminated feed intended for other species (e.g., pigs and poultry) may also be a contributing factor. Although in many countries, BSE has been identified in native-born cattle, no indigenous index case has been reported outside the UK (i.e., no case originating *de novo* or from cow-to-cow transmission). Whatever the origin of these cases, recycling of their contaminated tissues through livestock feed supplements could have occurred in the same way as in the UK.

BSE has not occurred in the United States or other countries that have historically imported little or no live cattle, beef products, or livestock nutritional supplements from the UK. Even though rendering procedures in other countries underwent changes similar to those in the UK during the late 1970s, BSE has apparently emerged solely within the UK. The most plausible explanation is that the proportion of sheep in the mix of

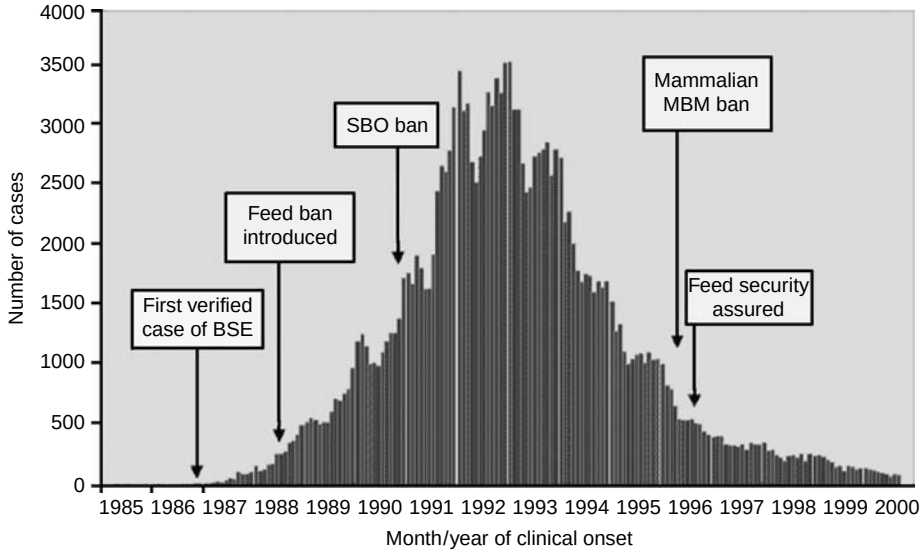

Fig. 1. Time course of epidemic bovine spongiform encephalopathy in the United Kingdom, 1986–2000, with dates of major precautionary interventions. The mammalian ban on meat and bone meal in March 1996 extended a 1994 ban for farmed food animal species to include *all* mammalian species. SBO = Specified bovine offals (brain, spinal cord, thymus, tonsil, spleen, and intestines from cattle >6 months of age); MBM = meat and bone meal (protein residue produced by rendering.)

TABLE 1. MEASURES TAKEN TO PREVENT THE SPREAD OF BOVINE SPONGIFORM ENCEPHALOPATHY (BSE) TO ANIMALS

Precautions	United Kingdom[a]	European Union[a]	United States
BSE made a notifiable disease	June 1988	April 1990	November 1987
BSE surveillance, with histologic examination of brains	June 1988	May 1990	May 1990
Ban on ruminant protein in ruminant feed	July 1988	July 1989	
Ban on export of UK cattle born before July 1988 feed ban		July 1989	
Ban on import of live ruminants and most ruminant products from all BSE countries			July/November 1989
Ban on export of UK cattle >6 months of age		March 1990	
Ban on SBO[b] for use in animal nutrition; ban on export of SBO and feed containing SBO to EU[c] countries	September 1990		
High-risk waste to be rendered at 133 °C/3 bar/20 min (or other approved procedure)		November 1990	
Ban on export of SBO and feed containing SBO to non-EU countries	July 1991		
Ban on MBM[d] from SBO in fertilizer	November 1991		
After January 1, 1995, rendering methods must sterilize BSE		June 1994	
Ban on mammalian MBM in ruminant feed		July 1994	
BSE surveillance includes immunohistologic features of brains			October 1993
Ban on mammalian protein in ruminant feed[e]	November 1994		August 1997
Ban on import of live ruminants and most ruminant products (including meat products) from all countries of Europe			December 1997
Immunologic testing for ruminant protein in animal feed		July 1995	
Mammalian MBM prohibited from all animal feed/fertilizer	March/April 1996		
Slaughtered cattle >30 months old (except certain beef cattle >42 months old) ruled unfit for animal use (hides for leather excluded)	March 1996		
Mammalian MBM and MBM-containing feed recalled	June 1996		
All mammalian waste to be rendered at 133 °C/3 bar/20 min (or other approved procedure)		July 1996	
Cattle tracing system improved	September 1998		
Quarantine of three sheep flocks imported from Europe with possible exposure to BSE (four animals die with atypical TSE[f])			October 1998
BSE surveillance of fallen stock (downer cows) is intensified			October 1998
Proposal to eradicate scrapie is rejuvenated			November 1999
Allow export of deboned beef from cattle >30 months old born after July 1996	August 1999		
Prohibit use of animal protein, including MBM and blood meal (but excluding milk, or fish meal for nonruminants) in feed for any farmed animal species (effective January 1, 2001)		December 2000	
Prohibit importation of rendered protein and rendering wastes originating or processed in Europe			December 2000

[a] In Northern Ireland and Scotland, dates of implementation sometimes differed from those shown for England and Wales; in addition, individual European Union countries often adopted different measures on different dates.
[b] SBO = Specified bovine offals (brain, spinal cord, thymus, tonsil, spleen, and intestines from cattle >6 months of age).
[c] EU = European Union.
[d] MBM = meat and bone meal (protein residue produced by rendering).
[e] Some exemptions, e.g., milk, blood, and gelatin.
[f] TSE = transmissible spongiform encephalopathy.

rendered animal carcasses and the proportion of scrapie infections in such sheep were probably higher in the UK than elsewhere. These proportions were apparently sufficient to bring very low levels of the etiologic agent in batches of rendered carcasses over the threshold of transmission in the UK, but not in other countries (Brown). An alternative explanation proposed in the recent *Report of the BSE Inquiry* is that a pathogenic mutation occurred in cattle in the 1970s.

Either of these two hypotheses satisfies the need for an etiologic "seed" to survive the altered rendering process and escalate through recycling of an ever-larger number of infected carcasses. However, the bovine origin

TABLE 2. REPORTED CASES OF BOVINE SPONGIFORM ENCEPHALOPATHY IN THE UNITED KINGDOM AND OTHER COUNTRIES (AS OF DECEMBER 2000)[a]

Country	Native cases	Imported cases	Total cases
United Kingdom	180,376[b]	0	180,376
Republic of Ireland	487	12	499

[a] Data from Organization of International Epizootics (Paris) and Ministry of Agriculture, Fisheries, and Food (UK).
[b] Includes 1,287 cases in offshore British islands.
[c] Includes cases detected by active surveillance with immunologic methods.
[d] Origin and dates of imported cases are under investigation.
[e] Case imported from Germany.

hypothesis assumes that a mutation occurred only in the UK and not in other countries where similar rendering processes would also have led to epidemic BSE if mutations were occurring. In humans, mutations have occurred all over the world, not just in the UK. There is no reason to suppose that humans differ in this respect from other mammalian species. It would therefore be peculiar if the UK had the misfortune to host the cattle world's only mutation.

Variant Creutzfeldt-Jakob Disease vCJD

Within weeks of identification of the first case of BSE, concern was expressed about human risk (Holt and Phillips, Taylor, Dealer and Lacey, Kimberlin, Will, and Brown), and as the epidemic unfolded, a series of measures was taken to eradicate BSE and prevent potentially infected tissues from reaching the human food chain (see Table 3). A surveillance unit to monitor CJD was established in the UK in May 1990, and three years later, surveillance was extended to several other European countries, coordinated through the European Union. By this means it was hoped that any change in the epidemiology of CJD in the UK could be detected quickly and that the significance of the change could be assessed by comparison with the epidemiology of CJD in continental Europe.

Concern was heightened by the discovery that some exotic zoo ungulates, as well as domestic and captive wild cats, were becoming infected (Jeffrey and Wells, Fleetwood and Furley, Wyatt et al., Kirkwood et al., Willoughby et al.). The ungulates and domestic cats had also been fed diets supplemented by meat and bone meal, and the wild cats had been fed uncooked tissues, including cattle heads and spines. The possibility could therefore not be ignored that the disease might also cross the species barrier to humans from the consumption of beef or dairy products, or perhaps from occupational contact with cattle by ranchers, dairymen, or slaughterhouse workers.

What muted concerns about human infection was the presumption that BSE originated from scrapie, and scrapie was not a human pathogen. Nevertheless, even those who considered human risk to be remote acknowledged that scrapie might unpredictably show an altered host range after passage through cattle. Experimental precedents for such behavior were well known: passage of mouse-adapted strains of scrapie through hamsters altered their transmissibility on back passage to rodents (Kimberlin, Cole, Walker, Kimberlin, et al.); human strains of kuru or CJD did not transmit to ferrets or goats until passaged through primates or cats (Gibbs and Gajdusek); and a bovine strain of BSE did not transmit to hamsters until passaged through mice (Foster et al.). Alternatively, if BSE originated from a spontaneous mutation in cattle, experimental studies of species susceptibility to this new strain of transmissible spongiform encephalopathy (TSE) had not sufficiently advanced to predict that humans would not be susceptible. Nevertheless, during the 10 years after the first case of BSE was identified, cases of CJD did not increase in groups at high risk and continued to occur in the general population with the same spectrum of clinical and neuropathologic features as before the appearance of BSE.

Then, from May to October 1995, the CJD Surveillance Unit was notified of three cases of CJD in patients 16, 19, and 29 years of age (Britton et al., and Bateman et al.). On neuropathologic examination, all three patients had amyloid plaques, which was unexpected in view of their occurrence in only 5–10% of sporadic cases of CJD. The comparative youth of the patients and this unusual neuropathologic finding prompted a search for similar features in patients whose deaths might have been attributed to other diagnoses. In particular, cases of subacute sclerosing panencephalitis (SSPE) were scrutinized in view of a report from Poland that cases of CJD in three young patients had been identified by SSPE surveillance (Kulczycki et al.). No such cases were found in a review of the UK SSPE register.

If CJD in young patients was not being obscured by misdiagnosis, perhaps it reflected increased physicians' awareness through publicity surrounding BSE and iatrogenic CJD in recipients of contaminated growth hormone, or the active CJD surveillance program instituted in the UK, or the availability of genetic and proteinase-resistant protein (PrP) immunocytochemistry. Although all these factors may have contributed to ascertainment bias, most of the excess cases were in older age groups, in which CJD was now being diagnosed more often than in earlier decades.

By December 1995, the Surveillance Unit had been informed of 10 suspected cases of CJD in persons <50 years of age. Some were found to have sporadic or familial CJD or some other disease; however, two of the patients, ages 29 and 30 years, were later confirmed neuropathologically to have CJD and, like the previous three CJD patients, had extensive plaque deposition. As of January 1, 1996, the relationship between these cases and BSE began to excite suspicion but remained tentative because critical information judged necessary to establish a probable connection was still missing (see Table 4).

During January, two additional cases of CJD in young patients were neuropathologically confirmed, and a distinctive clinical syndrome associated with plaque formation was beginning to emerge: young age at onset, early psychiatric symptoms, prominent ataxia, absence of periodic electroencephalographic activity, and a comparatively prolonged illness. However, each of these features, alone or in combination, may also be seen in classic sporadic or familial CJD. Caution was further justified by a review of the records of pre-1980 CJD patients in the UK, which identified three young patients who shared some of these features, and by the results of an inquiry about young patients with CJD in other European countries, which showed an age distribution similar to that in the UK. A major concern was that these seven apparently similar cases might represent a heterogeneous group of patients with sporadic and familial forms of CJD. Full comparative neuropathologic examination of both pre- and post-1980 cases of CJD in young persons was needed, along with PRNP gene sequence analysis of as many cases as possible.

During February 1996, an additional case was referred to the Surveillance Unit with a clinical evolution similar to that of the previous seven patients, and neuropathologic examination of recent and historical cases confirmed that the recent cases were indeed distinctive. In particular, a morphologically unusual form of plaque was present in all cases: the florid or "daisy" plaque in which an amyloid core was surrounded by "petals" of spongiform change. As of March 1, despite the likelihood that this group of patients had a "new variant" of CJD, it was still unclear whether mutations were involved and whether such a syndrome was also occurring outside the UK. Both points were essential to confirming the association of this variant disease with exposure to BSE.

On March 4, genetic analysis was completed for six of the cases, and no pathogenic mutation was identified. These results effectively ruled out a genetic cause for the syndrome (although they did not rule out a genetic predisposition) and left the only remaining uncertainty the geographic distribution of the variant phenotype–to be resolved by the European CJD surveillance system. The answer came by March 20: none of the young CJD patients in other European countries had the clinical and neuropathologic features of the UK cases. In the preceding week, two more variant cases had been neuropathologically confirmed, and a report

TABLE 3. MEASURES TAKEN TO PREVENT THE SPREAD OF BOVINE SPONGIFORM ENCEPHALOPATHY (BSE) TO HUMANS

Precautions	United Kingdom[a]	European Union[a]	United States
Compulsory slaughter of BSE-affected cattle	August 1988		
Destroy milk from affected cattle (except for milk fed to cows' own calves)	December 1988		
Ban on import of UK cattle born after July 1988 feed ban		July 1989	
Ban on SBO[b] for domestic consumption	November 1989		
Ban on export to EU[c] of SBO and certain other tissues, including lymph nodes, pituitaries, and serum.	April 1990	April 1990	
Ban on export of live UK cattle (except calves <6 months old)	June 1990	June 1990	
Ban on use of head meat after skull opened	March 1992		
FDA recommends use of BSE/scrapie-free sources for materials used in dietary supplements; request for safety plans			November 1992
Cell lines used for biologicals should be BSE agent-free			May 1993
FDA requests that bovine source materials (except gelatin) used in manufacture of regulated products be restricted to BSE-free countries			December 1993
Bone-in beef only from farms with no BSE for six years; if not BSE-free, must be deboned with visible nervous and lymphatic tissue removed		July 1994	
FDA requests that bovine-derived materials for animal use or for cosmetics and dietary supplements not be sourced from BSE countries			August 1994
Thymus and intestines from calves <6 months old made SBO	November 1994		
Import of beef only from UK cattle (1) >30 months, or (2) from herds BSE-free for six years, or (3) if not BSE-free, deboned with visible nervous tissue and specified lymph nodes removed		July 1995	
SBO ban broadened to include whole skull (SBM)	August 1995		
MRM[d] from bovine vertebral column banned and export prohibited	December 1995		
Removal of lymph nodes and visible nervous tissue from bovine meat >30 months exported to EU	January 1996		
Ban on export of all UK cattle and cattle products except milk		March 1996	
SBM[e] ban broadened to include entire head (excluding Uncontaminated tongue)	March 1996		
Slaughtered cattle >30 months (or certain beef cattle >42 months) ruled unfit for animal or human use (hides excepted)	March 1996		
FDA urges manufacturers of FDA-regulated human products to take steps to assure freedom from BSE agent			May 1996
Partial lifting of export ban on tallow and gelatin		June 1996	
SBM ban broadened to include certain sheep and goat heads, spleens, and spinal cords (SRM)	September 1996		
FDA recommends withdrawal of plasma and plasma products made from pools to which persons who later died of CJD had contributed			December 1996
CNS[f] tissues excluded from cosmetic products for use in EU		January 1997	
BSE cohort cattle in UK ordered slaughtered and destroyed	January 1997		
Proposed ban on SRM[g] in cosmetics for use in EU (effective October 2000)		July 1997	
SBM controls for cosmetics and medicinal products	March 1997		
FDA request to manufacturers that no bovine gelatin from BSE countries be used in injectable, implantable, or ophthalmic products; and that special precautions be applied to gelatin for oral and topical use			September/December 1997
Ban on marketing cosmetic products containing SRM prepared before April 1, 1998		March 1998	
Allow export of beef and beef products from cattle >30 months in certified BSE-free herds from Northern Ireland		March 1998	
Importation of all plasma and plasma products for use in UK	August 1998		
FDA limits plasma product withdrawals to pools at risk for contamination by vCJD donors			September 1998
Slaughter and destruction of offspring born to BSE-affected cattle after July 1996	January 1999		
FDA guidance to defer blood donors with >6 months cumulative residence in UK during 1980–1996			November 1999
Leukodepletion of whole blood donations from UK residents	July/November 1999		
Public FDA discussion about possible risk associated with vaccines produced with bovine-derived materials from BSE countries			July 2000
Withdrawal and destruction of a potentially tainted 1989 lot of polio vaccine from one manufacturer	October 2000		
SRM ban implemented (effective October 2000)		July 2000	
Ban on slaughter techniques that could contaminate cattle carcasses with brain emboli (e.g., pithing or pneumatic stun guns), effective January 2001		July 2000	
All cattle >30 months old must have brain examinations for proteinase-resistant protein (PrP) before entering the food chain (effective January–June 2001)		December 2000	

[a] In Northern Ireland and Scotland, dates of implementation sometimes differed from those shown for England and Wales; in addition, individual European Union countries often adopted different measures on different dates.
[b] SBO = Specified bovine offals (brain, spinal cord, thymus, tonsil, spleen, and intestines from cattle >6 months of age).
[c] EU = European Union.
[d] MRM = mechanically recovered meat.
[e] SBM = Specified bovine materials (SBO plus entire head, including eyes but excluding tongue).
[f] CNS = central nervous system.
[g] SRM = specified risk materials (SBM plus sheep and goat heads and spleens from animals of any age, and spinal cords from animals >1 year old).

on the entire group of 10 cases concluded that an unrecognized variant of CJD occurring only in persons <45 years of age was probably due to exposure to BSE (Will, et al.).

This link has now been convincingly established in laboratory studies showing identical, distinctive biological and molecular biological features of the pathologic agent isolated from BSE-infected cattle and human cases of vCJD (Collinge et al.; Bruce et al.; and Scott et al.). The source of contamination appears to have been beef. However, muscle has never been reproducibly shown to contain the infectious agent in any form of spongiform encephalopathy, whatever the affected species. Thus, infection

TABLE 4. EVOLVING ASSESSMENT OF CRITERIA USED TO LINK BOVINE SPONGIFORM ENCEPHALOPATHY AND VARIANT CREUTZFELDT-JAKOB DISEASE

	Assessment through early 1996				
Criteria	January 1	February 1	March 1	March 8	March 20
Novel clinical phenotype	Uncertain	Possible	Probable	Probable	Probable
Novel neuropathologic phenotype	Uncertain	Possible	Probable	Probable	Probable
Distinct from pre-1980 cases in UK	Unknown	Possible	Probable	Probable	Probable
No association with PRNP	Uncertain	Uncertain	Uncertain	Probable	Probable
Distinct from cases outside UK	Unknown	Unknown	Unknown	Possible	Probable

most probably resulted from beef products contaminated by nervous system tissue. Contamination could have occurred in any of the following ways: cerebral vascular emboli from cranial stunning instruments used to immobilize cattle before killing by exsanguination; contact of muscle with brain or spinal cord tissue by saws or other tools used during slaughter; inclusion of paraspinal ganglia in cuts of meat containing vertebral tissue (e.g., T-bone steaks); and perhaps most importantly, the presence of residual spinal cord and paraspinal ganglia tissue in the paste of "mechanically recovered meat" (a carcass compression extract) that could legally be added to cooked meat products such as meat pies, beef sausages, and various canned meat preparations. Measures have since been taken to eliminate these sources of potential contamination and limit the consequences of any contamination that may already have occurred (see Table 3).

Although the amount of infectious tissue ingested must be a critical determinant for the transmission of BSE to humans in the form of vCJD, the human genotype at polymorphic codon 129 of the PRNP gene appears to play an important role in susceptibility to infection. The encoding alternatives, methionine (Met) and valine (Val), are distributed in the general Caucasian population in the approximate proportions of 50% Met/Val, 40% Met/Met, and 10% Val/Val. All 76 vCJD patients tested have been homozygous for methionine, and the apparently single infecting strain of BSE may not be able to replicate in any other human genotype. However, it is also possible that (as in the analogous oral infection of kuru and in peripheral iatrogenic CJD infections) heterozygotes are comparatively resistant to disease and become ill after longer incubation periods than those of homozygotes (Cervenakova et al., Lee et al., d'Aignaux et al., and Brown et al.).

Predictions about the vCJD Outbreak. The onset of illness in the first case of vCJD occurred in early 1994, nearly a decade after the first case of BSE was recognized in cattle. Assuming that the earliest appearance of vCJD reflects the earliest exposure to BSE, this incubation period is consistent with those following peripheral infections in experimental animals and in cases of iatrogenic CJD in humans. Through the end of November 2000, the overall tally was 87 definite or probable cases of vCJD in the UK, two confirmed and one probable case in France, and a single confirmed case in the Republic of Ireland (see Table 5). The Irish patient had lived for some years in England; however, none of the French patients had lived in or visited the UK, so their infection must have come either from beef or beef products imported from the UK (approximately 5–10% of the beef consumed in France) or from BSE-affected cattle in France. From a European standpoint, it would be much more troubling if imported beef were the source, as most European countries also imported beef or beef products from the UK, although in smaller quantities.

TABLE 5. CHRONOLOGY OF VARIANT CREUTZFELD-JAKOB DISEASE (VCJD) IN THE UNITED KINGDOM AND OTHER EUROPEAN COUNTRIES, AS OF DECEMBER 2000

Year of onset	United Kingdom	France	Ireland
1994	8	1	
1995	10		
1996	11		
1997	14		
1998	17		
1999[a]	20(+4)	1(+1)	1
2000[a]	1(+2)		

[a] Parentheses indicate still-living persons with probable vCJD or deceased persons whose diagnoses have not yet been confirmed by neuropathologic examination. In 2000, additional cases have been identified that do not yet meet the minimum clinical criteria for a premortem diagnosis of "probable" vCJD. Dates are for year of onset of illness, not year of death.

Unlike the BSE epidemic, the vCJD outbreak has shown only a modest increase during its first six years, and the number of cases with onsets in 2000 remains well below the previous year's total, although additional cases will certainly be identified in coming months. The difference between BSE and vCJD may be due to the fact that in humans, recycling of infected tissue has not occurred, and thus the epidemic will evolve much more slowly than in cattle. The difference could also indicate a limited outbreak in humans due to very small infectious doses that, except in genetically susceptible persons, cannot surmount the combined effects of a species barrier and comparatively inefficient route of infection.

Much of the lingering uncertainty about the extent of the vCJD outbreak is attributable to the fact that the incubation period of vCJD is unknown. If the average incubation period is 10 to 15 years, the earliest patients with vCJD would have been infected in the early 1980s, when BSE was still silently incubating in small, but increasing numbers of cattle. In this case, the large increase in human exposure to contaminated tissues during the late 1980s could lead to a parallel increase in cases of vCJD during the next few years. If, however, the average incubation period of vCJD is 5 to 10 years, the earliest human infections would have begun in the mid- to late-1980s, when exposure to BSE was maximal. In this case, the outbreak of vCJD should remain small because of measures to eliminate both animal and human exposure to BSE instituted from 1987 to 1997. Depending on assumptions about the incubation period and other variables, mathematical modeling predicts that the total extent of the outbreak could range from fewer than one hundred to hundreds of thousands of cases (Cousens, et al.; Ghani, et al., and Donnelly, et al.).

If large numbers of infected persons are silently incubating the disease, the potential for human-to-human iatrogenic spread of vCJD is very real. Such apparently healthy persons would be subject to the same kinds of medical and surgical procedures experienced by the general population, including endoscopies, vascular catheterizations, operations for trauma or illness, and blood and organ donations. If, as suspected, the amount and distribution of the infectious agent in tissues of persons with vCJD is greater than in other forms of CJD, the exposure of medical and surgical instruments to possibly infectious internal tissues and the transfer of tissues as grafts and transplants become a matter of much greater concern than the nearly negligible risk currently posed by cases of sporadic CJD.

Recent and Future Policy Decisions. Several governments have implemented policies to minimize the risk for human-to-human disease transmission through blood donations from apparently healthy persons who may be in the incubation phase of vCJD. In the UK, where whole blood or blood products from some persons who later died of vCJD have been administered to others, all plasma is imported and all blood from UK donors is filtered to eliminate leukocytes, which are the most likely carriers of infectivity in blood (Brown 1995, Brown et al., 1999, 2000). In the United States, a blood donor policy excludes donations from anyone who has lived in or visited the UK for a cumulative period of six months or more during 1980 to 1996. The 6-month period was based on the fact that >80% of total US person-years in the UK would be excluded and that the 2–3% deficit of blood donors resulting from the deferral could be absorbed by the blood banking industry without undue shortages. Several countries (Canada, Australia, New Zealand, Switzerland, Japan, and Germany) have since applied these criteria and formulated similar policies.

Because of the possibility of widespread infection in the UK, concern extends beyond blood and organ donors to the safe use of medical and surgical instruments, particularly those used in neurosurgery and ophthalmic surgery. In the absence of a screening test, a zero-risk policy is untenable because it would require termination of the national organ

donor program. A compromise might be the temporary deferral of organ donors or perhaps only corneal donors younger than 30 or 40 years of age. However, this measure might so diminish (and panic) the donor population as to be inadvisable. Similar considerations apply to invasive medical and surgical procedures: sound medical practice cannot be suspended on a basis of the theoretical risk for vCJD, and it would be unethical to deny needed procedures to persons suspected of having CJD. Under the circumstances, disposable instruments should be used whenever possible, and a standard sterilization protocol for reusable instruments should be implemented that includes the most stringent possible disinfectants (e.g., the combined use of 1 *N* sodium hydroxide and autoclaving at 134 °C, as recommended in the recent World Health Organization guidelines on infection control for CJD. No effective sterilization procedure yet exists for instruments or instrument parts too delicate to withstand these harsh measures. Each such instrument must be disinfected to the maximum extent possible, for example, by washing repeatedly with detergent/proteinase solutions and exposing the washed instruments to less harsh chemicals (e.g., 6 M urea or 4 M guanidinium thiocyanate) that have shown moderate to good disinfection of TSE tissue extracts (Kimberlin, and Walker, Manuelidis, and Pocchiari et al.).

An equally important issue is whether the bovine-adapted scrapie agent has recrossed the species barrier to sheep, carrying its newly acquired ability to infect humans. The only reliable method to distinguish strains of TSE is a time-consuming comparison of incubation periods and topographic features of brain lesions after injection into different strains of inbred mice (Bruce et al.). Glycotyping of PrP strains extracted from diseased brain tissue is much faster, but has not been convincingly shown to discriminate reliably between BSE and scrapie. Moreover, neither method has been used to test a sheep-adapted strain of BSE (that is, after multiple passages through sheep), which might have lost the distinguishing characteristics found on primary passage from cow to sheep.

If BSE did back-cross to sheep fed the same contaminated meat and bone meal that infected cattle, the consequences for humans will remain limited to the same period of risk as BSE roughly 1980 through 1996 unless sheep BSE, like sheep scrapie, can be horizontally or maternally transmitted. Without a test to discriminate between the two diseases, there would be no defense against the development of endemic BSE in sheep and the consequent risk for human infection from sheep as well as cows. Therefore, global elimination of animal TSEs must seriously be considered.

Such a goal is more practical than it was even a few years ago. National programs to eliminate scrapie have historically relied on selective slaughter of blood lines or in some cases entire flocks in which scrapie was identified, and all such attempts have failed. Molecular genetic tools are now available to guide scrapie-resistance breeding programs that until recently depended on field observation and classical genetics, and immunologic tools can detect preclinical scrapie infection in tonsils, third eyelids, and possibly blood (Roels et al., O'Rourke et al.; Schmerr et al.; and Brown et al.) The environmental durability of TSE pathogens will make their eradication difficult (Palsson, and Brown, Gadjusek), however, the global elimination of TSE in sheep and other animals is a goal worth the expense, effort, and patience that will be needed for its achievement.

BOW ECHO. See **Winds and Air Movement**.

BOWEN RATIO. The ratio of sensible to latent heat fluxes from the earth's surface up into the air. This is equal to the psychrometric constant times the ratio of kinematic temperature flux to kinematic moisture flux. It can be estimated as the psychrometric constant times the ratio of potential temperature difference to mixing ratio difference, where the differences are measured between the same two heights in the atmospheric surface layer. Typical values are 5 over semiarid regions, 0.5 over grasslands and forests, 0.2 over irrigated orchards or grass, 0.1 over the sea, and negative in some advective situations such as over oases where sensible heat flux can be downward while latent heat flux is upward.

BOWERBIRD *(Aves, Passeriformes).* Birds of several species found in the Australian region. They build bowers or runs roofed with grass or sticks and decorated with bright articles of all kinds, used as playhouses and to attract females.

Bowerbirds are busy workers, neat housekeepers, and like beauty. They display most unusual and fascinating habits. They are known to build runways, sometimes 2 to 3 feet (0.6 to 0.9 meter) long and will furnish these with a colorful flooring of pebbles, bones, snails, and insect remains, all items selected for their high color and attractiveness. Sometimes bright colored feathers and orchid blossoms are strewn around. Also, the orchid stems may be used in constructing partitions of a wigwam type of design. It has been noted that fresh flowers are brought in to replace withered blossoms. It is believed that the orchid is selected because it retains its freshness and beauty over a relatively long period. These so-called bowerbird houses are associated with mating and are not the regular nests. The males dance until their death sometimes in a duel for their mate.

Species of bowerbirds include: The gardener-bird (*Anbylornis inornatus*), a species known for using moss in its house construction, sometimes banking the moss up to 18 inches (46 centimeters) in height around the trunk of a tree. Twigs are used to strengthen the walls, which are reported in some cases to have "windows." The satin-bird (*Ptilonorhynchus violaceus*) is found in southern Australia. The male has satin black plumage. The female and young are grayish-green. The hut of the satin-bird is usually dome-shaped and made of twigs a few inches long. The regent-bird (*Sericulus chrysocephalus*) is found north of Sydney, near the Brisbane River. It mainly uses snail shells as a material of construction. The spotted bowerbird (*Chlamydera maculata*) forms runs or walkways about 3 feet long (0.9 meter) filled with attractive colored objects as previously mentioned.

Many years ago, when the first naturalists came across the architectural skills of the bowerbirds, their houses were assumed to have been constructed by persons. But subsequent investigations over the years have demonstrated the abilities and habits of these particular birds to be unique among birds.

BOWFIN *(Osteichthyes).* The terms dogfish, grindle, spotfin, and mudfish have also been used in describing the bowfin (*Amia calva*) of the order *Protospondyli* and family *Amiidae*. In ancient times, this fish was widely distributed in the fresh waters of North America. It is now found principally in lakes and sluggish streams in the eastern and central United States. The fish is easily identifiable because of a long, spineless dorsal fin featuring about 58 rays. The bowfish has a well-developed air bladder with a cellular internal surface, thus enabling the fish to occupy waters that may contain no oxygen (or survival out of water) for as much as 24 hours. The normal bowfin weighs but a few pounds and has a length of about 2 feet (0.6 meter). However, some specimens weighing up to 8 pounds (3.6 kilograms) and 3 feet (0.9 meter) in length have been recorded. Although sometimes eaten, they are not considered a highly desirable food fish.

BOW SHOCK. In a planetary magnetosphere, the "bow shock" is the boundary at which the solar wind abruptly drops as a result of its approach to the magnetopause. See Fig. 1. The most, well-studied example of a bow shock is when the solar wind encounters the Earth's magnetopause, although bow shocks occur around all planets. The Earth's bow shock is about 100-1,000 km (62-621 miles) thick and located about 90,000 km (55,923 miles) from the Earth.

The defining criterion is that the bulk velocity of the fluid (in this case, the solar wind) drops from "supersonic" to "subsonic", where the speed of sound in plasma physics is defined as

$$c_s^2 = \gamma p/\rho$$

where c_s is the speed of sound, γ is the ratio of specific heats, p is the pressure, and ρ is the density of the plasma.

The particles making up the solar wind follow spiral paths along magnetic field lines. The velocity of each particle as it gyrates around a field line can be treated similarly to a thermal velocity in an ordinary gas, and in an ordinary gas, the mean thermal velocity is roughly the speed of sound. At the bow shock, the bulk forward velocity of the wind (which can be seen as the velocity of the points on the field lines about which the particles gyrate) drops below the speed at which the particles are corkscrewing. See also **Interplanetary Medium**.

BOW'S NOTATION. A standard method of representing, by letters of the alphabet, forces and stresses in graphical analysis. This analysis may consist of such problems as the graphical solution of stresses in simple framed structures or the determination of the resultant of an independent system of unbalanced forces lying in the same plane and having a common point of application. Figure 1 illustrates the method of applying Bow's notation to the latter system. Let P_1, P_2, P_3 and P_4 be a system of unbalanced forces lying in the same plane and having a common point of application. Denote the space between the line of action of each force by the letters A, B, C, and D. Next construct a figure called a force polygon. This is accomplished by drawing a line parallel to P_1 and laying off its magnitude to a definite scale denoting the ends of the line by the letters a and b. From point b lay off bc equal in magnitude and parallel to P_2. Repeat the operation for the other forces. Upon completion of this graphical figure it will be found, in general, that the line representing P_4 will not pass through point a. The distance from point a to end of this line, which will be lettered e, represents the value of the resultant of P_1, P_2, P_3 and P_4 according to the scale used. The direction of ae determines the line of action of the resultant. Thus, in Bow's notation a

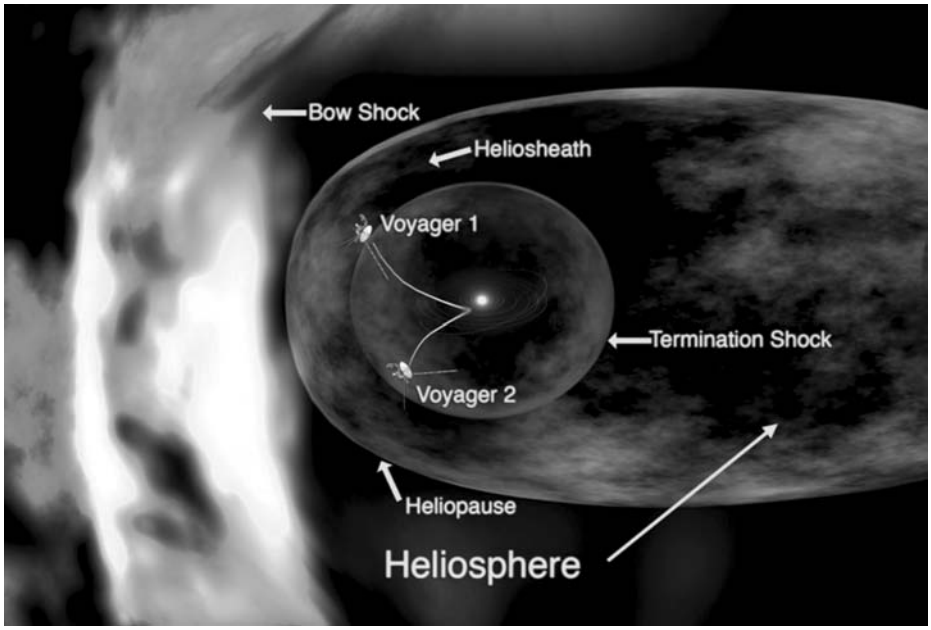

Fig. 1. The "bow shock" shown is the bow shock caused by the sun as it moves through the interstellar medium. (*Image courtesy of NASA/Walt Feimer*.)

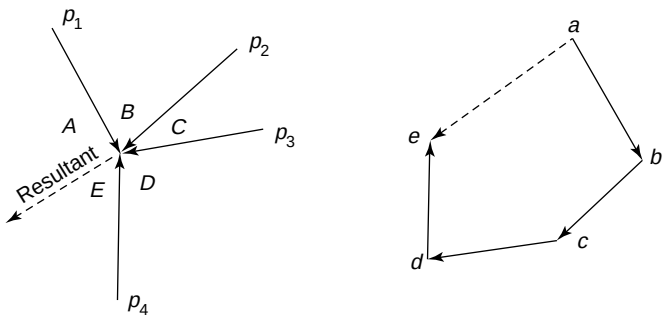

Fig. 1. Representation of Bow's notation: (left) force system; (fight) force polygon.

force in space is designated by the space letters on either side of it, whereas the forces as part of the force polygon are named by the letters at their extremities.

BOX TREES AND SHRUBS. Of the family *Aquifoliaceae* (holly family), genus *Buxus*, the common box, *Buxus sempervirens*, occurs naturally in southern Europe, north Africa, and Turkey. It is cultivated in some regions of North America. Depending upon height, the plant can be classified as an evergreen tree or small shrub. The plant can attain a height up to about 35 feet (10.5 meters). The box has short, oval, leathery leaves that produce a very dense foliage. The fruit is small. The flowers are of a pale green color, small, hardly noticeable. In the British Isles and Europe, the box is traditionally used for low hedges.

The wood of the box is even-grained and hard and a favorite for wood engraving blocks, rulers, instruments, and inlay work. It is called boxwood or, frequently, Turkish boxwood. The wood weighs about 65 pounds per cubic foot (1041 kilograms per cubic meter). Cape boxwood comes from *Buxus macowani*, a tree found in South Africa. The wood is somewhat softer than other boxwoods. Kamassi wood is from *Gonioma kamassi*, also a tree of South Africa. This wood is valued for making loom shuttles. Coast gray boxwood is from the *Eucalyptus bositoana* tree found in New South Wales. It is a durable wood with uniform texture, but of an interlocking grain. Maracaibo wood comes from *Casearia praecox*, a Venezuelan tree. The wood is knotless and considerable quantities are shipped in logs of about 8 feet (2.4 meters) in length and 8 inches (20 centimeters) in diameter. The wood is used for nearly all purposes served by other boxwoods, except for wood engraving blocks. Ginkgo wood comes from the large *Ginkgo biloba* tree of China and is frequently used for making chess men and chess boards. See also **Maidenhair Tree**.

BOYLE-CHARLES LAW. This law states that the product of the pressure and volume of a gas is a constant which depends only upon the temperature. This law may be stated mathematically as

$$p_2 v_2 = p_1 v_1[1 + a(t_2 - t_1)]$$

where p_1 and v_1 are the pressure and volume of a body of gas at temperature t_1, p_2 and v_2 are the pressure and volume of the same body of gas at another temperature t_2, and a is the volume coefficient of expansion of the gas. If the temperature is expressed in degrees absolute, this expression becomes

$$\frac{p_2 v_2}{T_2} = \frac{p_1 v_1}{T_1}$$

which is the ideal gas law, so-called because all real gases depart from it to a greater or lesser extent. See also **Characteristic Equation**.

BOYLE, ROBERT (1627–1691). Robert Boyle was a British natural philosopher who pioneered systematic experimentation, using it to vindicate his corpuscularian view of nature.

Robert Boyle was the youngest son of Richard Boyle, 1st Earl of Cork, Lord High Treasurer of Ireland under Charles I. After attending Eton College, Boyle spent five years traveling on the continent prior to settling on the family estate at Stalbridge, Dorset, in 1645. His earliest writings were on ethical topics, but around 1650 he developed a profound interest in the investigation of nature through experiment which was to dominate the rest of his life. In 1655 or 1656 he moved to Oxford to join the lively group of natural philosophers which had convened there. After the Restoration in 1660, he at first divided his time between Oxford and London, where he was active in the newly founded Royal Society; in 1668 he moved to London, where he lived for the rest of his life.

Boyle's principal significance for the history of science was his extensive use of controlled experiment; he combined extreme care in observing these trials with the use of profuse detail in writing them up. His most famous and influential experiments involved the use of an air-pump or vacuum chamber, which he deployed to investigate the characteristics of the air itself and its role in sustaining life through respiration. Equally important were Boyle's experiments aimed to test and vindicate a mechanistic theory of matter, to his own version of which he gave the name "corpuscularianism." He pioneered this in his crucial "Essay on Nitre," written in the mid 1650s and published in his *Certain Physiological Essays* (1661), to which such later works as his *Experiments, Notes &c. about the Mechanical Origin or Production of Divers Particular Qualities* (1675) are to be seen as sequels.

Boyle wrote a number of books in which he sought to prove the superiority of mechanical explanations of phenomena over those that had prevailed hitherto, both Aristotelianism (notably in his *Origin of Forms*

and Qualities, 1666) and the Paracelsian theory of the three principles (most famously in his *The Sceptical Chymist*, 1661). He was particularly hostile to views which made nature seem purposive, arguing in his *Free Enquiry into the Vulgarly Received Notion of Nature* (1686) that mechanical explanations were adequate without any reification of the powers inherent in nature itself. Both in this and other books he also considered the workings of the human body, which he saw as similarly susceptible to mechanical explanations.

Boyle's view of nature was eclectic; he was happy to accept the existence of intermediate properties of matter such as elasticity in the air, while his interpretation of chemical phenomena took it for granted that corpuscles were endowed with chemical, as against strictly mechanical, principles. He also pioneered a form of what was later to become known as emergentism, though he would have been shocked by the way in which such ideas subsequently developed, since he was convinced that a mechanical world supervised by an immanent deity was the best defense against the threat of irreligion. Indeed, one of his posthumous initiatives was the inauguration of the Boyle Lectures, in which Protestant Christianity was defended through expounding that the complexity and beauty of the universe presupposed an intelligent designer in the form of deity.

BOYLE'S LAW. This law, attributed to Robert Boyle (1662) but also known as Mariotte's law, expresses the isothermal pressure-volume relation for a body of ideal gas. That is, if the gas is kept at constant temperature, the pressure and volume are in inverse proportion, or have a constant product. The law is only approximately true, even for such gases as hydrogen and helium; nevertheless it is very useful. Graphically, it is represented by an equilateral hyperbola (see Fig. 1). If the temperature is not constant, the behavior of the ideal gas must be expressed by the Boyle-Charles law.

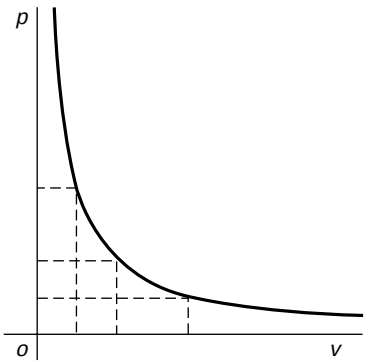

Fig. 1. Equilateral hyperbola representing Boyle's law. The rectangular areas (*PV*) are all equal.

The Boyle temperature is that temperature, for a given gas, at which Boyle's law is most closely obeyed in the lower pressure range. At this temperature, the minimum point (of inflection) in the *pV-T* curve falls on the *pV* axis. See **Compression (Gas)**; and **Ideal Gas Law**.

BOYS CAMERA. A camera used for the observation of lightning flashes. The early model of this camera consists of a fixed film plate and two lenses that revolve at the opposite ends of a diameter of a circle. The velocity and duration of a lightning stroke can be computed from a comparison of the two photographs and a knowledge of the rate of rotation of the lenses. A later model consists of a fixed lens and a rotating film drum. This construction allows greater ease of interpretation.

B. P. An abbreviation of "Before Present." This term is an indication of time calculation, used especially when referring to radiometric dating.

BRACHIAL. Pertaining to the arm, from the Latin term *brachium*.

BRACHIOPODA. A phylum of marine animals that resemble the bivalve mollusks superficially. In the remote past they were much more abundant, as is shown by extensive fossil remains of many more forms than exist today.

The brachiopods are characterized by the following structures: (1) The body is enclosed by a shell consisting of dorsal and ventral valves. (2) The animal is triploblastic and coelomate but not segmented. (3) A ciliated organ called the lophophore projects about the mouth. It maintains currents of water which carry food and oxygen to the animal and wash the wastes away.

The phylum is divided into two orders:

Order *Ecardines*. Valves of shell not joined by a hinge. Anus present.

Order *Testicardines*. Valves of shell joined by a hinge. Alimentary tract without an anus.

See also **Invertebrate Paleontology**.

BRACHISTOCHRONE. The characteristic curve along which a particle will slide from one point to another under the influence of gravity in the least possible time, friction being neglected. If the particle starts from rest at the origin of a Cartesian coordinate system (it is convenient to let the y-axis extend to the right and to measure x downward) and falls to the point (x_2, y_2) the following integral results

$$\sqrt{2g}t = \int_0^{x_2} \left(\frac{1 + y'^2}{x} \right)^{1/2} dx$$

where t is the time, g is the acceleration of gravity, and $y' = dy/dx$. When the resulting differential equation is solved, the curve is found to be a cycloid. See also **Abel Equation**.

BRACHYBLAST. In numerous plants, especially in the gymnosperms, the display of leaves to light is considerably advanced by the formation of short lateral branches called brachyblasts (or short shoots). In the larch, this short shoot is well developed. In this plant, it persists year after year bearing at its tip a small group of leaves. It does not, however, increase in diameter even after several years of growth. The brachyblast develops from a bud formed in the axil of a leaf. The maidenhair tree or *Ginkgo* is another tree having well-developed short shoots. In both these plants and in many others the short shoot bears at its tip a terminal bud from which the leaves of the following year develop. In the pines, on the contrary, the short shoot is very much reduced and bears no terminal bud. In these plants the short shoot is reduced to a single bundle of leaves that persist for a year or two and then drop off completely. That this condition in pines is a reduced condition is clear from the condition found in fossil pines, which have a well-developed brachyblast, bearing many leaves and having a terminal bud.

BRACHYCEPHALIC. Short-headed. As applied to measurement of the human skull, with a width which is more than $\frac{4}{5}$ of the length.

BRACKET CLOCK. See **Clocks**.

BRACKET FUNGI *(Polyporaceae;* also called Shelf Fungi*).* A large group of fungi the fruit-body of which forms a characteristic shelf-like outgrowth from the trunks of trees. This fruit-body arises from a mycelium of fine hyphae, which penetrate throughout the woody tissue of the host plant, from which they derive nourishment and which they slowly destroy. The fruit-bodies are often perennial, showing on sectioning the successive-growth-layers, which are added each year. See **Basidiomycetes**.

BRACT. In many flowering plants there is found at the base of the flower stalk a small leaf, often considerably modified; this is called a bract. In

many plants its minute size causes it to be overlooked; in others it is a conspicuous object. In the poinsettia, for example, the large showy red "flower" is really composed of bracts, as is also the conspicuous white petal-like structure surrounding the very small flowers of the flowering dogwood.

BRAGG'S CURVE. There are two types of curves to which Bragg's name is occasionally given: 1. A graph for the average number of ions per unit distance along a beam of initially monoenergetic alpha particles, or other ionizing particles, passing through a gas. 2. A graphical relationship between the average specific ionization of an ionizing particle of a particular kind, and some other variable, such as the kinetic energy, the residual range, or the velocity of the particle.

BRAGG'S LAW. The law expressing the condition under which a crystal will reflect a beam of x-rays with maximum distinctness, at the same time giving the angle at which the reflection takes place. For x-ray reflection it is customary to use the complement of the angle of incidence and reflection, that is, the angle which the incident or the reflected beam makes with the crystal planes, rather than with the normal. Let this "Bragg angle" be θ. If the planes or layers of atoms are spaced at a distance d apart, and if λ is the wavelength of the x-rays, Bragg's law is expressed by the equation

$$\sin\theta = \frac{n\lambda}{2d}$$

The condition for an intensity maximum is that n must be a whole number. For example if the planes of rock salt parallel to the natural cubical faces are spaced at $d = 2.814 \times 10^{-8}$ centimeters or 2814 x-units, and if the incident rays have a component of wavelength $\lambda = 714$ x-units, the above equation gives $\sin\theta = 0.1269n$. Then if the crystal is rotated slowly, there will be a distinct reflection where θ reaches $7^\circ 17'$ ($n = 1$), again at $14^\circ 42'$ ($n = 2$), also at $22^\circ 23'$ ($n = 3$), etc. See also **Crystal**.

BRAGG SPECTROMETER. An instrument for the x-ray analysis of crystal structure, in which a homogeneous beam of x-rays is directed on the known face of a crystal, C, and the reflected beam detected in a suitably placed ionization chamber, E. As the crystal is rotated, the angles at which the equation expressing Bragg's law is satisfied are identified as sharp peaks in the ionization current. See Fig. 1. This is one of the early, classical instruments in the laboratory field.

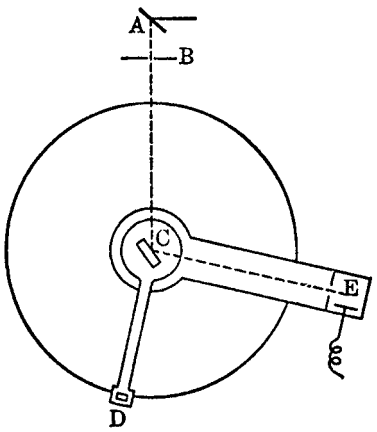

Fig. 1. Bragg spectrometer.

BRAGG'S RULE. An empirical relationship whereby an elements for mass stopping power of an element of alpha particles is inversely proportional to the one-half power of the atomic weight. This relationship is also stated in the form that the atomic stopping power is directly proportional to the one-half power of the atomic weight. The wide usefulness of the Bragg rule is due to the fact that it leads to relations between the stopping powers of different elements for alpha particles. It also applies to other charged particles as well as alpha particles, and to the same degree of approximation, which is about $\pm 15\%$.

See **Particles (Subatomic)**.

BRAGG, WILLIAM LAWRENCE SIR (1890–1971). Bragg was an Australian physicist. When he was a small boy, he shattered his elbow and an X-ray was taken. William Bragg's X-ray was the first medical X-ray in Australia. He received his early education at St. Peter' College in his birthplace, proceeding to Adelaide University to take his degree in mathematics with first-class honors in 1908. He came to England with his father in 1909 and entered Trinity College, Cambridge, as an Allen Scholar, taking first-class honors in the Natural Science Tripos 1912. Bragg's father, William Henry Bragg, was also a professor of physics and the two men worked together. They determined the crystal structures of basic substances such as diamonds, zinc blende, and calcite to mention a few. In 1915, he received with his father, the Nobel Prize in Physics for work in X-ray crystallography.

J. M. I.

BRAHE, TYCHO (1546–1601). Brahe is considered the greatest astronomical observer of pre-telescopic times. He was born in Denmark. He was drawn to astronomy after he witnessed a partial eclipse of the sun and was told that such phenomenon could be predicted. He began building unprecedented sighting instruments including one, which was a quadrant 19 feet across.

On November 11, 1572, Brahe independently discovered an exploding star in the constellation of Cassiopeia. This brilliant star was visible in broad daylight for weeks and is one of the brightest novae on record. With his superb instruments, Tycho proved that the star was stationary in the sky.

King Frederick II of Denmark was so impressed with Brahe's achievements that he gave Brahe the island of Hveen near Copenhagen and supplied him with the means to build the famous observatory of Uraniborg. During the 20 years he spent at this observatory, Brahe and his assistants measured the positions of 777 stars. Brahe also proved that the parallax of the comet of 1577 was smaller than that of the Moon, proving that it was further away.

See also **Cassiopeia (chair).**

J. M. I.

BRAILLE SYSTEM. A printing or writing system for the blind in which letters and characters are represented by raised dots or points, which are discernible to the touch. Invented by Louis Braille, a French teacher of the blind in 1829. Modified slightly since its origin, Braille writing is an almost universal system. Special books, newspapers, and periodicals are available in Braille. A second form of literature is referred to as *Moon's type*. It consists of raised lines and curves and is chiefly valuable for the small percentage of persons who do not seem able to learn Braille. Books in Moon's type are bulky and expensive and rather scarce. Braille literature, by contrast, is available in many public libraries, even of moderate size. Phonograph records and tape recordings also have augmented the Braille system of communication during the last several decades. See also **Vision and the Eye**.

BRAIN. See **Central and Peripheral Nervous Systems**.

BRAIN CHEMICALS. See **Enkephalins and Endorphins**.

BRAIN DISORDERS. Among the principal causes of brain disorders are genetic (inborn errors of metabolism, etc.), hemorrhage, pressure, displacement, inflammation, and atrophy. Several of the foregoing conditions, of course, may result from physical injury to the head.

Probably the most publicized during the 1980s is Alzheimer's disease. See **Alzheimer's Disease and Other Dementias**. Several other brain disorders are described in separate articles in this encyclopedia. Check alphabetical index.

As with other aspects of brain research, the investigation of brain disorders was hindered by the inability of researchers to explore the living brain as contrasted with examining dead brain tissue. Most of the early information was obtained at autopsy. X-rays were the first practical tool for examining the living brain. A relatively recent development, known as *pneumoencephalography*, has enhanced the value of x-ray examination. In this technique, the fluid that normally surrounds the brain is replaced with air, thus more clearly revealing structure. In still another technique, known as *cerebral angiography*, a dye opaque to x-rays is injected into the bloodstream. This enables the viewing of the pathological development of the blood vessels in the brain on the x-rays. A limitation of this method is that overlapping abnormal and normal structures are not distinguishable. The more recent computed axial tomography (CAT) technique does not

have these limitations. In this technique, numerous x-ray views are taken from various angles to form a reliable, computer integrated presentation of the internal structure of the brain. Abnormal tissues, such as tumors and hemorrhage damage, are made quite visible with this method. Aside from the radiation risk associated with any x-ray procedure, the CAT scan technique can be safely used on living human patients and experimental laboratory animals. The technique serves a very useful purpose as a diagnostic as well as research tool.

Because, as discussed in the entry on **Central and Peripheral Nervous Systems**, there is much electrical activity occurring within the brain, this activity can be measured by picking up electric signals from the skull. By moving detector electrodes around the skull, distribution of electrical activity can be traced to specific regions and locations of the brain. See also **Electroencephalogram**.

During and since the 1960s, great progress has been made in the use of chemical indicators as criteria for brain function analysis. In a technique developed by N.A. Lassen (Bispebjerg Hospital, Copenhagen) and D.H. Ingvar (University of Copenhagen), brain blood flow and glucose consumption by the brain can be measured instrumentally and projected on a cathode-ray tube. Thus, variations in blood glucose consumption can be related to mental activities, such as reading, talking, etc. In a refinement of this technique. L. Sokoloff and associates (National Institute of Mental Health) have been able to pinpoint brain metabolic activity, greatly enhancing the mapping of brain function, both for research and diagnostic applications.

The use of various staining techniques is described in the entry on **Central and Peripheral Nervous Systems**. Also in that entry, mention is made of a growing understanding of the biochemistry that occurs in synapses. Disturbances of the synapses (connections) within the brain are associated with such mental disorders as schizophrenia and manic-depressive psychosis. Although they are still in a pioneering stage, it is believed that these new techniques will be invaluable to research and diagnosis in psychiatry. See Fig. 1.

Etiology of Brain and Nervous System Disorders

Although there are numerous causes of serious, exotic, and rare mental and nervous system disorders, by far the majority of brain disorders arise out of a deficiency of blood supply to the brain. Continuing day and night, the brain requires 20% of the body's blood supply. As pointed out in the entry on **Central and Peripheral Nervous Systems**, blood glucose furnished to the brain represents 20% of the body's total oxygen needs (when resting). *Atherosclerosis*, a major disorder of the blood vessels, is the main underlying cause of inadequate blood to the brain. See **Arteries and Veins (Vascular System)**. This condition leads to a thrombus, which may progressively decrease the blood supply or cut the supply fully. Atherosclerosis also weakens blood vessels, causing them to rupture and resulting in a cerebral hemorrhage. These accidents occur over a variety of conditions and range from a small loss of blood supply or, in the case, of a weakened blood vessel, small amounts of bleeding, all the way to quickly fatal consequences. A majority of serious head injuries damage the brain blood supply, as also is the case of brain tumors. See **Brain (Injury)**.

Epilepsy is a disorder of the brain that has been known since antiquity, but still is not clearly understood. Improved treatment of seizures (the symptoms of the disorder) has far outpaced an understanding of the fundamentals. Some neuroscientists believe that one major precipitating factor of epilepsy may involve neuron transmitters and, in particular, gamma-aminobutyric acid (GABA), which is an inhibitory transmitter. See **Seizure (Neurological)**.

Genetic Factors. A number of enzyme catalysts are involved in brain functions. When the genetic ordering of the amino acids required to manufacture protein molecules is disturbed, a number of abnormalities, frequently resulting in mental retardation, occur. Diseases involving such enzyme deficiencies include **Galactosemia** and **Phenylketonuria**, for which there are separate entries in this encyclopedia. Genetic disorders are not limited to deficiencies of genetic material. Excesses also may cause brain disorders. Among the genetically derived mental disorders not previously mentioned are *Down's syndrome*, *Huntington's chorea*, and the *Lesch-Nyhan syndrome*. See **Alzheimer's Disease and Other Dementias**; **Chorea (Huntington's)**; **Down's Syndrome**; and **Lesch-Nyhan Syndrome**. Also, there is *porphyria*, which is described in the entry on **Dermatitis and Dermatosis**.

As suggested by Linus Pauling in the late 1960s, genetic differences among people may be reflected in their minimum daily requirements for vitamins. This hypothesis has at least been partially authenticated by the successful therapeutic use of certain vitamins in the cases of a few childhood mental disorders. For major adult psychoses, however, such therapy has not provided convincing evidence to date.

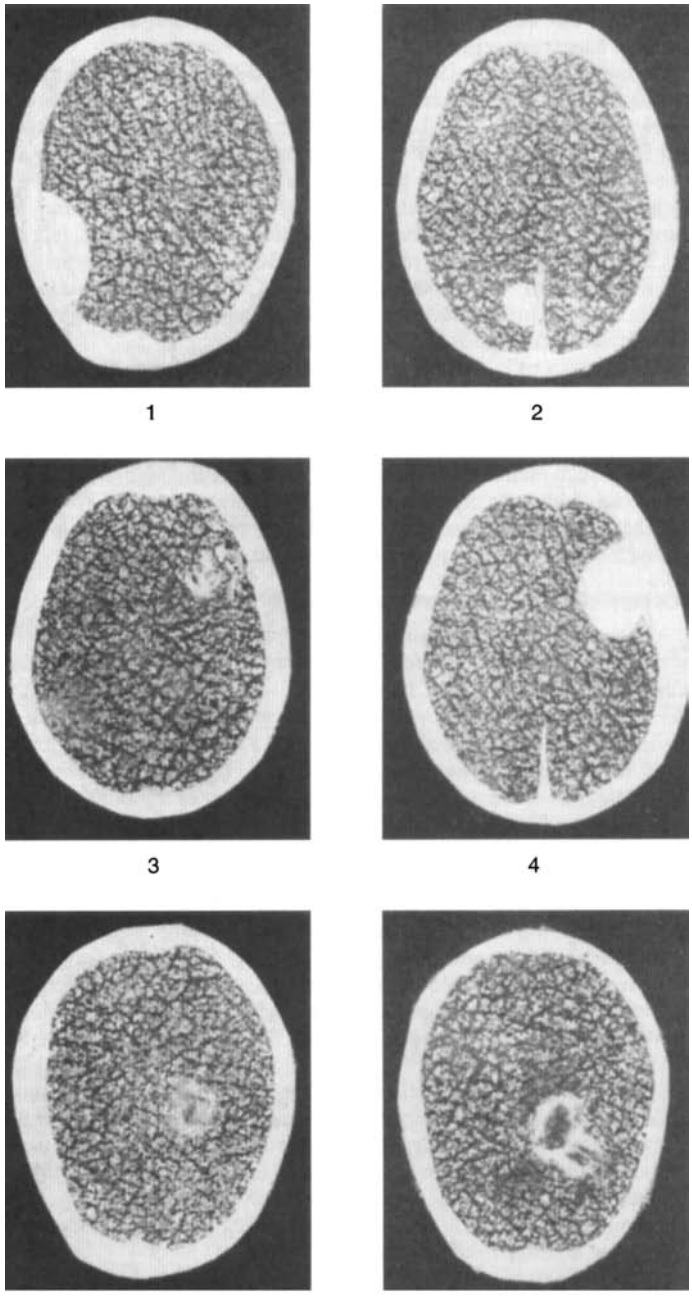

Fig. 1. Artist's replicas of CAT scans of human brains: (1) Blood clot at left between brain and skull caused by injury. No iodine solution was required to enhance this image. (2) Tumor. Iodine solution required. (3) Meningioma (benign tumor) only shows faintly without iodine solution. (4) Same tumor enhanced by iodine solution. (5) and (6) Malignant tumor in center of view. Iodine solution used. When white ringlike zones appear in an iodine enhance image, this usually indicates a malignant tumor. Other imagery techniques are used. Check alphabetical index.

For many years, neuroscientists have observed familial associations in the occurrence of schizophrenia and manic-depressive disorders. These observations have been supported by research involving identical twins.

Fetal Development. Brain and central nervous system disorders also arise from abnormalities in fetal development. For examples, see **Kernicterus**; and **Rubella**. Serious injuries to the pregnant woman may also cause fetal injury, but most frequently such situations result in a miscarriage.

Bacterial Infections. A number of brain disorders result from bacterial infections. A notable example is the brain and nervous system involvement in the later stages of syphilis. In recent years, antibiotic therapy has shortened the course of most bacterial infections and has prevented brain damage. See also "Bacterial Meningitis" in the entry on **Meningitis**.

Viral Infections. Particularly notable among the virus-caused nervous system disorders is *poliomyelitis*, which is an infection of the motor neurons. Although the incidence of this disease has been dramatically reduced, freedom from the disease is entirely dependent upon the routine use of vaccines. See **Poliomyelitis**. An example of a slow virus is the influenza virus (of the epidemic of 1918) which many years later produced *Parkinson's disease* in large numbers of individuals. See **Parkinson's Disease**. *Kuru*, a disorder thus far encountered only in tribal people of New Guinea, is a neurological disorder of viral origin. *Creutzfeldt-Jakob disease, Alzheimer's disease, progressive multifocal leukoencephalopathy* (PML) and *subacute sclerosing panencephalitis* (SSPE) also are diseases resulting from prior viral infections. Viruses also cause mental disorders among animals, such as chimpanzees, lower primates, sheep, and other animals. These disorders include *scrapie* and *transmissible mink encephalopathy*. See **Virus**. Also see, "Aseptic Meningitis" in the entry on **Meningitis**.

In the entry on **Central and Peripheral Nervous Systems**, the manner in which the brain is well protected (skull, blood-brain barrier, etc.) is discussed. Nevertheless, a number of chemical substances are highly toxic to brain tissue. There are, of course, the halucinogenic drugs, such as LSD. There are also numbers of industrial chemicals, such as mercury, manganese, and lead metals and compounds, and many identified and unidentified industrial organic chemicals, which can lead to brain disorders, some of these substances requiring several years to cause sufficient damage to be noted by the affected individual.

BRAIN (Injury). Within the skull, either the brain or its covering (*dura*) may be damaged. Injury to the dura causes bleeding which may, in turn, injure the brain tissue. When bleeding is on the undersurface of the dura, it is termed a *subdural hematoma*. If the bleeding is above the dura, it is termed an *extradural hematoma*. The latter almost always occurs in the region of the temple. Individuals with hematomas have a characteristic course of symptoms. A blow on the head, for example, may or may not cause temporary loss of consciousness. This is followed by headache, which becomes increasingly severe during the next two or three hours, often followed by nausea and vomiting. There may be drowsiness, speech difficulties, and weakness in various parts of the body. If the drowsiness continues, the patient becomes stuporous and finally goes into a deep coma. Blood collects in the area of the wound. Since the skull is rigid and non-expansile, the collecting blood can only depress the brain tissue. When this lasts for only a short time, there may be no permanent damage. When it lasts for a long period, there is usually permanent damage to the brain tissue.

Once the diagnosis of extradural clot is suspected, there should be immediate surgical exploration. This is a rather simple procedure. Two small holes are bored into the skull, and the clot is located. Then, a larger hole is made. The clot is sucked out. The bleeding artery is tied off. When treated promptly, there is an excellent chance the patient will recover.

Subdural hematomas usually develop over a period of days or weeks. Chronic subdural hematomas are more common than formerly suspected. They often follow minor head injuries and usually occur in infants and persons over 40 years of age. The bleeding is slow, and often fluid from the surrounding tissue is drawn into the clot. This results in a slowly enlarging mass which allows the brain tissue some adjustment to the increased pressure. The symptoms, which appear after weeks and months, are usually similar to those of brain tumor. Headache is present in most cases. Drowsiness is another conspicuous sign. Both of these symptoms may fluctuate from day to day in the same patient. Dizziness often accompanies these symptoms and vomiting may also occur. Older patients usually are confused. Personality changes are so insidious and vague that the family cannot state just what is wrong, but only that the patient is "different." There may be weakness or complete paralysis of various parts of the body. Diagnosis of this condition is sometimes difficult, and made only through an exploratory operation. The procedure may be simple, as previously described for extradural hematomas, or it may be more extensive. Recovery is good in many of these cases, particularly if the underlying brain tissue is healthy.

Injuries to the brain are extraordinary varied in their effect. For example, the trauma of a bullet entering the brain may cause life to cease almost immediately; or the tearing and depriving brain tissues of blood and oxygen can make the difference between functional living and vegetable-like existence. In rare instances, a bullet entering the skull has been known to miss vital areas and leave the victim with little more than a severe headache. Brain injury may occur without damage to other structures of the head.

Brain injury is usually subdivided into the following classes: (1) concussion, (2) contusion, and (3) laceration. Concussion is a jarring of the brain that usually results in a transitory period of unconsciousness. It is one of the most common and mild forms of brain injury. Recovery is almost always complete. Contusion is a bruising injury to the brain. The patient's symptoms are a combination of two effects: (1) non-function of some nerve centers, and (2) overactivity of others that are normally inhibited by higher control centers. Disturbance of consciousness is a sign of generalized disturbance in the brain, whatever the cause. This may be a mild, transient change, or a profound and prolonged coma. A boxer's "k.o." is an example of concussion. Many fighters have no lasting effects, while others become "punch drunk" and portray unusual symptoms.

Recovery from complete loss of consciousness is attained by certain stages. The entire process may require only a few minutes. However, any of the phases may be prolonged for hours or days. In severe injury, paralysis of major brain functions, even of respiration, may occur. The latter returns quickly in nonfatal cases. Death occurs rapidly if artificial respiration is not applied in those instances when return of respiration is delayed. Deep coma is marked by flaccid paralysis and even loss of involuntary motion. As coma lightens, the patient passes into stupor, and reflex activity returns. He responds automatically to forceful commands, but is unaware of his surroundings. The next phase, excitement or delirium, is marked by extreme restlessness and confusion, and often the patient is violent. He gradually becomes quiet, but remains extremely confused mentally. In the next stage, automatism, the patient answers questions and performs simple tasks in a fairly orderly, but automatic way. The highest functions of judgment and insight are the last to return.

Laceration of the brain results in actual tearing or destruction of the brain tissue itself. Swelling of the brain occurs and probably accounts for at least part of the widespread changes that follow. Slowing of the blood flow results in poor oxygen supply, which further increases the damage.

On recovery of consciousness, there may be loss of memory (amnesia) for the accident itself. Often, this amnesia includes events that occurred before the accident (retrograde amnesia) and a variable period of time after the accident (posttraumatic amnesia). The presence of retrograde amnesia is evidence of the severity or extensiveness of the brain injury. The duration of posttraumatic amnesia varies because the patient often has isolated memories of events before the complete return of memory.

In severe injuries, if the patient arouses sufficiently to answer questions, as a rule he is fairly certain to recover from the initial generalized brain injury, but he is still liable to such complications as meningitis and hemorrhage. Personality and intellectual impairment also may occur. In general, the older the patient, the slower and less certain is the improvement. Children tolerate head injury with fewer aftereffects than adults. Some, however, show behavior disorders. In general, the duration of posttraumatic amnesia is the best single criterion for prognosis; the longer it lasts, the poorer the outlook. Improvement may continue slowly for 12 to 18 months.

Infections, such as brain abscess or meningitis, may complicate head injury. Most brain abscesses result from compound fractures or from penetrating wounds, both of which introduce bacteria into the brain. The injured brain provides an ideal place for the growth of bacteria. If the organisms are virulent, meningo-encephalitis may develop rapidly. If they are less virulent, a brain-abscess develops.

Convulsive seizures of any type may occur at any time after brain injury. The occurrence of seizures immediately following the injury does not necessarily mean that the patient will continue to have them, nor does their absence during the acute phase guarantee against them in the future. They may develop months or years after the original injury. They are more apt to occur in those injuries that produce penetration of the dura and brain damage. Retention of a foreign body of any sort leads to a higher incidence of convulsions. Laceration of the brain and small intracerebral hemorrhages also result in tissue changes which may cause convulsions.

The condition known as "punch drunk" is seen in people who have had repeated head injuries, such as professional football players and particularly boxers. The condition is thought to result from small hemorrhages throughout the brain. The changes begin gradually with the loss of dexterity, which the patient may claim is as good as ever. Lack of attention, concentration, and memory follow. Impediments of speech and glazed, staring eyes make the usually too talkative, too social person look partially drunk, hence the term for the condition. Tremor of the hands, unsteadiness of gait, and failing vision and hearing develop in severe cases. The victim is unable to engage in even simple intellectual activities and is without insight regarding his disability.

In contrast with the "punch drunk" person, the individual with post-concussion syndrome complains of greater incapacity, of which he gives little outward sign. Authorities differ as to cause. Some believe that the condition is caused by organic damage to the brain. Others believe that it is the result of psychological factors. The condition is not related to the severity of the injury. Headache, which is quite variable in character, is the most common complaint. The patient may suffer from intolerance to cold, fatigue, and insomnia. Some memory impairment and confusion in thinking may be noted. In more severe cases, the patient may have an emotional outburst, particularly of rage. Treatment usually consists of the administration of mild sedatives and psychotherapy. See also **Headache**.

Concussion in Sports*

Concussion can occur during any sport, even in those in which a helmet is routinely worn, such as football or cycling. Helmets do not necessarily prevent concussions, but they usually lessen their severity.

The Committee on Head Injury Nomenclature of the Congress of Neurological Surgeons defines concussion as "A clinical syndrome characterized by immediate and transient post-traumatic impairment of neural function, such as alteration of consciousness, due to brain stem involvement."

Three types of brain injury can result from blows to the head. The extent of the injury is proportional to the head's acceleration during the injury. A *coup injury* is caused by a forceful blow to the resting but movable head. The side of the brain that is hit incurs the most damage. A *countrecoup* injury occurs when the moving head hits an unyielding object. In this case, the side of the brain opposite the impact incurs the most damage. In a *skull fracture* (the greatest injury to the brain) usually lies directly below the fracture site.

The skull and scalp give the brain considerable protection from outside forces, and the fluid that surrounds the brain acts as a shock absorber. This protection, however, may falter in cases of severe, blunt head trauma.

The severity of concussion can vary considerably. No system for grading severity levels has been accepted universally. However, a number of grading schemes have been developed. These are based on (1) duration of amnesia (loss of memory) following the blow to the head (post-traumatic amnesia), (2) the duration of *unconsciousness*, or (3) a combination of the two symptoms. A concussion generally is considered mild if there is no loss of consciousness and the post-traumatic amnesia is brief.

Loss of consciousness requires evaluation in a hospital setting, as does post-traumatic amnesia if it persists for over a half-hour. Where other symptoms, such as vision disturbance, headache, dizziness, or nausea and vomiting persist for over 12 hours, additional testing is indicated.

For the sports participant, there is no standard concerning when a player should be returned to competitive action. Generally, athletes who experience a moderate or severe concussion may require up to a month before returning to play. A second concussion may require withdrawal from competition for the remainder of a season. An athlete who has suffered a concussion often is more likely to suffer a second concussion.

The effects of concussion can be cumulative, and the effects are greatest in terms of impairing skills and rapid-thought processes, as well as the reliable recollection of new information.

BRAKING ELLIPSES. A series of ellipses, decreasing in size due to aerodynamic drag, followed by a spacecraft in entering a planetary atmosphere. In theory, this maneuver will allow a spacecraft to dissipate the heat generated in entry without burning up.

BRANCH (Computer). A set of instructions that may be executed between a couple of successive decision instructions. Branching enables

* Source of this information: Hughston Sports Medicine Foundation, Columbus, Georgia.

parts of a program to be worked on to the exclusion of other parts and provides a computer with considerable flexibility. The branch point is a junction in a computer routine where one or more of two choices is selected under control of the routine. Also refers to one instruction that controls branching.

BRANCHING. In radioactivity, branching denotes the occurrence of more than one mode of disintegration by a radionuclide. See **Radioactivity**. The two modes operate jointly, a portion of the atoms of the radionuclide undergoing one mode, and another portion undergoing the other–both modes having characteristic rates. The branching fraction is the ratio of the number of atoms disintegrating by a particular mode to the total number of atoms disintegrating (per unit time). The branching ratio is the ratio of two specified branching fractions.

BRANCH POINT (Mathematics). If $f(z)$ is a multivalued function of the complex variable z and there exists a single-valued analytic function $g(z)$ such that at each z for which $f(z)$ is defined, the value of $g(z)$ coincides with one of the values of $f(z)$, then $g(z)$ is called a *branch* of $f(z)$. A curve in the domain of definition of $f(z)$ such that, if the points on this curve are removed, the remainder of the domain of definition is an open set for which there exists a branch of $f(z)$, is called a *branch cut*. A point at which a branch cut originates is called a branch point. Thus, if $f(z) = z^{1/2}$, the negative real axis, including the origin, is an example of a branch cut, while the origin itself is a branch point. See also **Node**.

BRASS. See **Copper**.

BRASSICA. A genus of the family *Cruciferae* (mustard family) and composed of three major groups: (1) the rapes; (2) the cabbages (or coles); and (3) the mustards. There are also numerous plants termed *cress*.

Rape

Brassica napus L. is characterized by foliage that is dark bluish-green and glaucous (covered with a bloom or whitish substance that rubs off) and smooth, or with a few scattered hairs near the margins. The leaves have the same general shape in all varieties. The inflorescence is an elongated raceme, the flowers large, clustered at the top but not prominently overtopping the terminal buds, often with open flowers along the axis below.

The rapes are represented by four varieties: (1) winter rape; (2) summer rape; (3) rutabaga; and (4) rape-kale. Winter rape, a biennial or winter annual, is planted for fall and winter pasture. The variety *Dwarf Essex* is planted almost exclusively so that the name is often used synonymously for winter rape. Summer rape, an annual producing comparatively little leafage, is essentially an oilseed crop. Rutabaga is grown for the young tops, which are used for greens, and for the tubers, which are for table use and stock feed. The rape-kales may be used as a forage crop and one variety, the *Dwarf Siberian* kale, may be planted for greens.

Cabbage or Cole

With exception of some of the kitchen kales, most of the cultivated forms of cole, or cabbage (*Brassica oleracea* L.) are characterized by foliage that is thick and somewhat leathery, glaucous, and smooth. The inflorescence is an elongated raceme with large open flowers along the axis below the terminal buds, much as in winter rape.

Mustard

The mustards may be annual or biennial, the foliage varying in shape and color from bright green and hairy to lightly glaucous and smooth. The species may be grouped roughly into three classes: (1) turnip and allies; (2) the true mustards; and (3) the oriental, or Chinese mustards. The turnip group includes three types of plants: (1) the edible turnip; (2) the so-called wild turnip; and (3) turnip-rape, annual and biennial oilseed crops. With the exception of the strap-leaved or Japanese turnips, the leaves are lyrate in form, bright green or lightly glaucous in the annual forms, sparingly to copiously hairy; the flowers are small, clustered at the top of the raceme and usually overtopping the terminal buds.

Four species are included in the true mustards: (1) brown mustard, with several horticultural varieties; (2) black, or Trieste mustard; (3) white mustard; and (4) charlock, or wild mustard. These mustards are used chiefly in the manufacture of condiments, as table greens, and for planting as cover crops. Charlock is a widespread field weed and is sometimes screened in quantity out of grain. It finds limited use as a quick cover crop in situations where close cultivation is practiced. All four species are annuals and flower early. They are readily distinguished in early stages of growth and later by the character of the inflorescence and seed pods, or siliques.

BRAVAIS-MILLER INDICES. A modification of the Miller indices suitable for describing hexagonal crystals. In this system, three axes are taken, perpendicular to the hexagonal axis and at angles of 120° to one another. The symbols then consist of the reciprocal intercepts on these axes, followed by the reciprocal intercept on the hexagonal axis, all reduced to integers, e.g., (0001). The first three indices are not independent but must add to zero.

BRAYTON CYCLE. See **Gas and Expansion Turbines**; and **Solar Energy**.

BRAZIL CURRENT. See **Ocean Currents**.

BRAZIL-NUT TREE. Of the family *Lecythidaceae*, the giant *Bertholletia excelsa* grows in the forests of northern Brazil. The seeds of this tree are called Brazil nuts, or *Pará chestnut*; *tacari* (in Brazil); *toura* (in French Guiana). The tree commences to bear at eight years and may yield up to a half-ton of large round fruit pods each year. Each pod contains from 18 to 24 hard-shelled kernels (the commercial nuts). The oil content of the nut is high and would be an excellent food oil except that the nuts are the more highly valued form and there is insufficient harvest to serve both purposes. The fruits develop high on the tree and fall to the ground without opening. This favors the gathering of the fruits, which are then split open and the seeds removed. Very large quantities of Brazil nuts are consumed in Brazil and the United States.

BRAZILWOOD. This term is used to describe the wood obtained from several species of tropical American trees in the family *Caesalpiniaceae* (senna family). At one time, the wood from *C. brasiliensis*, *C. drista*, and *C. echinata* was an important Brazilian export. Its principal use was as a dyewood, producing purple shades when used with a chrome mordant, and crimson shades with alum. Synthetic dyes now fill requirements for these shades. However, brazilwood extract still is used in limited quantities in connection with inks, wood stains, and silk dyeing. The wood finds continued limited demand for high-quality furniture and items such as violin cases because of the rich bright-red coloration and its capability of accepting a high polish. *Sapanwood*, also sometimes called brazilwood, is obtained from *C. sappan*, which grows in Sri Lanka, India, and Malaya.

BRAZING. Brazing may be defined as the joining of metals through the use of heat and a filler metal whose melting temperature is above 840 °F (450 °C), but below the melting point of the metals being joined. A more exact name for many brazing processes would be "silver brazing," since the filler metal used most often is a silver alloy. Brazing may be the most versatile method of metal joining today. Brazed joints are strong-on nonferrous metals and steels, the tensile strength of a properly made joint will often exceed that of the metals joined. Brazed joints are ductile, able to withstand considerable shock and vibration. Brazing is essentially a one-operation process. There is seldom any need for grinding, filing, or mechanical finishing after the joint is complete. In comparing brazing with welding, it should be noted that welding, by its nature, presents problems in automation. A resistance weld joint made at single point is relatively easy to automate, but once the point becomes a line (a *linear joint*), the line has to be *traced*.

In contrast, a brazed joint is made in a completely different way from a welded joint. The first big difference is in temperature. Brazing does not melt the base metals; therefore, brazing temperatures are invariably lower than the melting points of the base metals, and they are always lower than welding temperatures for the same base metals. Brazing joins metals by creating a *metallurgical bond* between the filler metal and the surfaces of the two metals being joined. See Fig. 1. The principle by which the filler metal is drawn through the joint to create this bond is *capillary action*. In brazing, heat is applied broadly to the base metals. The filler metal is then brought into contact with the heated parts. It is melted instantly by the heat in the base metals. Because of this action, brazing joins almost any configuration with equal ease. See Fig. 2.

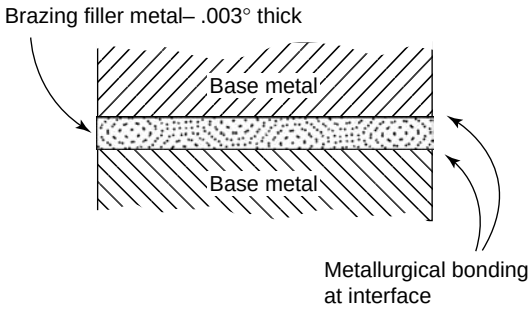

Fig. 1. The principle by which the filler metal is drawn through the joint to create a bond between the base metals is capillary action. In brazing, heat is applied broadly to the base metals. The filler metal is then brought into contact with the heated parts, whereupon the filler metal melts instantly and is drawn completely through the joint. (*Lucas-Milhaupt, Inc., A Handy & Harman Company.*)

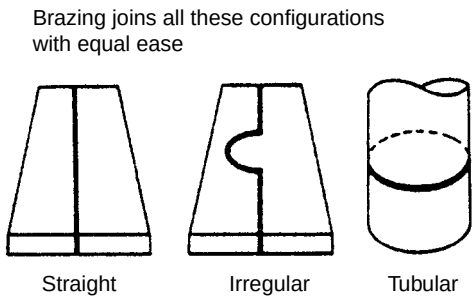

Fig. 2. Representative brazing joint configurations. (*Lucas-Milhaupt, Inc., A Handy & Harman Company*.)

The six basic steps in brazing are: (1) *Good fit and proper clearance* — Because brazing depends upon capillary action to distribute the molten filler metal between the surfaces of the base metals, care must be taken to make certain that the clearance between the base metals is right, which in most cases can be described as a *close clearance*. (2) *Cleaning the metals* — because oil, grease, rust, scale, dirt, etc. form barriers between the base metal surfaces and the brazing materials. (3) *Fluxing the parts* — With few exceptions, flux is applied to the joint surfaces before brazing. A coating of flux on the joint area shields the surfaces from air, preventing oxide formation. The flux also dissolves and absorbs any oxides that form during heating, or that were not completely removed in the cleaning procedure. (4) *Assembly for brazing* — After cleaning and fluxing, the parts must be held in firm position for brazing. The simplest way to hold parts together is by gravity, providing the shape and weight of the parts permit. Where there are several assemblies to braze and their configurations are too complex for self-support or clamping, a brazing support fixture is indicated. (5) *Brazing the assembly* — which involves the application of heat. Commonly a torch is used to furnish the heat. Well suited to automation (providing other variables permit) is furnace brazing, a method that has been used quite successfully in the manufacture of heavy-duty electrical contacts. If the furnace has an inert atmosphere, fluxing can be eliminated. (6) *Cleaning the brazed joint*.

The physical properties of the filler metal are based on its metallurgical properties. The composition will determine whether the filler metal is compatible with the metals being joined — capable of wetting them and flowing completely through the joint area. There are also special requirements, such as brazing in a vacuum where a filler metal free of any volatile elements, such as cadmium or zinc, must be selected. Some electronic components require filler metals of exceptionally high purity. Corrosion-resistant joints require filler metals that are both corrosion-resistant and compatible with the base metals jointed. The melting behavior of the filler metal is based on its metallurgical composition. Since filler metals are alloys, they usually do not melt in the same manner as pure metals, which go from a solid to a liquid state at one temperature. An important exception is the eutectic alloys which do melt in the same way as pure metals. One such eutectic composition is a simple silver-copper alloy (72% Ag and 28% Cu), also known as *Harman's Braze 720*, which

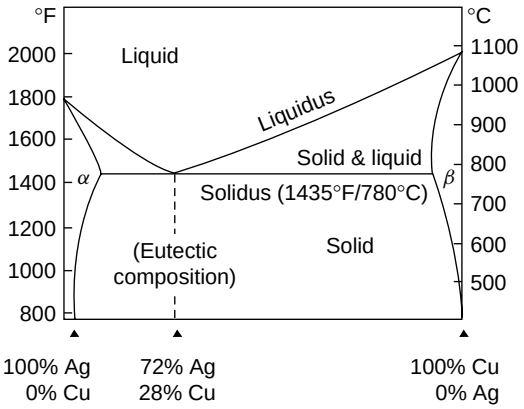

Fig. 3. Silver-copper equilibrium diagram. For a 72% silver-28% copper alloy, liquidus and solidus temperatures are the same. Alloys to the left or to the right of this eutectic composition do not go directly from a solid to a liquid state, but pass through a "mushy" range where the alloy consists of both solid and liquid states. Some brazing alloys are formulated to melt in a narrow temperature range. They are very fluid when melted and thus flow easily into close-clearance joints. Other brazing alloys are formulated for a wide melting range. Their relatively sluggish flow is desirable for filling wide gaps, or for building up stress-distribution fillets at the joint edges. (*Lucas-Milhaupt, Inc., A Handy & Harman Company*.)

melts completely at a single temperature, 780 °C (1435 °F). The melting behavior is shown by Fig. 3.

In all brazing applications, a critical factor is the "flow point" of the brazing filler material. This is the temperature above which the filler metal is liquid and flows readily, as distinguished from the melting point, when melting begins. Since in brazing the base metals must not be melted, a filler metal whose flow point is lower than the melting point of either of the base metals being joined must be used. A practical problem sometimes arises wherein there are two brazed joints in relatively close proximity (Fig. 4). So that the second brazing operation will not adversely affect the first operation, the filler metal selected for the second joint will have a flow point that is lower than that used for the first joint.

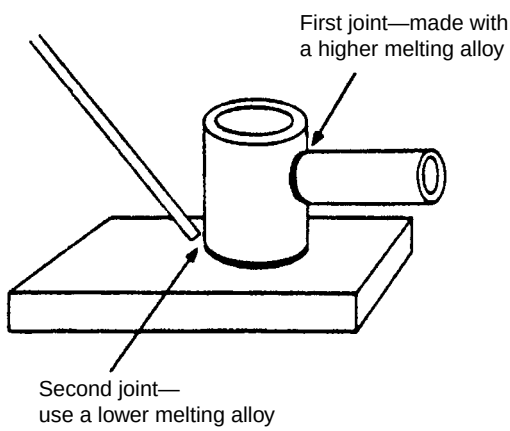

Fig. 4. Demonstration of the use of a higher melting alloy for first joint and a lower melting alloy for an adjacent second joint so that first joint will not be disturbed when the second joint is made. (*Lucas-Milhaupt, Inc., A Handy & Harman Company*.)

Brazing is widely used in assembling heat exchangers, piping systems, electrical products, cutting tools, bicycles, and control instruments, among many other applications.

BREAD AND BREADMAKING. See **Bakery Processes, Yeast-Raised Products**.

BREAKDOWN VOLTAGE. This is the voltage necessary to cause the passage of appreciable electric current without a connecting conductor. It

is commonly used to express the voltage at which an insulator or insulating material fails to withstand the voltage and ceases to behave as an insulator.

BREAKER. A sea surface wave that has become too steep to be stable and that breaks on the shore or in the open ocean. Breakers can be classified into four categories: 1) A spilling breaker breaks gradually over a considerable distance; 2) plunging breakers tend to curl over and break with a crash; 3) surging breakers peak up, but then instead of spilling or plunging, they surge up on the beach face; 4) collapsing breakers break in the middle or near the bottom of the wave rather than at the top.

BREAKING-DROP THEORY. A theory of thunderstorm charge separation based upon the suggested occurrence of the Lenard effect in thunderclouds, that is, the separation of electric charge due to the breakup of water drops. This theory, advanced by Sir George C. Simpson (1972), was initially intended to account for a bipolar charge distribution within a thundercloud having the main positive charge center near the base of the cloud and the main negative charge center higher up. Simpson's theory, however, does not explain this phenomenon well because temperatures are below the freezing point in this region of the cloud. Evidence does remain to support a weak positive charge center that lies slightly below the lower main negative charge concentration in many, if not all, thunderclouds where the temperature is above the freezing point. Hence, the breaking-drop theory is best ascribed to this localized secondary positive charge center.

BREAKWATERS. Breakwaters are coastal structures used to protect harbor and shore areas by dissipating and reflecting wave energy. They are built to

- reduce wave disturbance in coastal and harbor areas and preserve related activities;
- protect ships and boats from wave forces;
- when located near shore, in the same direction as the coastline, they can stabilize the coastline, modifying cross-shore and long-shore sediment transport.

The choice of the type of structure depends on the availability of materials used, the characteristics of the incident wave, the bottom morphology, the geotechnical parameters of the soil, and the necessity of obtaining a flexible or rigid structure. Breakwaters can be classified as rubble-mound structures, vertical breakwaters, and floating breakwaters.

Rubble-Mound Structures

The typical cross section of a rubble-mound breakwater is sketched in Fig. 1. It consists of different layers of stones. The center core is made up of quarry run. The external layer (armor) consists of large armor units, which can be either rock or specially designed concrete units (cubes, tetrapods, dolos). The breakwater crest is generally 1–2 m (3.28–6.56 ft) over the still water level (SWL). The crest width should be large enough to allow transport and installation of material during construction and when a repair is made.

Because of the relative dimensions of the units of the armor and those of the core, in some cases, it is necessary to build the breakwater as a filter of three or four layers (underlayers), so that the finer material of the core cannot be removed by the waves through the voids of the armor layer. To prevent removal of finer material, the filter must satisfy the following relations:

$$D_{15}(upperlayer) < 4 \div 5 D_{85}(lowerlayer), \tag{1}$$

$$D_{15}(upperlayer) < 20 \div 25 D_{15}(lowerlayer), \tag{2}$$

where

D_{15} = nominal size that is exceeded by the 85% of the sample
D_{85} = nominal size that is exceeded by the 15% of the sample

A toe filter is necessary if the breakwater is built on erodible material. The toe filter prevents breaking waves from removing material from the base of the structure. If the breakwater is located in shallow water, the filter toe is exposed to extreme wave action. To avoid, or just limit, wave overtopping, it is possible to use a concrete structure (crown wall) located over the crest (Fig. 1).

When the breakwater is small and not high, it is possible to avoid using a center core. This kind of structure, of single sized stones, is called a "reef breakwater," and it is normally used for small submerged breakwaters.

The rubble-mound breakwater causes the dissipation of wave energy by generating eddies due to the breaking. The voids and the roughness of the structural material, as well as the permeability of the structure, are very important in the dissipation process. The wave energy entering through the structure creates shear stresses that can move the masses causing loss of stability.

Vertical Breakwaters

Vertical breakwaters are rigid and not as flexible as rock armored ones. It is necessary to know very well the wave climate (direction, intensity, frequency, and duration of waves) to obtain a good design. A typical cross section of vertical breakwaters is sketched in Fig. 2a, 2b, 2c.

Forces on Vertical Structures

Nonbreaking Wave. A nonbreaking wave is perfectly reflected (coefficient of reflection = 1.0) and can be considered static because the period is longer than the natural period of oscillation of the structure. This stationary and static wave is called "clapotis." Assuming perfect reflection, the seaward wave has a height double the incident wave.

If the vertical breakwater is overtopped, a reduction of wave pressure occurs because it is truncated at the crest level. According to Sainflou, the pressures are (Fig. 2a)

$$p_1 = p_2 + \rho_w g h_s \left(\frac{H + \delta_0}{h_s + H + \delta_0} \right), \tag{3}$$

$$p_2 = \frac{\rho_w g H}{\cosh(2\pi h_s / L_0)}, \tag{4}$$

$$p_3 = \rho_w g (H - \delta_0), \tag{5}$$

$$\delta_0 = \frac{\pi H^2}{L_0} \coth(2\pi h_s / L_0), \tag{6}$$

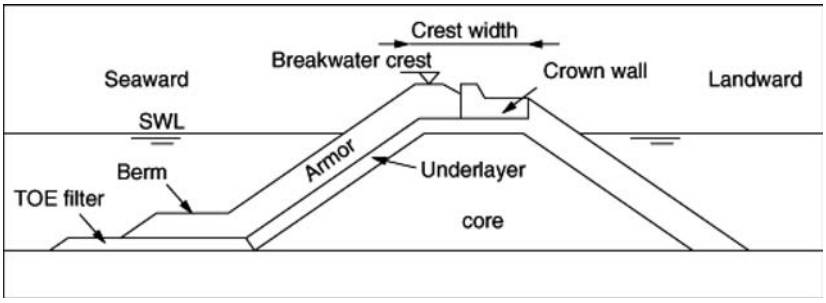

Fig. 1. Typical section of a rubble-mound breakwater.

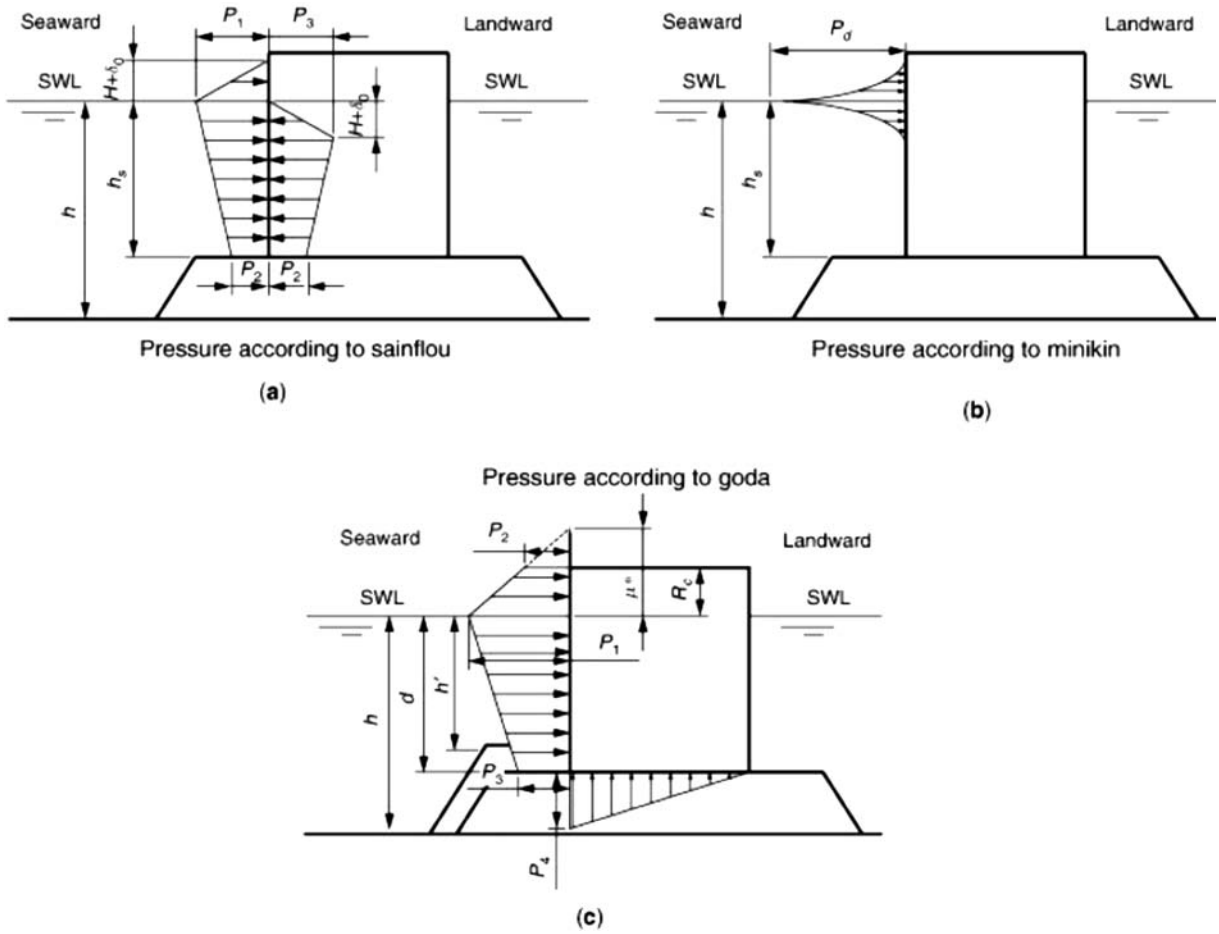

Fig. 2. Pressure on vertical breakwaters.

where

H = wave height;
p_1 = pressure at the still water level (SWL), corresponding to wave crest;
p_2 = pressure at the base of a vertical wall;
p_3 = pressure at the still water level, corresponding to a wave trough;
δ_0 = vertical shift in the wave crest and trough at the wall;
ρ_w = water density;
h_s = water depth at the foot of the structure;
L_0 = wavelength in deep water.

Breaking Waves. The worst condition for a vertical breakwater occurs when the water depth in front of the structure causes the wave to break. In this case, the dynamic component of the pressure must be considered, especially if the breaking is sudden, as happens for plunging waves. The forces generated by breaking are very high and a very short duration. According to Minikin, the dynamic pressure (Fig. 2b) is

$$P_D = 100\frac{h_t}{h_s L_0}(h_s + h_t)\rho_w g H, \tag{7}$$

where

H = wave height;
p_d = dynamic pressure at the still water level, corresponding to the wave crest;
ρ_w = water density;
h_s = water depth at the foot of the structure;
h_t = height of the caisson between the SWL and the berm;
L_0 = wavelength in deep water.

Another expression that can be used to determine the total pressure for breaking waves is

$$p_1 = 0.5(1 + \cos\beta)(\alpha_1 + \alpha_2 \cos^2\beta)\gamma H, \tag{8}$$

$$p_2 = p_1\frac{\eta^* - h_c}{\eta^*} \tag{9}$$

$$p_3 = \alpha_3 p_1, \tag{10}$$

$$p_4 = 0.5(1 + \cos\beta)\alpha_1\alpha_3\gamma H, \tag{11}$$

$$\eta^* = 0.75(1 + \cos\beta)H, \tag{12}$$

$$\alpha_1 = 0.6 + 0.5\left(\frac{2kh}{\sinh 2kh}\right)^2, \tag{13}$$

$$\alpha_2 = \min\left\{\frac{h_b - d}{3h_b}\left(\frac{H}{d}\right)^2, \frac{2d}{H}\right\}, \tag{14}$$

$$\alpha_3 = 1 - \frac{h}{h}\left(1 - \frac{1}{\cosh kh}\right), \tag{15}$$

$$H = \min(1.8H_s, H_f), \tag{16}$$

$$H_f = 0.18\frac{gT^2}{2\pi}\left(1 - \exp\left\{\frac{3\pi^2 h_b}{gT^2}[1 + 15(\tan\vartheta)]^{4/3}\right\}\right), \tag{17}$$

where

h_b = water depth at a distance of $5H_s$ from the vertical breakwater (seaward);
β = angle of incidence of the wave;
ϑ = bottom angle within the horizontal.

The other symbols are explained in Fig. 2c.

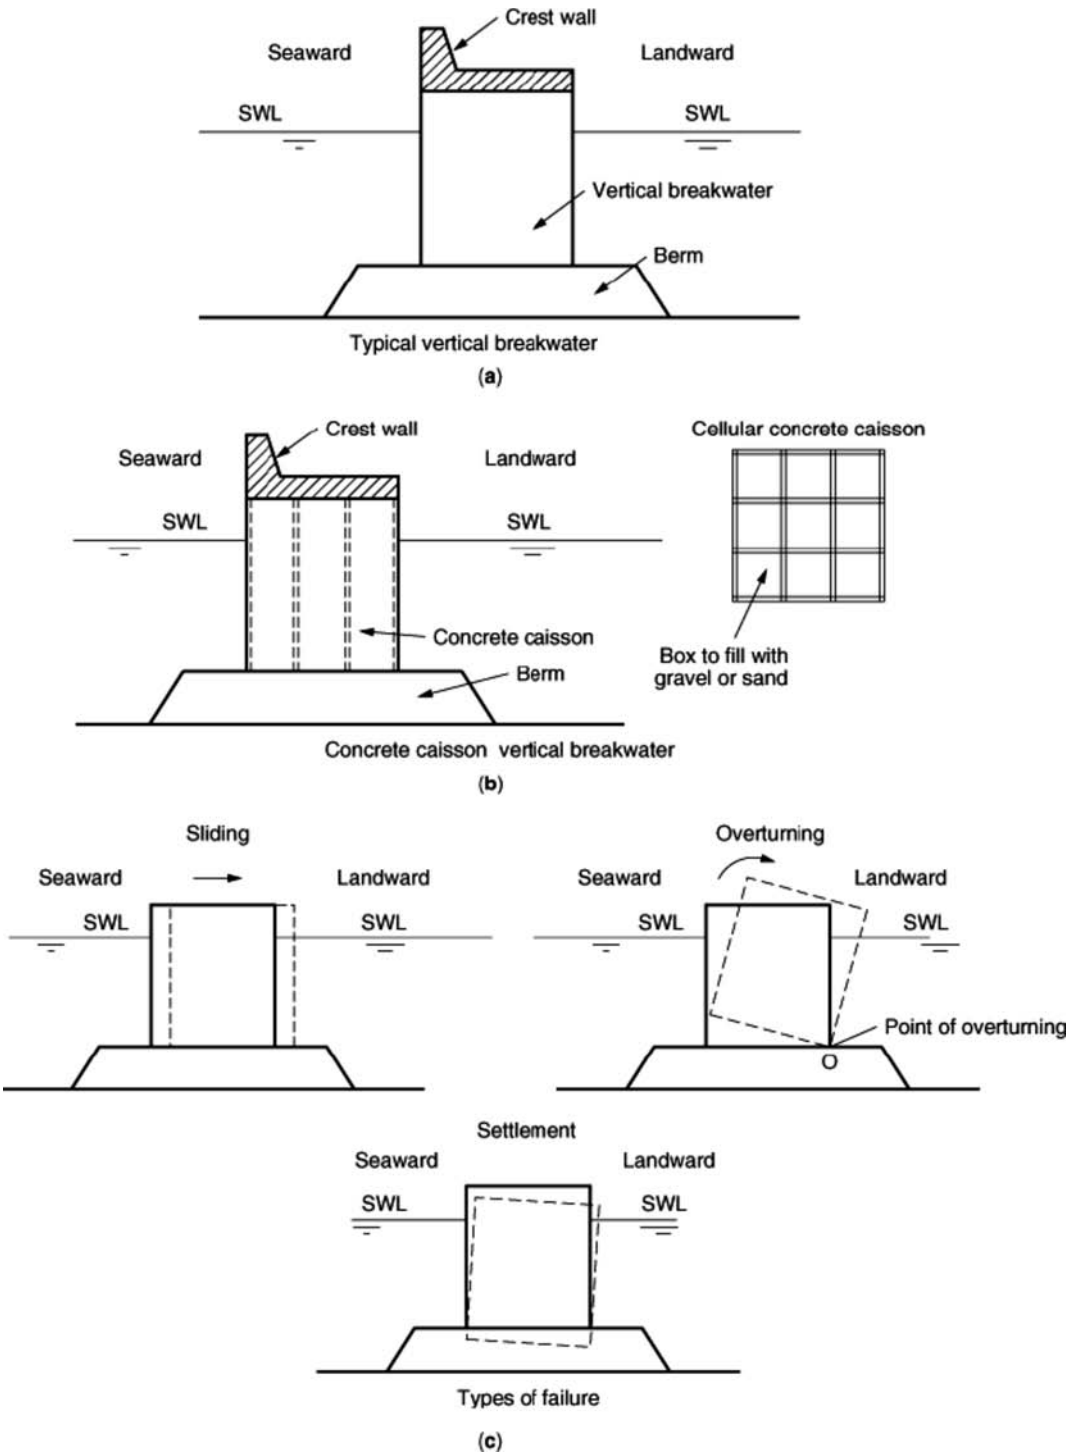

Fig. 3. Vertical breakwater sections and types of failure.

Concrete Caissons. The main component of a vertical breakwater is a cellular concrete caisson, a hollow box that is floated and *in situ* is filled with granular material to be sunk and placed on a berm prepared with sand or rock to form a stable structure (Fig. 3b). Sometimes, the berm is a partial rubble-mound structure forming a composite breakwater. In some locations, the seaward face of the caisson is protected by sloping armor to avoid the breaking of incident waves in the front of the structure. The types of failure of a vertical caisson are shown in Fig. 3c. Normally, the loss of stability occurs from

- sliding of the caisson over the base;
- overturning of the caisson around its landward corner;
- loss of geotechnical stability of the base.

The forces acting are total wave pressure seaward (different for breaking or nonbreaking waves), hydrostatic force landward due to the still water depth, the buoyancy and the uplift force under the caisson, and the weight of the caisson. In some locations, ice force must be considered.

Sliding is verified if the total normal force multiplied by the coefficient of friction between the caisson and the berm is greater then 1.3 times the horizontal sliding force. Overturning is verified if the total stabilizing moment is greater then 1.5 times the overturning total moment. The point of overturning is the landward corner of the caisson. The last verification is to see if the resistance of the base (its critical value) is greater than the pressure due to the resultant of the acting forces. Stress is transmitted from the bottom of the caisson to the soil at an angle of 45°; this is ensured if the berm is large enough with respect to the caisson.

Sheet Piling Breakwater. Sheet piling structures are a particular type of vertical breakwater that consist of a series of piles engaged to form a continuous structure. The material most used is steel, but it possible to use reinforced concrete and timber. The choice depends on economic considerations and the availability of material. A vertical breakwater can be made of a single line of sheet piling, a double wall of sheet piles, or a cellular unit that has its the cavity filled with sand or rock. The head of a sheet piling is generally of rock, concrete slab, or paving. If steel piling is used, protection against corrosion should be provided.

The forces acting on sheet piling are the same as on caissons. Generally the worst conditions happen when the trough of the waves passes. In this case, the saturated backfill soil could cause the wall to fail seaward. The penetration of the sheet pile in to the soil has to develop the necessary resistance to cantilever action. The double wall ensures more resistance; the walls are as far apart as the depth of the water, and can be connected by cross-walls to form boxes. These boxes can be filled with sand or rocks to increase stability. A cellular sheet piling is necessary in deep water to stiffen the structure. Timber sheet pilings are used in shallow water locations where wave conditions are moderate.

Floating Breakwaters

Floating breakwaters consist of composite structures that float on water. They can be used where waves are moderate and have a very short period. These structures are low in cost, insensitive to water depth and are easily portable, even if they provide less protection than fixed breakwaters. Generally, they consist of a box, pontoons, tethered floats, and floating docks affixed to piles. The floating breakwater reduces wave energy by reflection, dissipation interference, and conversion of the energy into a mono-oscillatory motion. The dimensions of floating breakwaters (the penetration depth, in particular) depend on the amount of energy that is necessary to dissipate and the mooring force on the anchor of the structure. The more the structure extends to the bottom the greater the reflection and the dissipation, but the mooring force also increases.

BREAST. The upper aspect of the chest. A mammary gland. The breasts are modified skin glands that lie in the outermost layer of connective tissue, called the fascia. In men, the breasts remain undeveloped and without specific use. In women, they are active, functioning parts of the body throughout much of life. On a well-developed, well-nourished woman who has not borne a child, the breasts may extend from the second or third rib to the sixth or seventh rib, and from the outer border of the breastbone (sternum) to the folds of the armpit. A woman who has borne children normally has somewhat larger breasts. The size and shape of the breasts in different individuals varies from round to conical. The consistency is usually firm and elastic, but varies a great deal, depending upon the presence and amount of fatty tissue. Rarely are the two breasts equal in size; the left is usually larger. There is a great divergence in breast sizes among individual women. The average breast in a woman who has not borne a child ranges from 4 to 6 inches (10 to 15 centimeters) in diameter and weighs between $2\frac{1}{2}$ ounces (71 grams) to $\frac{1}{2}$ pound (227 grams) or more. These figures depend a great deal upon age, climatic conditions, race, and general health of the individual.

The skin of the breasts is covered with tiny soft hairs associated with sebaceous glands and sweat glands like those found on the rest of the body. The skin is thin, and often, superficial veins may be seen through it. The skin of the breast is elastic and flexible, despite the fact that it adheres to the fatty layer beneath it. At the tip of each breast in both men and women is a projection called the nipple, surrounded by a pigmented area (the areola) which is about $1\frac{1}{2}$ inches (3.8 centimeters) in diameter. The nipples are not in the exact middle of the breasts, but slightly to the side. The skin is wrinkled and the same color as the areola. They are usually round or cone-shaped, and the tip contains the tiny depressions which are really the openings of the milk ducts. The size of the nipple is usually directly proportionate to the size of the breast proper, but large nipples may be found on small breasts, and vice versa. In the deeper layers of the nipples, circular muscular fibers help to empty the breast of milk. When they contract, the nipple becomes harder, narrower, and more erect.

The breasts are composed primarily of a round, flattened mass of glandular tissue called the corpus mammae. This tissue is whitish or reddish-white in color and is thickest under the nipple and thinnest at the edges. The corpus mammae is a complex structure consisting of 15 to 20 separate and distinct lobes, which are separated by varying amounts of fat. They are arranged in a pattern like a wagon wheel, with the nipple as the hub. Each lobe contains a single milk duct (lactiferous duct) which opens into a tiny depression on the tip of the nipple. The lobes do not communicate with each other at any point, although two or more may have the same opening in the nipple.

The first significant changes in the female breast usually occur when the girl is 11 to 13 years of age. The activities of the gland are apparently related to changes in the reproductive system. If no function of the ovaries has been established, the breasts remain underdeveloped. During puberty, the child's breasts become more prominent, and the projection of the nipple and areola form the tip. The breasts become elastic and firm in consistency. The areola begins to attain some coloring, and the skin becomes tense; sometimes, mild pain may be felt as a result of this tenseness of the skin. Between ages 14 and 16, a fat layer is deposited under the skin, softening the contour of the breast and making it more hemispherical in form. The greater part of the breast consists of this fatty layer and connective tissue. The milk glands are fully developed at this time, but only a small amount of glandular tissue has been formed; and this is found at the base and at the borders of the breast. After puberty, the amount of glandular tissue gradually increases, as well as the fat and connective tissue. Both before and after menstruation, the girl may attempt to disguise or alter the appearance of her breasts by tight, ill-fitting brassieres, or poor posture. Understanding and kindness are prerequisites for the adjustment and happiness of a young girl during this cycle.

Changes take place in the breasts during pregnancy. From five to six weeks after pregnancy begins, the breasts begin to enlarge and continue to increase rather rapidly in size until mid-pregnancy. The surface veins dilate; and if the breast has enlarged very much, bluish-white streaks may appear in the skin. The nipple becomes larger, and the size of the areola increases. The pigmentation of the areola deepens. The sebaceous glands at the base of the nipple and on the areola become more obvious. The skin covering the nipple becomes thin and may be extremely sensitive.

Even though a milk-like substance (colostrum) can be squeezed from the nipples about the fifth month of pregnancy, the real production of milk does not commence until three or four days after the baby is born. See also **Colostrum**. Following birth and before the milk secretion is apparent, the breasts become more distended and tender. They may be hard and swollen, and tenderness is usually more severe in that part of the breast nearest the armpit.

Human milk is a bluish-white or slightly yellowish fluid with a characteristic odor and a rather sweetish taste. It is approximately seven parts water and one part solids and is an emulsion of fat, suspended in a solution of protein, carbohydrates, and inorganic salts. The essential food elements are present in sufficient amounts to make milk the most satisfactory food for the infant. Except for vitamins B and D, human milk also contains adequate vitamins and inorganic salts for the growing infant. Antibodies to infection are also found in breast milk. Certain drugs taken by the mother may pass into the milk, thus affecting the nursing child. Drugs that may be transmitted in this manner include iron, arsenic, lead, quinine, alcohol, and opium and its derivatives.

The breast, following the change of life, becomes quite different in appearance. Although it may retain its size (because of added fat deposits), the amount of glandular tissue diminishes, and the fibrous tissue gradually becomes more dense.

Rarely an individual will have more than the normal number of breasts. This is known as polymastia. The condition appears about twice as frequently among men as in women. These extra breasts appear more frequently on the left side of the body than on the right, and more such breasts are found below the normal breasts, than above them. They are usually in line, along the so-called "mammary line." Extremely rare is the absence of one or both breasts (amastia).

Inflammation of the breast is called mastitis. See also **Mastitis**. Persons whose health is otherwise quite normal may develop cystic nodules in their breasts. They seldom have a history of discomfort or abnormalities connected with their menstrual periods or with childbirth. The cysts associated with the disease are occasionally discovered during pregnancy, but usually appear at or near the menopause. There may be only one cyst or several. Treatment of persons with chronic cystic mastitis consists of surgical procedures or endocrine therapy. As this disease may be related to a later development of malignant conditions, careful diagnosis and continued observation are necessary.

A benign tumor is an abnormal new growth of tissue that does not spread to other body areas. Fibroadenoma is the most common benign tumor of the breast found in young females (21 to 25 years of age). They grow rapidly during pregnancy. Fibroadenomas, like other breast nodules, can be diagnosed with certainty only after surgical removal of all or some of the tissue for microscopic examination. Another tumor is intraductal papillary hyperplasia and is recognized by the discharge of blood or blood-tinged fluid from the nipple when the breast is compressed. The growths occur most often in women between the ages of 35 and 55 years. Malignant conditions of the breast are described under **Cancer and Oncology**.

Abnormal enlargement of the breasts is called hypertrophy. This condition is less common in the United States than in the tropics. It may occur in males or females, and both breasts usually are enlarged, but generally are not painful. The four most common types are: (1) infantile hypertrophy, which occurs in girls before the age of puberty; (2) gynecomastia, which occurs in males, most often at the time of adolescence; (3) virginal hypertrophy, which occurs in young females during adolescence; and (4) gravid hypertrophy, which appears during pregnancy or lactation. These conditions are treated in various ways, ranging from chemotherapy to surgical procedures. Aside from discomfort, no problems may arise in some instances.

As is so well publicized by various public organizations, frequent self-examination of the breasts is encouraged in the interest of very early detection of swelling, lumps, and abnormalities of contour and symmetry of the two breasts, any of which may indicate conditions that require immediate professional medical attention.

Mammography as a diagnostic technique is described under **Cancer and Oncology**.

BRECCIA. A rock formed of angular fragments in a matrix that may be of similar or different material.

Fault breccias result from the grinding action of the two fault blocks as they slide past each other. Subsequent cementation of these broken fragments may occur by means of mineral matter introduced by the ground water. Talus slopes may become buried and the talus cemented in a similar manner.

Volcanic breccias result from the cementation of fragments that have been broken by volcanic action. Sometimes the surface of a lava flow will harden while the interior will be yet liquid; the fracturing of this surface material and its subsequent cementation by the uncooled lava produces a flow breccia.

The intrusion of plutonic rocks will often shatter the invaded country rock, forming a shatter breccia. In the case of plutonic rocks partly cooled and subsequently broken by further invasions of the magma, intrusive breccias are formed.

BRED VECTORS. Perturbations generated by the breeding method. Also called *bred modes*.

In complex physical systems the bred vectors depend on the perturbation amplitude, which is the only free parameter in the breeding technique. For example, linearly fast-growing perturbations such as convective instabilities do not amplify after reaching a certain amplitude since they become nonlinearly saturated (i.e., other processes prevent them from growing any further). The bred vectors are primarily used as initial perturbations in ensemble forecasting and for studying the instabilities of the atmosphere.

BREED. A type of animal produced within the species by artificial selection, distinguished by definite hereditary characteristics but usually capable of interbreeding freely with other members of the species and so maintained only through artificial control of its propagation. Thus Guernsey and Angus cattle are breeds which would soon cease to exist in a state of nature, while the Michigan beaver and the Pacific beaver are self-maintaining in nature and are called subspecies.

BREEDER REACTOR. See **Nuclear Power Technology**.

BREEDING METHOD. A method of generating balanced, fast-growing perturbations to a nonlinear model trajectory for a given finite perturbation amplitude.

The technique consists of generating a control run of a nonlinear model for a short period of time (e.g., 6 h), then perturbing the atmospheric initial conditions and running the same model again for the same period of time (perturbed run). The difference between the two model runs at the final time is adjusted to the amplitude of the initial perturbation and is added to the new control initial condition. The method is then repeated. After a few days of iteration, the difference between the control and perturbed model runs represents a sample of fast-growing nonlinear perturbations. Multiple breeding cycles, started with different arbitrary initial perturbations, provide a broader sample of fast-growing perturbations. The technique can also be applied to a series of atmospheric analysis fields, where the control forecast always starts from the latest available analysis. See also **Bred Vectors**.

AMS

BREMSSTRAHLUNG. A German word, meaning literally "braking radiation," which denotes the process of producing electromagnetic radiation (or the radiation itself), by the acceleration of a fast charged particle, usually an electron. A commonly occurring form of such acceleration results from deflection by another charged particle, such as a nucleus. During the bremsstrahlung-producing process the electron can give up any

amount of energy ranging from near zero to its maximum kinetic energy. The resulting radiation has a continuous spectrum, as exemplified by the continuous x-ray spectra from an ordinary x-ray tube. *Outer* (or *external*) *bremsstrahlung* is a term applied in cases where the radiation is formed (the electron decelerated) in matter foreign to the source of the electron. *Inner* (or *internal*) *bremsstrahlung* is a term applied to comparatively infrequent processes occurring in beta decay, in which the bremsstrahlung is formed because of acceleration of the electron (beta particle) in the same atom in which it was formed. The abrupt change in the electric field in the region of the nucleus of the atom undergoing disintegration sometimes results in the production of a photon, in a manner similar to the emission of a photon in the ordinary (outer) bremsstrahlung process. In both negatron and positron emission the photon energy is obtained at the expense of the electron-neutron pair, and the spectral distribution decreases continuously with increasing energy of the beta particles. In electron capture, the photon energy is obtained at the expense of the neutrino, and the spectral distribution is greatest at about one-third of the normal neutrino energy, reaching zero at zero energy and at the normal neutrino energy.

In the operation of the highest energy electron synchrotrons and betatrons the acceleration required to maintain the electrons in their circular orbits is sufficiently large to produce visible bremsstrahlung.

See **Particles (Subatomic)**.

BRENNER, SYDNEY (1927–). Sydney Brenner is a British scientist who played a major role in the development of molecular genetics and established a major new field of research on the nematode worm *Caenorhabditis elegans*.

Sydney Brenner was born in Germiston, South Africa, on 13 January 1927 of Russian parents. As a small boy he was a voracious reader and became interested in science, carrying out experiments extracting pigments from plants at home when he was 10 years old. At 15, he went to the University of Witwatersrand to read medicine but part way through the course, he did an MSc, publishing his first paper (in *Nature*) when he was 18 years old. Brenner completed his medical and pharmaceutical degrees (MB, BCh) in 1951. He was determined to do research and in 1952 went to the University of Oxford to work with Sir Cyril Norman Hinshelwood, a chemist who won the 1956 Nobel Prize for Chemistry. Hinshelwood had an interest in biology and particularly the analysis of bacterial growth. He approached this as a problem in chemical kinetics, a strategy that did not find much favor with bacteriologists. This was not the sort of research that Brenner wanted to do, but he nevertheless completed his doctorate in 1954. See also **Hinshelwood, Cyril Norman (1897–1967)**.

During this period, Brenner met many of the leading scientists in England, most notably Francis Crick and James Watson. In April 1953, Brenner went with Leslie Orgel and Jack Dunitz to Cambridge, to see the model of the newly completed double helix. This was the first occasion on which he had met Watson and Crick, and, he wrote later, the experience of talking to them led to his decision that molecular genetics was the research area for him. Brenner kept in correspondence with Watson and a further initiation into his newly chosen field came when, during the summer of 1954, he worked at Cold Spring Harbor and visited other centers of phage research in the United States. Brenner returned to South Africa in December 1954 and set up a laboratory to carry out phage genetics. However, in January 1957, Brenner returned to England, to take up a Medical Research Council fellowship with Francis Crick in Cambridge, in what later became the MRC Laboratory of Molecular Biology. See also **Bacteriophage**; **Crick, Francis Harry Compton (1916–2004)**; and **Watson, James Dewey (1928–Present)**.

Brenner has made significant contributions to three areas of modern experimental biology. The first is the development of molecular genetics (1953–1966), where he is known especially for four classic studies, three of which dealt with the elucidation of the genetic code. While still in South Africa, Brenner wrote a very elegant theoretical paper in which he showed that a particular type of genetic code was impossible. Later Crick and Brenner and their colleagues designed a beautiful set of experiments, making mutations in *E. coli*, which demonstrated that the genetic code was undoubtedly made up of triplets of nucleotides (which Brenner named codons). The third study, carried out by Brenner, François Jacob and Matthew Meselson, found messenger RNA (mRNA), which had been predicted on theoretical grounds as an intermediate between DNA and the cellular machinery that carries out protein synthesis. Finally, just as the genetic code was being deciphered by biochemical rather than genetic means, Brenner used genetic analysis to elucidate the "nonsense" codons in DNA that determine where synthesis of mRNAs should stop. See also **Jacob, François (1920–Present)**.

By 1965, Brenner and some other pioneers of molecular genetics believed that only "mopping-up" the details remained and that new conceptual advances in this area were unlikely. They moved to other fields although in Brenner's case he created a new area of research. Brenner began a systematic search for a higher organism that would permit genetic analysis of complex biological processes such as development and the functioning of the nervous system. He settled on *Caenorhabditis elegans*, a hermaphroditic nematode worm with only about 1000 cells. Brenner was joined by John Sulston, who carried out a detailed analysis of the development of *C. elegans* and determined how each cell in the adult worm was derived from the fertilized egg. Furthermore, it was easy to make and detect mutations in *C. elegans*, and then to do genetic analysis to determine what genes were involved. Brenner's promotion of *C. elegans* is, perhaps, his greatest contribution to biology. It is the research tool for thousands of scientists, and between 1995 and 2000, no fewer than 3500 papers were published on *C. elegans*.

Brenner's third change of career was from *C. elegans* to genomics, the study of organisms through the knowledge of their entire genetic information. Brenner was an early enthusiast for genome projects and, indeed, *C. elegans* was the first multicellular animal to have its genome completely sequenced. Brenner turned to vertebrates and again searched for an organism more suitable for genomic studies than mice or humans. He selected *Fugu rubripes*, the Japanese puffer fish which has a genome approximately one-tenth that of other vertebrates, making it easier to carry out genome-based research. Brenner founded the Molecular Sciences Institute (MSI), June, 1996 in Berkeley, California, to pursue his interests in genomics. Brenner is widely known for his ability to identify important avenues for the future development of biology. He received a Nobel Prize in 2002 for his contributions towards discoveries about how genes regulate organ growth and the process of programmed cell death.

Brenner is famous as a conversationalist, wit ("Occam's Broom" to be used for sweeping awkward facts under the carpet) and coiner of words (codon and replicon). He writes humorous articles for a science journal; these were published as a collection and convey much of Brenner's personality.

Brenner is a Companion of Honor (1987) and a Fellow of many societies including theRoyal Society (1965) and Foreign Associate of the National Academy of Sciences (1977). His many prizes include the Albert Lasker Medical Research Award (1971); the Royal and Copley Medals of the Royal Society (1974, 1991); and the Kyoto (1990) and King Faisal International Prize for Science (1992).

BREWSTER ANGLE. The Brewster angle, or polarizing angle, of a dielectric is that angle of incidence for which a wave polarized parallel to the plane of incidence is wholly transmitted (no reflection). An unpolarized wave incident at this angle is therefore resolved into a transmitted partly-polarized component and a reflected perpendicularly-polarized component. See Fig. 1.

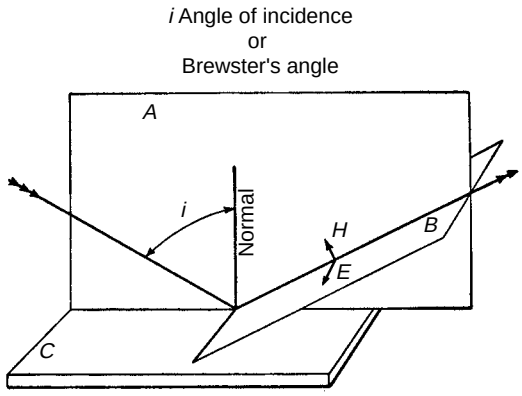

Fig. 1. Brewster angle. *A*, incident plane (plane of polarization or plane of magnetic vector, after reflection); *B*, plane of vibration (plane of electric vector, after reflection); *C*, reflecting surface (dielectric).

BREWSTER LAW. In 1815 Sir David Brewster discovered that for any dielectric reflector there is a simple relationship between the polarizing angle for the reflected light of a particular wavelength and the refractive index of the substance for the same wavelength. The relationship is that the tangent of the polarizing angle is equal to the refractive index. For example, if the refractive index of flint glass for sodium light is 1.66 the polarizing angle for the reflection of sodium light by this glass is $50^\circ 56'$.

The law may be used to determine the refractive index of a solid that is opaque or obtainable only in a small piece, since only one small reflecting surface is required.

BRICK. Brick ordinarily refers to a rectangular prism of clay or shale that has been burned in a kiln. Clay is no longer the only material for brick manufacture, being supplemented by slag, cement and lime. However, when other than the ordinary structural clay brick is meant, a descriptive term such as fire-brick and sand-lime brick is employed. The principal classifications of brick are for structural purposes in buildings, for paving, and for lining furnaces, the latter known as refractory brick, or fire brick. Ordinary bricks are made from a selected clay soil first by preparation of the clay by grinding and thoroughly mixing with enough water to make the mud. The bricks are then formed in the required shapes by one of several methods. In the soft mud method the prepared clay is quite plastic and the bricks are molded to shape by hand or machine. This is the principal method for making bricks by hand. The commercial manufacture of bricks is more frequently by the stiff mud process, in which the mud is less plastic, and is extruded through a die by pressure and wire-cut to the proper size. Brick made from clay that is hardly more than dampened must be formed in molds by application of a great deal of pressure. As hydraulic presses are frequently used, these dry-pressed bricks are sometimes referred to as hydraulic-pressed brick. This process gives a dense surface to the bricks, which makes them suitable for facing work.

After the bricks have been molded they are air dried and piled in the kiln for burning. It is quite difficult, in any other than the continuously fired kilns, in which the bricks move slowly through the kilns on conveyors, to obtain uniform characteristics in all the brick; therefore, the product of the ordinary brick plant consists of various grades, ranging from hard brick to softer bricks, such as salmon brick. Hard-burned brick should be used for face work exposed to the weather, and soft brick for filling, for foundations, and the like. The standard brick measures approximately $2\frac{1}{4} \times 4 \times 8$ inches ($5.7 \times 10.2 \times 20.3$ centimeters), and has a crushing strength of between 1,000 and 3,000 pounds per square inch (68 and 204 atmospheres), depending on the quality. A highly impervious and ornamental surface may be laid on brick either by salt glazing, in which salt is added during the burning process, or by the use of a "slip," which is a glaze material into which the bricks are dipped. Subsequent reheating in the kiln fuses the slip into a glazed surface integral with the brick base.

A refractory brick is built primarily to withstand temperature. Good resistance to heat flow is not to be secured simultaneously with refractoriness. Indeed, the most refractory bricks usually have the highest thermal conductivities. It is important for the refractory brick to have high resistance to erosion by ash-laden gases and to the fluxing action of molten slag. It should not spall badly under rapid temperature changes, and its structural strength should hold up well under rapid temperature changes. Fire clay bricks are made from certain clays, including a plastic clay which binds the others into brick form. The firing in the kiln is carried out at a temperature such that the brick is partly vitrified. For special purposes they may be glazed by one of the methods previously described. The fire clay brick contains 30–40% alumina and about 50% silica. Progress in the art of combustion of fuels in furnaces has advanced the service requirements of refractory brick, sometimes to the point where they are so severe that a refractory superior to fire clay is needed. High alumina bricks containing 50–80% alumina, and correspondingly less silica, and silicon carbide, a product of the electric furnace, are typical of these super-refractories. Of course fire clay bricks are preferred wherever they give satisfactory service because they are lowest in cost of all the refractory bricks. The standard size of fire brick is $9 \times 4\frac{1}{2} \times 2\frac{1}{2}$ inches ($22.9 \times 11.4 \times 6.4$ centimeters).

BRICKWORK. When laid, bricks are bedded into a mortar that, hardening, bonds the separate bricks into a brickwork unit. A solid brick wall of more than one layer thickness has the different layers of brick bonded into each other by the use of headers, that is, brick laid perpendicular to the face of the wall. There are different systems of bonding, each of which gives a somewhat different appearance to the wall. In the common bond every fourth or fifth course is composed entirely of headers. In the English bond, every other course is a header course, while in the Flemish bond headers and stretchers alternate in each course.

The strength and durability of brickwork depend on the quality of mortar and excellence of workmanship with which the brickwork is laid. The proportions of the mortar are from one to three parts of dry sand to one part of Portland cement, depending on the strength needed. The cement mortar is much stronger than lime mortar, but the addition of a small amount of lime (see **Calcium**) to cement mortar renders it more readily worked without materially impairing its strength. In estimating brickwork, one rule is to allow 1,000 standard bricks, and 1/2 cubic yard of mortar for each 2 cubic yards of brickwork in place. Some masons estimate number of bricks by assigning 7 to each superficial square foot of area of wall 1 brick thick. Brickwork varies in weight from 1.5 to 1.9 tons per cubic yard, depending on the density of the bricks used. The maximum crushing strength to which brickwork should be subjected is 170 pounds per square inch when set in cement mortar, although this may be increased to 250 pounds if the effects of eccentric loading and lateral forces are fully analyzed.

BRIDGE AMPLIFIER. A commercially available extensively used amplifier for instrumentation purposes. The commercial configuration generally is a direct-coupled amplifier, offering reasonably wide bandwidths up to 50 kHz at gains ranging from near unity to 1000. The use of four subamplifiers in a bridge-amplifier configuration is shown in Fig. 1. The output voltage, assuming that the open-loop gains G_1, G_2, G_3, and G_4 of the separate amplifiers are quite large, is given by

$$V_0 = \frac{R_1 + R_2}{R_1} V_1 - \frac{R_2}{R_2} \times \frac{R_1' R_2'}{R_1} \times V_2$$

Voltage V_1 is the sum of the differential voltage $V_{\text{signal}} = V_1 - V_2$ and the common-mode voltage. Voltage V_2 is the applied common-mode voltage V_{cm}. Substituting these factors in the foregoing expression, the output voltage is given by

$$V_0 = \frac{R_1 + R_2}{R_1} V_{\text{signal}} + \left(1 - \frac{R_2 R_1'}{R_2' R_1}\right) V_{\text{cm}}$$

The closed-loop gain of the amplifier thus is $(R_1 + R_2)/R_1$. The common-mode rejection ratio is $|G/[1 - (R_2 R_1')/(R_1 R_2')]|$. If $R_1'/R_1 = R_2'/R_2$, the condition for a balanced resistive bridge, theoretically infinite common-mode rejection can be obtained. This analysis does not bring out the practical limitations of matching resistors and of other errors. Thus, the common-mode performance is finite. However, values in excess of 120 dB can be achieved. The common-mode rejection ratio of this type of amplifier is directly proportional to gain. For most differential amplifiers, the common-mode rejection ratio is largely independent of the gain. See Fig. 1.

See also **Amplifier**; and **Analog Input**.

THOMAS J. HARRISON, IBM Corporation, Boca Raton, FL

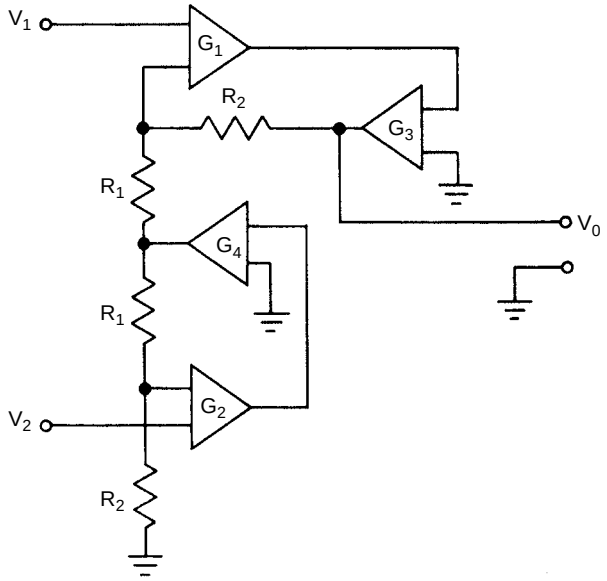

Fig. 1. Dynamic bridge amplifier.

BRIDGE CIRCUITS (Electrical/Electronic). Whether macro or micro, bridge circuits are widely used in modern industrial and electronic instrumentation, control, and communication systems.

The Wheatstone bridge circuit was designed by S.H. Christie in 1833. Although the concept of resistance had not been formulated at that time, a few years later, in 1843, Sir Charles Wheatstone used Christie's circuit to measure resistance. Because Wheatstone was the first to use the circuit in a practical way, it ultimately became known as the Wheatstone bridge. The circuit has undergone a number of modifications, but for several decades the basic principle has been used in making precise measurements of electrical quantities. Bridge circuits are used to compare impedance elements by comparing the voltages or currents associated with them. The voltages and currents can be compared by using known impedance ratios to make potentiometers and current comparators. In essence, a bridge circuit is an arrangement of dividers for comparing the equivalent circuits of impedance elements. Therefore, bridges also can be used for the comparison of divider ratios.

Originally, *bridge* referred only to the detector connection between the divider tap points. In current practice, however, the bridge circuit includes the dividers, the generators, and the null detectors needed for furnishing power and for finding the bridge balance.

Impedance is the ratio of voltage to current at a single frequency. In a series circuit with the same current in all elements, the voltage will be proportional to the impedance. In a parallel circuit with the same voltage across all elements, the current will be inversely proportional to the impedance. These relationships make it possible to connect impedance elements in bridge circuits so that their impedances can be compared by comparing their voltage or current ratios.

Impedance elements most commonly are visualized as having only two terminals. However, terminals have stray impedances associated with them. In practice, there may be varying amounts of extension wire and contact impedances connected in series between the impedance element and its connection point in the circuit. Leakage impedances also occur from terminals to surrounding conductors. Such stray impedances frequently make it desirable to use 3- and 4-terminal impedance elements. Bridges are available for measuring the resulting 3- and 4- terminal impedance values.

A *Wheatstone bridge* suitable for both A.C. and D.C. resistance measurements, is shown in Fig. 1. The bridge measures two-terminal resistance.

The balance equation is

$$R_u = R_s\left(\frac{M}{N}\right)$$

A *Kelvin bridge* for measuring four-terminal resistors is shown in Fig. 2. A bridge of this type is used for low-value resistors or precision measurements. Lead resistances of the unknown R_u, and standard R_s, resistors are included in M', N', Y, and the generator leads. The remaining

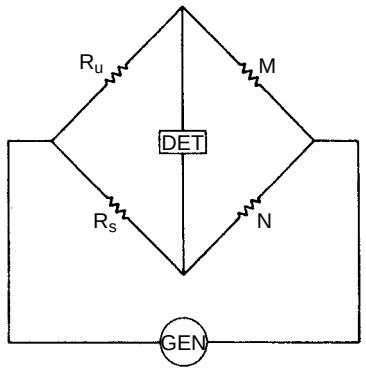

Fig. 1. Wheatstone bridge.

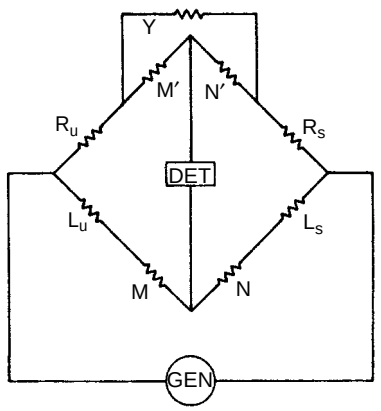

Fig. 2. Kelvin bridge.

lead resistances are L_u and L_s. When $R_u : R_s = M : N = M' : N' = L_u : L_s$, then $R_u = R_s$ (M/N). The balance equation for this bridge is

$$R_u = R_s\frac{M}{N} + \frac{N'Y}{M'+N'+Y}\left[\left(\frac{M}{N}-\frac{M'}{N'}\right) + \frac{L_u}{N}\left(\frac{M'}{N'}-\frac{L_s}{L_u}\right)\right] + L_u\frac{R_u}{N}\left(\frac{R_s}{R_u}-\frac{L_s}{L_u}\right)$$

Error term

A *Mueller bridge* for use with resistance thermometers is shown in Fig. 3. This bridge measures 4-terminal resistors by averaging two readings with lead resistance effects reversed. It should be observed that $R_u = R_s$ (Avg). The balance equation is

$$R_u = \frac{R_{s(1)} + R_{s(2)}}{2}$$

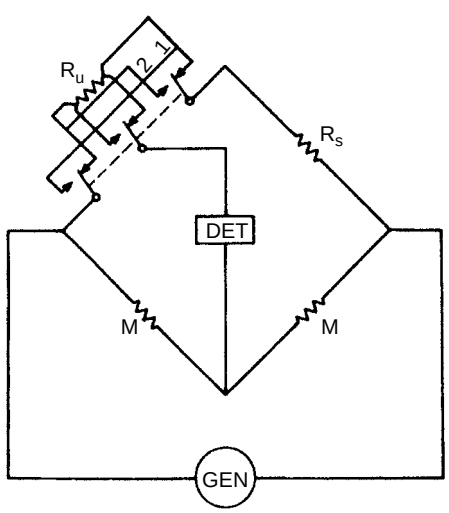

Fig. 3. Mueller bridge.

A *Smith III bridge* also for use with resistance thermometers is shown in Fig. 4. This bridge also measures 4-terminal resistors. The balance equation is

$$R_u = R_s \frac{M}{N}$$

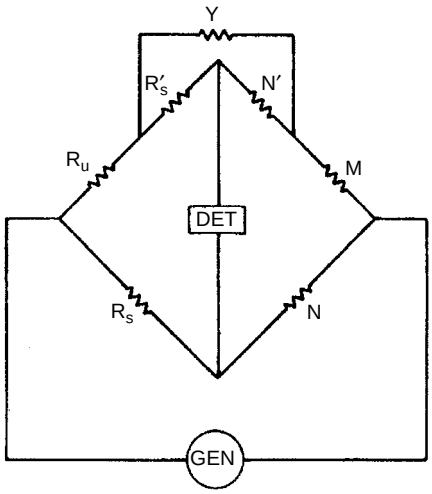

Fig. 4. Smith III bridge.

A *Murray bridge* for use in fault location is shown in Fig. 5. This bridge measures the distance from the near end of a line to a line fault. The balance equation is

$$A = \frac{N}{M+N}$$

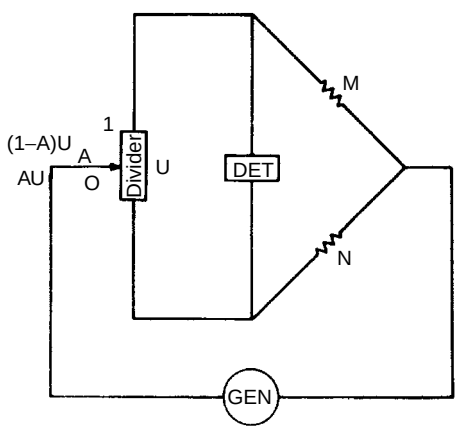

Fig. 5. Murray bridge.

The configuration of Fig. 6 measures the distance from the near end of a line to a line fault. The distance is found in terms of the line length L and the ratio M/N. The balance equation is

$$AL = \frac{2LN}{M+N}$$

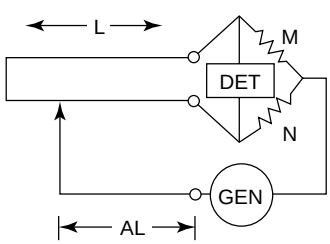

Fig. 6. Special configuration of Murray bridge.

A *Varley bridge* for use in fault location is shown in Fig. 7. The balance equation is

$$A = \frac{R}{U}\frac{M}{M+N} + \frac{MU - WN}{(M+N)U}$$

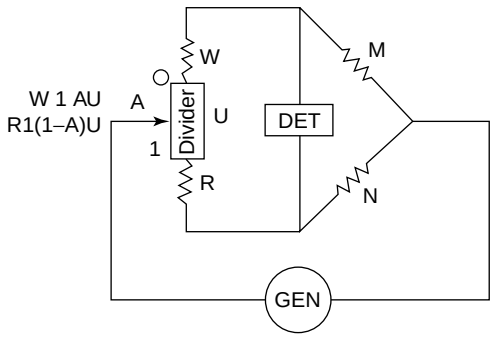

Fig. 7. Varley bridge.

For $M/N = W/U$, $A = R/U \times M/(M+N)$; and $R = AU \times (M+N)/M$.

In the configuration of Fig. 8, the bridge measures the distance from the far end of a line to a line fault. The distance is found in terms of the line length L, the line resistance U, the ratio M/N, and the resistance R. The balance equation is

$$AL = \frac{RLM}{(M+N)U}$$

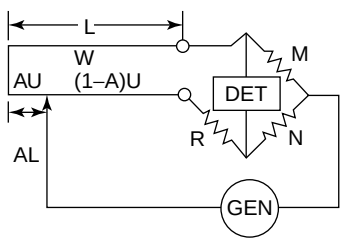

Fig. 8. Distance-measuring Varley bridge.

In the configuration of Fig. 9, the bridge measures the resistance R in terms of the divider setting A and the ratio M/N, after the equality M : N = W : U is established.

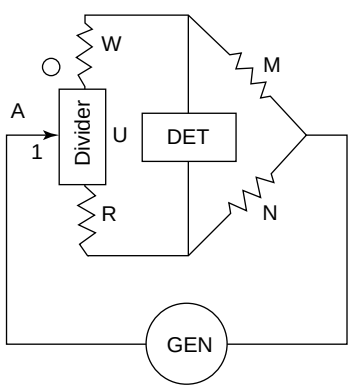

Fig. 9. Special configuration of Varley fault-locating bridge.

A general-purpose, equivalent-circuit bridge for series capacitance is shown in Fig. 10. The bridge measures unknown impedance in terms of equivalent circuit. Equivalent circuit is a capacitor and resistor in series. The bridge is used for capacitors that have a low dissipation factor. The balance equations are

$$C_u = C_s \frac{N}{M} \quad R_u = R_d \frac{N}{M}$$

$$D_u = D_s = R_d \omega C_s$$

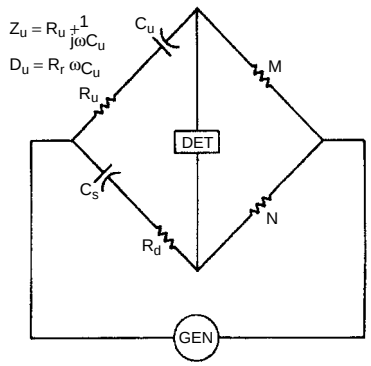

Fig. 10. General-purpose, equivalent-circuit bridge for use with capacitors that have a low dissipation factor.

The bridge shown in Fig. 11 measures unknown impedance in terms of equivalent circuit. Equivalent circuit is a capacitor and resistor in series. The balance equations are

$$C_u = C_s\frac{A}{R}(1 + D)$$

$$D_u = \omega C_s R_s$$

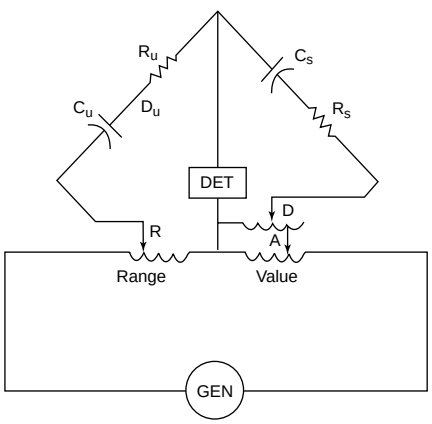

Fig. 11. Series capacitance, general-purpose, equivalent-circuit bridge.

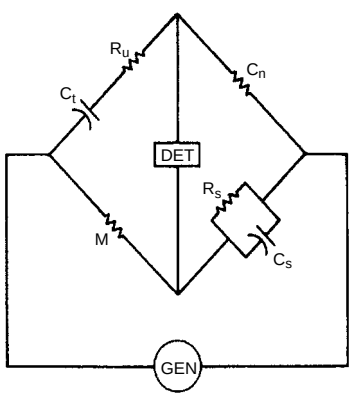

Fig. 12. Schering bridge.

A *Schering bridge* is shown in Fig. 12. This bridge measures unknown impedance in terms of equivalent circuit. Equivalent circuit is a capacitor and resistor in series. The bridge is used for precision capacitance measurement and high-voltage insulation leakage measurement. The balance equations are

$$C_u = R_s\frac{C_n}{M} \qquad R_u = C_s\frac{M}{C_n}$$

$$D = \omega R_s C_s$$

A general-purpose, equivalent-circuit bridge for parallel capacitance measurements is shown in Fig. 13. This bridge measures unknown impedance in terms of equivalent circuit. Equivalent circuit is a capacitor and resistor in parallel. The bridge is used for capacitors that have a high dissipation factor. The balance equations are

$$C_u = C_s\frac{N}{M} \qquad R_u = R_Q\frac{N}{M}$$

$$D_u = \frac{1}{Q_u} = \frac{1}{R_Q\omega C_s}$$

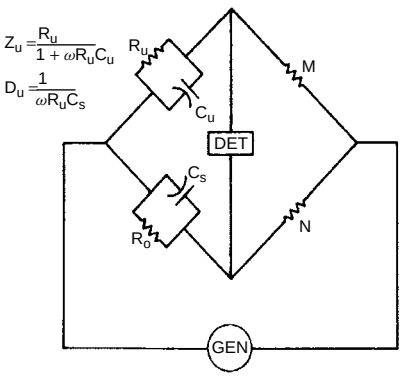

Fig. 13. Parallel capacitance, general-purpose, equivalent-circuit bridge for use with capacitors that have a high dissipation factor.

Another general-purpose, equivalent-circuit bridge for parallel capacitance measurements is shown in Fig. 14. The balance equations are

$$C_u = \frac{1}{B}(A_1C_{s1} + A_2C_{s2} + \cdots)$$

$$\frac{1}{R_u} = \frac{1A_R}{R_sB}$$

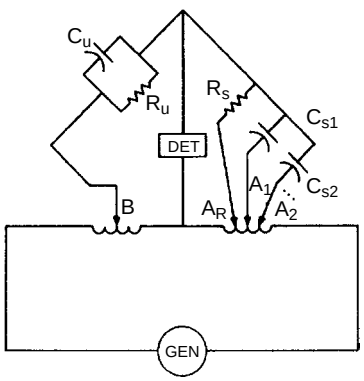

Fig. 14. Parallel capacitance, general-purpose, equivalent-circuit bridge.

A *Maxwell commutator bridge* is shown in Fig. 15. This bridge measures unknown capacitance and is used for precision measurement of capacitors with low dissipation factor. The balance equation is

$$C_u = \frac{N}{fR_sM}$$

A *parallel-T bridge* is shown in Fig. 16. This bridge measures an unknown frequency or low dissipation factor capacitor. It is used at higher frequencies. The balance equations are

$$\omega^2C_1C_2 = \frac{2}{R_2{}^2} \qquad \text{for } R_2 = 2R_1 \text{ and } C_2 = 2C_1$$

$$\omega^2C_1{}^2 = \frac{1}{2R_1R_2} \qquad f = \frac{1}{2\pi R_1C_2} = \frac{1}{2\pi R_2C_1}$$

$$C_2R_2 = 4C_1R_1$$

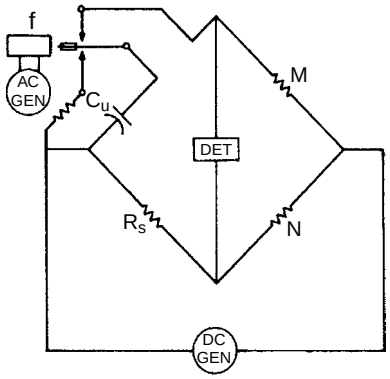

Fig. 15. Maxwell commutator bridge.

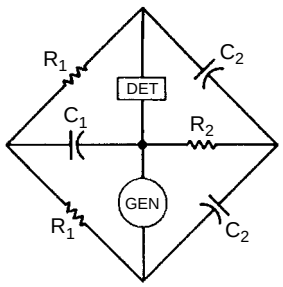

Fig. 16. Parallel-T bridge.

A *Wien bridge*, shown in Fig. 17, measures unknown frequency in terms of resistors and capacitors. The bridge is frequently used as the frequency-determining element of oscillators. Prior to development of the Schering bridge, this bridge was used for capacitance measurement. The balance equations are

$$\frac{C_u}{C_s} + \frac{R_s}{R_u} = \frac{Z_N}{Z_M} \qquad C_u = C_s \frac{Z_N}{Z_M}\left(\frac{1}{1+\omega^2 C_s^2 R_s^2}\right)$$

$$C_s = C_u \frac{Z_M}{Z_N}\left(1+\frac{1}{\omega^2 C_u^2 R_u^2}\right)$$

$$\omega^2 = \frac{1}{R_u C_u R_s C_s} \qquad R_u = R_s \frac{Z_M}{Z_N}\left(1+\frac{1}{\omega^2 C_s^2 R_s^2}\right)$$

$$R_u = R_u \frac{Z_N}{Z_M}\left(\frac{1}{1+\omega^2 C_u^2 R_u^2}\right) \qquad f = \frac{1}{2\pi\sqrt{R_u C_u R_s C_s}}$$

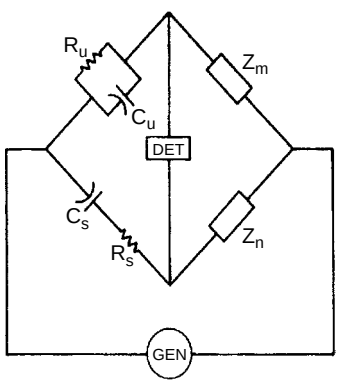

Fig. 17. Wien bridge.

A bridge of the *Carey-Foster* and *Heydweiler* types is shown in Fig. 18. The Carey-Foster bridge measures unknown impedance in terms of equivalent circuit. Equivalent circuit is a capacitor and resistor in series. The Heydweiler bridge measures mutual inductance. The balance equations are

$$M_u = C_s R_u N \qquad C_s = \frac{M_u}{R_u N}$$

$$L_u = C_s R_u (R_s + N) \qquad R_s = \frac{N(L_u - M_u)}{M_u}$$

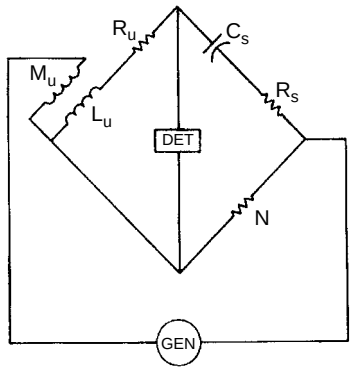

Fig. 18. General configuration of Carey-Foster and Heydweiler bridges.

A *resonance bridge*, shown in Fig. 19, is used to measure unknown impedance in terms of equivalent circuit. Equivalent circuit is an inductor and a resistor in series. The balance equations are

$$L_u = \frac{1}{\omega^2 C_s}$$

$$R_u = R_s \frac{M}{N}$$

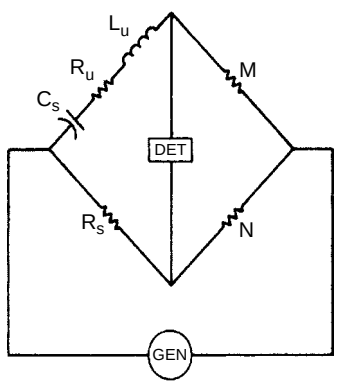

Fig. 19. Resonance bridge.

An *Owen bridge*, shown in Fig. 20, measures unknown impedance in terms of equivalent circuit. Equivalent circuit is an inductor and a resistor in series. The balance equations are

$$L_u = R_s C_N M$$

$$R_u = \frac{C_N M}{C_s} - R_N$$

The *Anderson, Stroud and Oates bridges* are somewhat similar and the general configuration is shown in Fig. 21. The Anderson bridge is used for precision inductance measurement. If the generator and detector are interchanged, this becomes the Stroud and Oates bridge. The balance equations are

$$L_u = C_s M\left[R_s\left(1+\frac{N}{R_Q}\right)+N\right] \qquad R_u = \frac{MN}{R_Q}$$

$$Q_u = \omega C_s\left[\frac{R_Q R_s}{N} + R_Q + R_s\right]$$

A *Maxwell bridge* for measuring unknown impedance in terms of equivalent circuit is shown in Fig. 22. Equivalent circuit is an inductor and

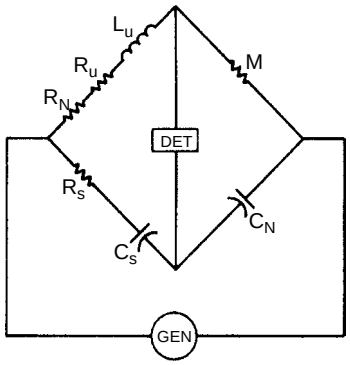

Fig. 20. Owen bridge.

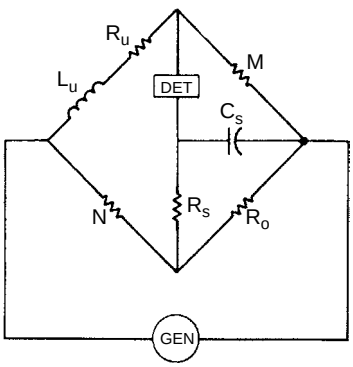

Fig. 21. General configuration of Stroud and Oates bridge and Anderson bridge.

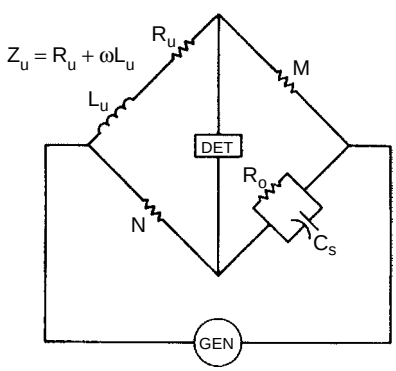

Fig. 22. Maxwell bridge.

a resistor in series. This bridge is used for inductors with a low quality factor. The balance equations are

$$L_u = MNC_s \quad R_u = \frac{MN}{R_Q}$$

$$Q_u = R_Q \omega C_s$$

An inductance-comparison bridge for use in high-frequency measurements is shown in Fig. 23. The equations of balance are

$$L_u = L_s \frac{M}{N}$$

$$R_u = R_s \frac{M}{N} \quad Q_u = \frac{\omega L_s}{R_s}$$

A *bridged-T bridge* is shown in Fig. 24. This bridge measures unknown impedance in terms of an equivalent circuit. Equivalent circuit is an inductor and resistor in parallel. The circuit is very frequency sensitive. The bridge is used at higher frequencies. The balance equations are

$$L_u = \frac{1}{2\omega^2 C_s} \quad D = \omega R_s C_s$$

$$R_u = \frac{1}{\omega^2 C_s^2 R_s}$$

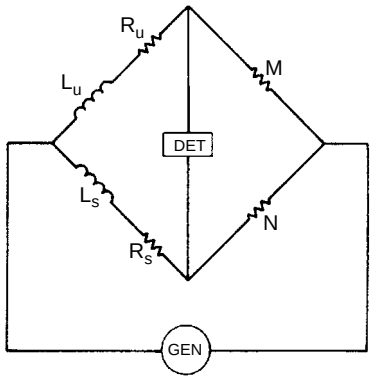

Fig. 23. Inductance comparison bridge.

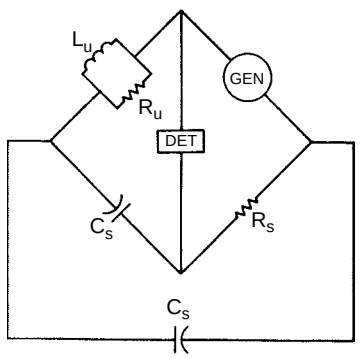

Fig. 24. Bridged-T bridge.

The *Hay bridge*, shown in Fig. 25, measures unknown impedance in terms of equivalent circuit as in the case of the foregoing bridge. This bridge is used for inductors with a high quality factor. The balance equations are

$$L_u = C_s MN \quad R_u = \frac{MN}{R_D}$$

$$Q_u = \frac{1}{R_D \omega C_s}$$

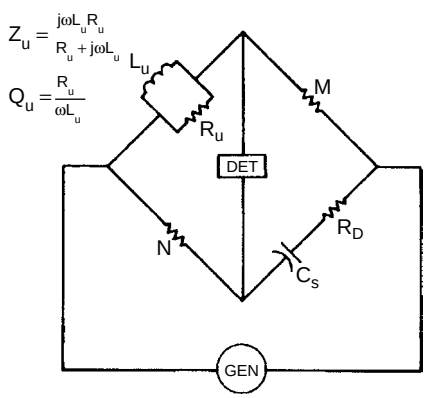

Fig. 25. Hay bridge.

The *Campbell bridge*, shown in Fig. 26, measures unknown impedance in terms of equivalent circuit. Equivalent circuit is a mutual inductor with a resistor and inductor in series on the primary side. With the switches in position 1, balance for R_u and L_u; in position 2, balance for M_u. The balance equations are

$$M_u = M_s \frac{M}{N} \quad L_u = L_s \frac{M}{N}$$

$$R_u = R_s \frac{M}{N}$$

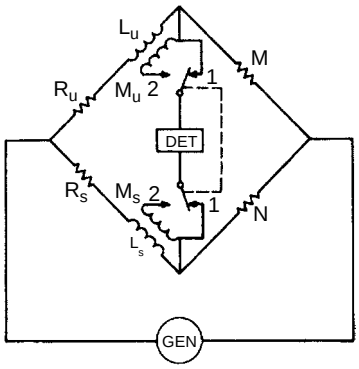

Fig. 26. Campbell bridge.

The *Heaviside bridge*, shown in Fig. 27, measures mutual inductance. The balance equations are

$$M_u = \frac{ML_s - NL_u}{M + N}$$

$$R_u = R_s \frac{M}{N}$$

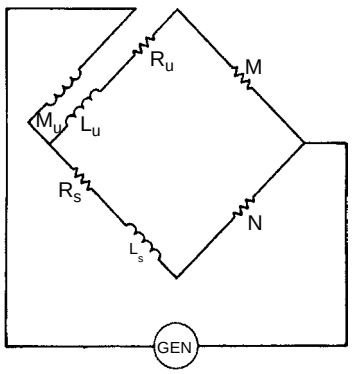

Fig. 27. Heaviside bridge.

A series-opposition bridge for measuring mutual inductance by comparing two equal mutual inductances is shown in Fig. 28. The balance equation is $M_u = M_s$.

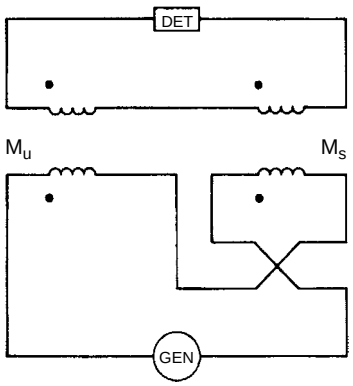

Fig. 28. Series-opposition bridge for measuring mutual inductance.

A bridge circuit can be developed from a voltage divider. Two equal ratio voltage dividers can be bridged by a detector to compare impedances. With a constant-voltage source, the resulting circuit will maintain a fixed voltage across unknown impedances of various values.

A transformer bridge can be made by using transformers to supply the bridge voltages in a desired ratio, or to compare bridge currents in a desired ratio, or to compare bridge currents in a desired ratio, or both.

J.C. RILEY, Consulting Engineer, Portland, OR

BRIDGES, CALVIN BLACKMAN (1889–1938). Bridges was an American geneticist who pioneered the first genome project.

Orphaned at the age of three, Calvin Bridges was brought up by his paternal grandmother. He received almost no education until he was fourteen and then worked his way through grammar and high school. In 1909, aged twenty, he went to Columbia University on a one-year scholarship, supporting himself from then on by a mixture of work and scholarships. In his second undergraduate year he was taken on as a bottle washer by Thomas Hunt Morgan. The *Drosophila* project was just taking off and Bridges' skill at spotting new mutants persuaded Morgan to promote him to a desk in the 'Fly Room'. Bridges stayed with Morgan for the rest of his life, up to 1915 as Morgan's part-time assistant and after that as an independent investigator funded by the Carnegie Institution of Washington. He died from heart disease at the early age of 49. See also **Morgan, Thomas Hunt (1866–1945)**.

It was Bridges who transformed *Drosophila* into the eukaryotic organism with the best genetics. The project of creating genetic linkage maps for all four *Drosophila* chromosomes was begun by A. E. Sturtevant and Bridges in 1913 but it was Bridges who carried out this mammoth task, inventing and improving the methodology as he went along. In the 1930s, when the cytology of *Drosophila* was transformed by the discovery of polytene chromosomes in the salivary glands, he went on to produce detailed physical maps, correlating the genetic maps with cytologically visible landmarks. The existence of salivary chromosome maps was a key factor in the early lead established by *Drosophila* in eukaryotic molecular genetics and they still provide a resource unrivalled by any other organism.

Bridges also made major theoretical contributions. His PhD thesis combined genetics and cytology to provide the classic proof of the chromosome theory of heredity ('Non-disjunction as proof of the chromosome theory of heredity', 1916) and his study of haploids and triploids led to the balance theory of sex ('The origin of variations in sexual and sex-limited characters', 1922). This was generalized into a theory of genic balance, described by Morgan as 'The most direct contribution genetics has made to physiology'. In both cases an unexpected result led to a bold hypothesis and a patient search for the predicted evidence. He also discovered deficiency, duplication, translocation and tandem repeats.

In 1933 Milislav Demerec persuaded Bridges to join him in launching a Drosophila Information Service (DIS). After Bridges' death DIS 9 was expanded to become *The Mutants of Drosophila melanogaster* (1944). This was known as 'The Red Book' and became the bible of the *Drosophila* community. In many ways it perpetuated Bridges' role as the ultimate authority on *Drosophila* mutants and stocks.

Bridges' personality has become a myth. He was left-wing, unconventional and generous. His power of observation was seen by his contemporaries as extraordinary.

BRIDGE (Structural). In civil engineering, a bridge is a structural unit or a series of structural units called spans designed primarily for the purpose of supporting moving loads, in addition to its own weight. The term bridge is generally associated with a structure that provides a means for foot, highway, or railroad traffic to pass over water, ground depressions or congested districts, although certain kinds of traveling cranes used for loading or unloading bulky materials, such as ore or coal, are sometimes referred to as bridges. All bridges are either stationary or movable. Movable spans are used in connection with low level bridges over navigable waters where these bridges interfere with shipping.

Bridges may also be classified as framed truss, beam, or suspension bridges, depending upon the way in which they support the loads. All bridges are either straight or skew. When the end supports are not on lines at right angles to the longitudinal center line of the span, the resulting structure is called a skew bridge.

Bridges are usually constructed of structural steel, reinforced concrete, or prestressed concrete, although wood is sometimes used, particularly

for temporary spans. In recent times several bridges have been built of aluminum alloy. Stone or brick are occasionally used for very short spans of the arch type. Reinforced concrete is particularly well adapted for use in connection with the beam or arched bridge since it can be molded into any desired form.

Framed Bridge. As shown in Fig. 1, the ordinary framed bridge is composed of two vertical trusses, a floor system, upon which the roadway or railroad is directly supported, a certain amount of bracing and the end bearings.

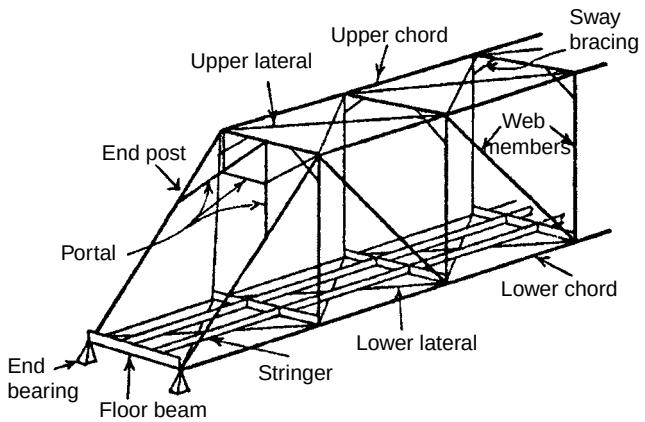

Fig. 1. Skeleton diagram of through-type truss bridge.

The floor system consists of longitudinal beams called stringers, which transfer the effects of the moving loads to transverse beams known as floor beams. The floor beams are connected to the trusses at the lower intersection points of the truss members. Each intersection point is called a panel point. The truss is composed of an upper and lower chord and web members, which are joined together in the form of triangles. Figure 2 shows some typical trusses. Since the loads are applied to the truss at the panel points, the primary stresses will be axial. When the structure deflects under load, some bending is induced in the truss members because the members are not free to rotate at the panel points. The resulting stresses are called secondary stresses. In this particular illustration the top chord will be in compression and the lower chord in tension. Some of the web members will be in tension, others in compression, but there are certain web members near the center of the span that may have either tension or compression depending upon the position of the moving loads. The bracing is usually made up of an upper and lower lateral system, sway frames, and portal bracing. These bracing systems resist the horizontal loads caused

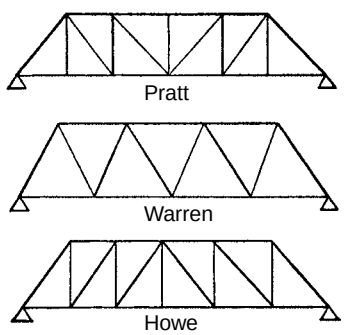

Fig. 2. Typical framed bridge trusses.

by wind and lateral forces, and, together with the floor system, tie the truss together forming a relatively rigid unit. Short-span framed bridges which do not require trusses sufficiently deep to allow for top chord, sway or portal bracing, because of interference with vehicular traffic are called pony truss spans. The trusses are the principal load-carrying components of the bridge, since they must support their own weight and the weight of the floor system in addition to the moving loads and wind loads. The total load on each truss is transferred through a horizontal pin to the end bearings or shoes, generally castings, which distribute the load to the supporting masonry. At one end of the bridge the bearings will be firmly fastened to the masonry, but at the other end they will be of the expansion type, which allows a limited amount of longitudinal movement to take care of the temperature changes in the structure. The separate structural members of a truss bridge are composed of rolled steel shapes or built-up sections formed by riveting two or more rolled shapes together. The truss members are connected at their intersections by riveting or bolting into gusset plates or by welding. Framed trusses are also used for industrial machines as shown in Fig. 3.

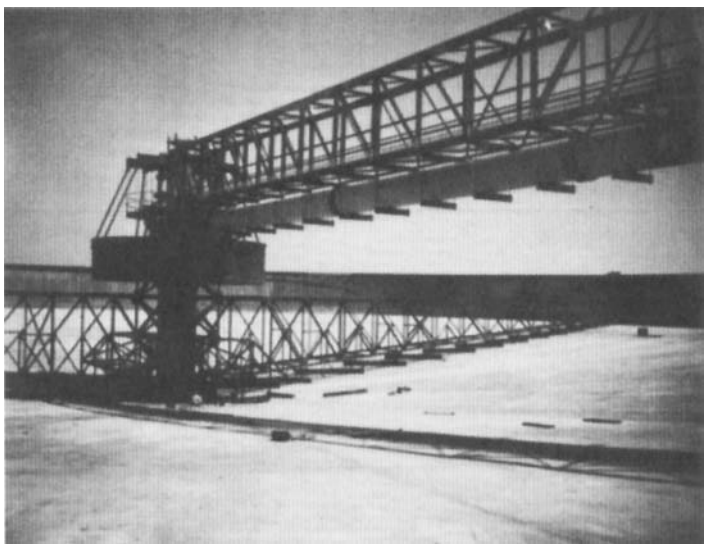

Fig. 3. Framed bridge trusses used in connection with very large settling basin. These members rotate slowly through 360°. (*Dorr-Oliver.*)

Bridge bearings are used to relieve stresses caused by temperature changes, winds, and changing soil pressures by providing slippage between the bridge and its supports. Bearings may be steel-on-steel sandwiched between lead inserts, self-lubricating bronze plates with graphite inserts, or polytetrafluoroethylene blocks that slide on stainless steel, among others. Assemblies of roller bearings and roller bearing nests may be used. Bearings must support many hundreds of tons of weight at locations selected by the bridge designer. In recent years, more attention has been directed to the maintenance of bridge bearings and the design essentially maintenance-free bearings. Corrosion and dirt over long periods of time can cause severe damage to bridge bearings.

As pointed out by Phillips, "Maintenance-free means do exist for taking up bridge movements. For example, some expansion and contraction can be absorbed within a properly designed bridge structure, and large shifts of up to three inches (7.5 centimeters) can be absorbed in flexible blocks called *elastomeric bearings*. Often made of high-quality neoprene, these pliant cushions come close to being the perfect solution to the bearing problem, because they have no moving parts to freeze, nothing to corrode, and therefore eliminate maintenance altogether."

Beam Bridge. This class of bridge is composed of two or more beams laid parallel to the direction of traffic. The roadway or track may be supported directly on the beams or by a stringer and transverse floor beam system connected to beams called girders. The construction of a simple deck plate girder bridge, frequently used for short railway spans, is shown in Fig. 4. Each girder is composed of a steel plate called the web to which are riveted four angles. Additional plates called covers are riveted to the angles. The two top or bottom angles and the attached cover plate form the flanges. The girders are stiffened laterally by the lateral system and the cross frames. A through bridge is a span of the beam or framed truss type in which the floor system is placed between the girders or trusses usually near the plane of the bottom flange or chords. In deck spans the floor system is placed between the girders or trusses near the plane of the top flanges or chords, or rests upon them.

Suspension Bridge. The simplest type of suspension bridge, applicable for short spans, consists of a floor system connected by hangers to two cables or chains. The latter pass over towers and are firmly anchored at the end of the span. The crudest type of suspension bridge may consist

of two parallel stout ropes or cords anchored firmly on either side of the creek or area to be spanned, and to which will be attached a light wooden, step-like platform, usually just wide enough for one person to walk across. See Tables 1 and 2.

Several of the world's longest bridges today are of the suspension type. For long spans, designed for heavy loads and moving trucks, autos, and pedestrians (sometimes), it is necessary to connect the floor systems to stiffening trusses or girders, which distribute the moving loads more uniformly to the hangers. This method of distribution reduces the distortion of the cable or chain. The hangers are formed of twisted wire ropes, while the cable may consist of twisted wire ropes or a number of parallel wires securely bound together into a compact unit of circular cross section. The chain is made up of a number of separate tension links called *eye-bars*. The floor system, stiffening truss, and towers are constructed of rolled steel or alloy shapes. For large bridges, such as the Golden Gate bridge (San Francisco Bay), the towers will be several hundred feet high, as shown in Fig. 5 on p. 547.

Brooklyn Bridge (New York). The oldest and most notable suspension bridge in the United States is generally considered to be the Brooklyn Bridge, which was opened to traffic in May 1883 and thus is over a century old.

John Roebling, the designer, and his son, who completed the bridge after Roebling died, were devoted to sound design principles. Other designers of the period (1830–1870) were sometimes much less conservative and increased suspension span lengths with inadequate regard for stability, particularly under windy conditions. While other designers called for large

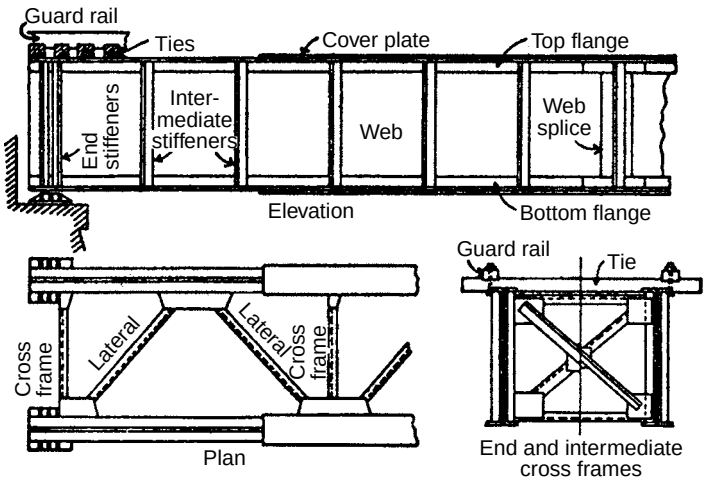

Fig. 4. Deck-type girder bridge.

cables composed of several small ones laid side by side, Roebling's cables were designed to become a single compact bundle.

Manhattan Bridge (New York). This bridge, dedicated in 1909, was the first suspension bridge to be designed on the basis of the Melan theory. Joseph Melan of Austria developed a theory for analyzing a stiffened suspension bridge. The theory worked and stiffness became recognized as essential to suspension bridge design. In fact, some later bridges were over-designed, adding unnecessary weight and cost. Some of the shortcomings experienced on early suspension bridges were associated with other problems — use of non-galvanized wire on the Williamsburg Bridge (New York City, dedicated in 1903); also in connection with the Manhattan Bridge, cables were not effectively designed for carrying the dead load uniformly and, in a design change, the actual load had to be distributed to the four cables by means of the floor beams, which were not originally designed for that purpose.

Tacoma Narrows Bridge. Some of the bridges of the 1930s were designed with a relatively shallow plate girder instead of the heavier, conventional truss adjacent to the platform. The objective was to provide the minimal stiffness necessary to prevent excessive movement of the roadway under heavy loads while at the same time gaining economy of construction and improved aesthetics (slender, gossamer structure). The extreme reached by this design approach was the first Tacoma Narrows Bridge. (Tacoma, Washington). During and shortly after completion, some weird effects were found as, for example, travelers noting cars ahead disappearing behind a wave in the floor. The engineers realized the undulating structure was less than desirable, but did not foresee a catastrophe ahead. Alteration of the bridge was delayed until models could be analyzed, but before the latter were completed, the bridge collapsed in November 1940. The collapse was attributed to the harmonics induced by a broadside wind (relatively modest, 45 miles/hour). This led to two solutions — increasing the stiffness of the deck, and designing a bridge cross section with a shape less affected by the wind (aerodynamic approach). Uplift effects of wind were also alleviated by providing open strips in the deck floor. Bridges incorporating the revised design schemes include the second Tacoma Narrows Bridge, the Mackinac Bridge, the Delaware Memorial and Walt Whitman Bridges, and the Throgs Neck and Verrazano Narrows Bridges. Bridge designers also turned to testing models in wind tunnels. Computerized mathematical models are also used.

The stayed-girder design has also been used. In this design, the roadway and towers of a suspension bridge remain the same, but the cables are straight stays from the top of the tower to various points on the roadway. There are no massive flexible suspension cables in which harmonics can develop.

Nonlinear Effects. Although engineers were satisfied with the redesign of the Tacoma Narrows Bridge, dedicated in 1950, some remain uncertain concerning the analysis and final conclusions drawn as the result of the earlier bridge, which had collapsed. McKenna and Lazer (University of Miami), for example, have devoted considerable time toward developing a new mathematical model that may provide a more satisfactory explanation pertaining to the collapse. An explanation that regards resonances and oscillations as a major cause of the collapse does not appear to suffice. (It is interesting to note that the first recorded collapse of a suspension bridge was that which crossed the River Tweed (Scotland) and was built in 1817. It was 260 feet (79 m) long. Later explanations of cause were attributed to wind-generated oscillations.) McKenna and Lazer have introduced the concept that suspension bridges have a very distinctive characteristic — namely, their nonlinearity. Are linear differential equations, used by engineers in developing bridge models and designs, ample? As pointed out by Peterson, the new Lazer/McKenna theory may provide insights into why suspension bridges oscillate, as well as other large-scale, flexible structures. Much more excellent detail can be found in the Peterson reference listed.

Arched Bridge. This type of bridge is popular in connection with grade-separation work in highway and railways. The relatively shallow central portion of the span results in the use of less landfill. The type of bridge to be used at a particular location depends upon many considerations. Typical arched bridges are shown in Fig. 6 on p. 550. Satisfactory foundations, possible pier locations, and access to the bridge are some of the local conditions that will influence the selection of a particular type. From an architectural standpoint the type which is used should harmonize with the natural surroundings. When the cost of a bridge project is limited to a predetermined amount certain types of bridges are automatically eliminated.

Cantilever Bridge. In its simplest form, the cantilever bridge consists of a suspended span and two anchor spans. Each anchor span, which rests on two piers, is made up of an anchor arm and a cantilever arm. The latter projects beyond the river pier to form a support for one end of the suspended span. Cantilever bridges may be either trusses or plate girders.

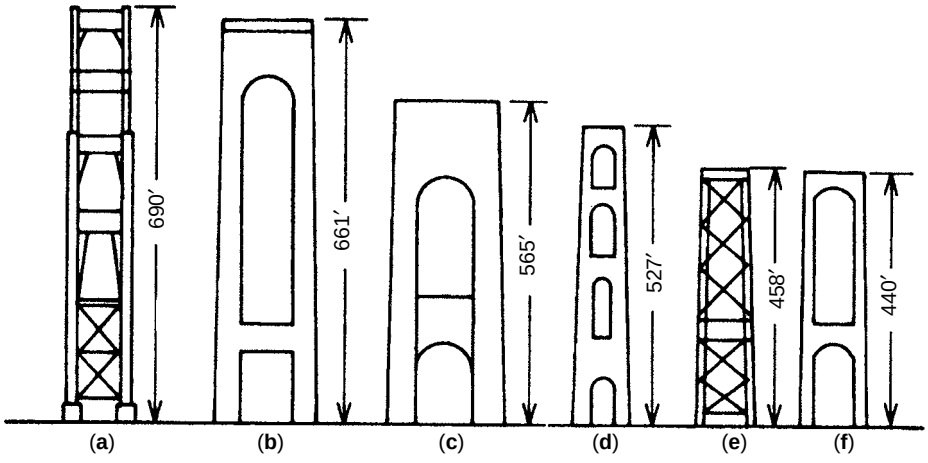

Fig. 5. Schematic cross sections of towers used for large suspension bridges: **(a)** Golden Gate; **(b)** Verrazano-Narrows; **(c)** George Washington; **(d)** Mackinac Straits; **(e)** San Francisco-Oakland (Transbay); and **(f)** Delaware Memorial bridge.

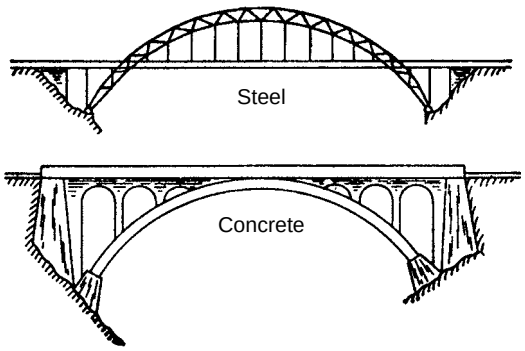

Fig. 6. Typical arched bridges.

The former are particularly well adapted to long-span construction. See Fig. 7 on p. 550.

It is interesting to note that the Forth Bridge (Scotland) was completed in 1890 and truly represented a monumental task for that time. The bridge furnished an important link in the direct railway communication between Edinburgh and Perth and Dundee. At that time the bridge was the longest in the world, including entrance and exit ways, a length of nearly $1\frac{5}{8}$ miles (1 km), with a headway for navigation of 150 feet (46 m) and a greatest height of 361 feet (110 m). See Table 3.

Other Bridge Designs. A continuous bridge is one that rests on three or more supports and is capable of transmitting both shear and moment throughout its length. These bridges which are statically indeterminate structures may be plate girders or trusses. The continuous bridge is more rigid than the cantilever bridge but settlement of the supports has an effect on the stress distribution.

A bridge of two or more spans, which is supported at each intermediate pier by a hinged quadrilateral, is called a Wichert truss. This type of bridge is determinate and therefore the stresses are not affected by settlement of the supports.

A pontoon bridge is a floating roadway used to bridge narrow bodies of water. It consists of barges called pontoons that carry a roadway made up of beams that, in turn, support a plank floor. The pontoons must be firmly anchored so that they will not float out of position. The pontoon bridge is generally used for military purposes although there are instances in which this type of bridge has been constructed for ordinary vehicular and pedestrian traffic. See Tables 4–8.

Movable Spans. There are three general types of movable spans, namely, the bascule, the vertical lift, and swing bridge. The bascule bridge pivots about a horizontal axis or rolls back on circular segments. If the entire span rotates about a horizontal axis near one end, it is called a single leaf bascule. A double leaf bascule is one that consists of two cantilevers, each of which rotates about a horizontal axis, forming a single span when closed. When the entire movable section may be lifted vertically, parallel to its original position, the bridge is called a vertical lift span. Swing bridges are those which turn in a horizontal plane about a vertical axis located at the center of the bridge. Movable bridges, when closed, are similar and perform the same service as the stationary types.

BRIDGING GAIN. The ratio of the power a transducer delivers to a specified load impedance under specified operating conditions, to the power dissipated in the reference impedance across which the input of the transducer is bridged. If the input and/or output power consist of more than one component, such as multifrequency signal or noise, then the particular components used and their weighting should be specified. This gain is usually expressed in decibels.

In contrast, a *bridging loss* is the ratio of the power dissipated in the reference impedance across which the input of a transducer is bridged, to the power the transducer delivers to a specified load impedance under specified operating conditions. If the input and/or output power consist of more than one component, such as multifrequency signal or noise, then the particular components used and their weighting should be specified. This loss is usually expressed in decibels. In telephone practice this term is synonymous with the insertion loss resulting from bridging an impedance across a circuit.

BRIGHT BAND. Radar signature of the melting layer; a narrow horizontal layer of stronger radar reflectivity in precipitation at the level in the atmosphere where snow melts to form rain. The bright band is most readily observed on range–height indicator (RHI) or time–height indicator (THI) displays.

As ice crystals fall toward warmer temperatures at lower heights, they tend to aggregate and form larger snowflakes. This growth accounts for an increase in radar reflectivity as the falling particles approach the melting level. As they cross the 0 °C (32 °F) level, the particles begin melting from the surface inward and finally collapse into raindrops. The reflectivity maximum in the melting layer is explained partly by the difference in the value of the dielectric factor, $|K|$, of water and ice. See also **Radar Reflectivity**. When a water film begins to form on a melting snowflake, its radar reflectivity may increase by as much as 6.5 dB because of the thermodynamic phase change. The reflectivity decreases below the melting level because when flakes collapse into raindrops, their fall velocities increase, causing a decrease in the number of precipitation particles per unit volume. The size of the particles also becomes smaller in the melting process, as their density increases from that of the snow and melting snow to that of liquid water. Both the reduction in size of the precipitation particles and the decrease in their concentration lead to a decrease in the strength of the radar echo at altitudes below the melting level, so that an isolated, horizontal layer of high reflectivity is established, usually centered about 100 meters (328 feet) below the 0 °C (32 °F) isotherm. The bright band is observed primarily in stratiform precipitation. The strong convective currents in active showers and thunderstorms tend to destroy the horizontal stratification essential for creating and sustaining the bright band.

AMS

BRIGHTNERS. See **Detergents**.

BRIGHTNESS. Brightness is the attribute of visual perception in accordance with which an area appears to emit more or less light. Luminance is recommended for the photometric quantity, which has been called "brightness." Luminance is a purely photometric quantity. Use of this name permits "brightness" to be used entirely with reference to the sensory response. The photometric quantity has been often confused with the sensation merely because of the use of one name for two distinct ideas. Brightness may continue to be used properly, in non-quantitative statements, especially with reference to sensations and perceptions of light. Thus, it is correct to refer to a brightness match, even in the field of a photometer, because the sensations are matched and only by inference are the photometric quantities (luminances) equal. Likewise, a photometer in which such matches are made should be called an "equality-of-brightness" photometer. A photoelectric instrument, calibrated in foot-lamberts, should not be called a "brightness meter." If correctly calibrated, it is a "luminance meter." A troublesome paradox is eliminated by this distinction of nomenclature. The luminance of a surface may be doubled, yet it is permissible to say that the brightness is not doubled, since the sensation which is called "brightness" is generally judged to be not doubled.

BRILLIANCE. Brilliance is that attribute of any color in respect to which it may be classed as equivalent to some member of a series of grays ranging between black and white. Yellow is the most brilliant color in the spectrum of white light.

BRILLOUIN EFFECT. Upon the scattering of monochromatic radiation by certain liquids, a doublet is produced, in which the frequency of each of the two lines differs from the frequency of the original line by the same amount, one line having a higher frequency, and the other a lower frequency.

BRILLOUIN ZONE. An electron moving within an ionic crystal moves in a potential field which may be approximated to as that of a constant potential within the crystal (as in the elementary Drude-Lorentz theory), modified by a varying potential which varies as the periodicity of the lattice. The allowed solutions of the wave equation for such a system are those for which the energy lies in a series of bands, the wave vector k of the electron being imaginary at other values. The values of k at which discontinuities occur lie at the surfaces of polyhedra in k-space called Brillouin zones. The Brillouin zones may be calculated for a given lattice structure. In the study of complex metals and alloys, where there may be several overlapping bands, the geometry of the zones plays an important role. See also **Fermi Surface**.

BRINE. Seawater containing a higher concentration of dissolved salt than that of the ordinary ocean.

Brine is produced by the evaporation or freezing of seawater, for, in the latter case, the sea ice formed is much less saline than the initial liquid, leaving the adjacent unfrozen water with increased salinity. The liquid remaining after seawater has been concentrated by evaporation until salt has crystallized is called bittern.

BRINE-FLY *(Insecta, Diptera).* Flies whose larvae live in strong briny or alkaline waters. They belong to the family *Ephydridae*, which also contains species whose larvae live in fresh water and one remarkable insect that lives in pools of crude petroleum in the California oil fields.

Large quantities of the larvae of certain species are washed ashore along some of the western alkaline lakes and are gathered by the Indians as food under the native name kootsabe.

The brine-fly and the brine shrimp are among the very few life forms that inhabit the waters of the Great Salt Lake in Utah. The brine-fly can live in nearly pure salt.

BRINELL HARDNESS TEST. The standard method of measuring the hardness of metals. The smooth surface of the metal is dented by a steel ball under force. The standard load and time are 500 kg for 60 seconds for soft metals and 3000 kg for 30 seconds for steel and other hard metals. The size (diameter) of the resulting dent is measured, and the hardness determined from a chart or formula.

BRINELL SCALE. See **Hardness**.

BRISA. See **Winds and Air Movement**.

BRISTLEMOUTHS *(Osteichthyes).* Of the order *Isospondyli*, suborder *Stomiatoidea*, family *Gonostomatidae*, the bristlemouths are abundant deep sea fishes, with a herring-like appearance and incorporation of photophores (light organs) on their sides. Of the some 30-plus species, the largest does not exceed 3 inches (7.5 centimeters) in length. There remains much to be learned pertaining to the habits of the bristlemouths. Despite their abundance, the bristlemouths are seldom seen.

BRITISH THERMAL UNIT (BTU, Btu). See **BTU (British Thermal Unit BTU, Btu)**.

BRITTLE FRACTURE. A fracture involving very little expenditure of energy. Brittle fracture usually occurs with very little accompanying plastic deformation. Brittle fractures in engineering structures have been of concern ever since it became the practice to weld large steel structures. Thus, for example, the hull of a welded ship is really one continuous piece of steel. A crack that starts in such a structure can pass completely around it, causing it to break in two. A number of failures of this type over the years have occurred. Similarly, brittle fractures have been known to travel as far as half a mile in welded gas pipelines, often with extremely high velocities. A brittle crack usually starts at a notch or stress raiser, which may be due to faulty design or to accidents of construction. Most brittle fractures also occur at low ambient temperatures — the middle of winter. Finally, the metal must be subjected to a stress that furnishes the energy causing the fracture to expand.

Most brittle fractures in steel are transcrystalline, with the body-centered cubic ferrite crystals cleaving on cube planes. Cleavage is promoted by high stresses. Since plastic flow by slip tends to relieve an applied stress, the conditions that promote cleavage are normally those that restrict plastic deformation. Thus, rapid application of a load, a state of multi-axial stress, and low temperatures all limit slip deformation while encouraging cleavage. It should be noted, however, that cleavage in steels only approaches a true brittle fracture, such as that which occurs in glass, at very low temperatures like that of liquid nitrogen ($-196\,^{\circ}$C). Glass at room temperature fractures without any appreciable amount of accompanying plastic deformation. In steels, some plastic deformation usually proceeds or accompanies fracture due to cleavage, the amount of deformation, however, decreasing with decreasing temperature.

In a normal steel most failures at room temperature or above are ductile fractures which involve a large expenditure of work. As the temperature is lowered, the failure becomes partly ductile and partly brittle, with a corresponding decrease in the work to cause fracture. This fact may be clearly shown by making Charpy impact tests at a number of temperatures. This test measures the energy to suddenly fracture a notched bar. The presence of the notch produces a state of multi-axial tensile stress. An important feature of the Charpy impact test is that it tends to reproduce the ductile-brittle transformation of steel in about the same temperature range as that actually observed in engineering structures. A representative curve, showing the transition from ductile to brittle behavior, as measured by the Charpy test, is shown in the first figure. See Fig. 1. One of its important features is that the transition is not sharp, but occurs over a range of temperatures. It is, therefore, necessary to arbitrarily define the transition temperature. There are several ways of doing this that are commonly employed. In one case, the transition temperature for ductile to brittle fracture is taken as the temperature at which an impact specimen fails with a half-brittle, half-ductile surface. The brittle fracture portion of the surface can always be identified by its cleavage facets, which reflect light sharply. On the other hand, the ductile portion of the fracture surface is always dull and gray. A second definition uses the average energy criterion: the temperature at which the energy absorbed falls to one-half the difference between that needed to fracture a completely brittle specimen. The temperature at which a specimen fails with a fixed amount of energy, usually 15 or 20 ft-lb, is also widely employed as a basis for the transition temperature. The last two of the above criteria are illustrated in Fig. 2.

BRIX SCALE. See **Specific Gravity**.

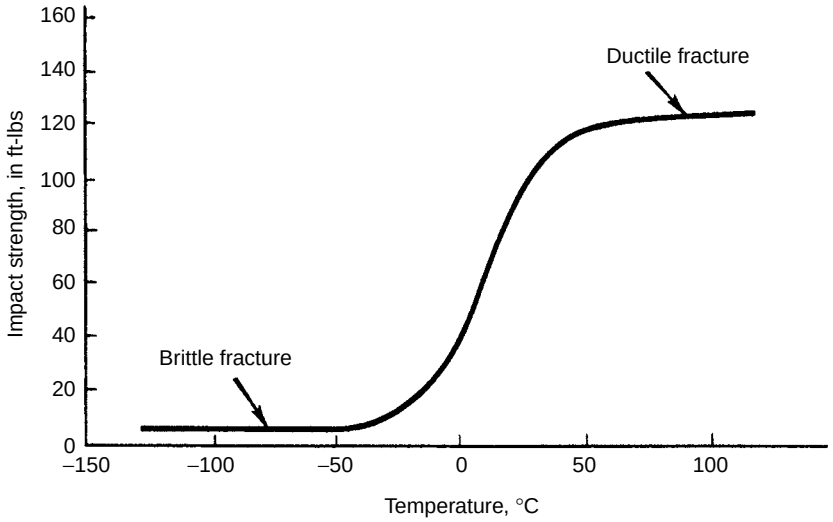

Fig. 1. Representative Charpy impact ductile to brittle fracture transition curve.

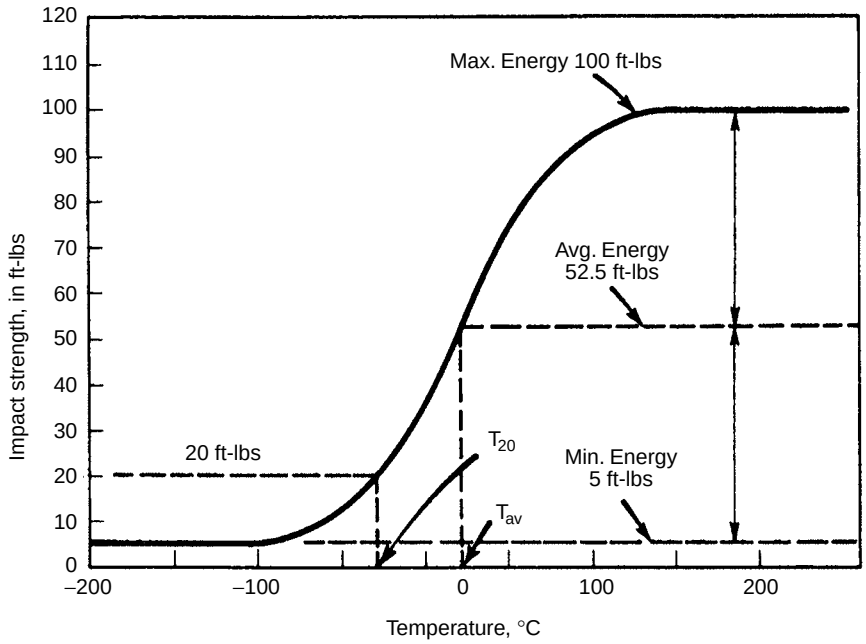

Fig. 2. The transition temperature can be defined in several ways, two of which are shown above. T_{20} is the transition temperature, using the 20-ft-lb (27.12-joule) criterion; T_{av} is the temperature for the average energy criterion.

BROAD BAND X-RAY TELESCOPE (BBXRT). See **Space Science Missions:Universe**.

BROADBILLS *(Aves, Passeriformes).* These birds belong to the suborder *Desmodactylae* and consist of only one family (*Eurylaimidae*). These birds have large heads and are generally broadbilled. There are 15 cervical vertebrae (other passeriformes have 14). There are small scales on the rear of the tarsus. The wings are short and round, and thus the birds only fly short distances. There are eight genera with 14 species, two of which are found in tropical Africa, and the rest in the Orient.

This family falls naturally into two groups: the Typical Broadbills (subfamily *Eurylaiminae*), which have very large beaks; the Green Broadbills (subfamily *Calyptomeninae*), with the single genus Calyptomena, with a rictal brush. The size varies from that of a sparrow to that of a jay; the body is compact, and the wings are short and round. The eyes are large, and the bill is flat, wide and hooked at the tip; the green broadbill is the only bird of the family with a smaller beak, which is covered at the base with a dense hood of feathers. The sexes are usually different in appearance.

Broadbills are mainly forest birds; some prefer mountains, and some prefer plains. Most broadbills are insectivorous; only the black-and-red broadbill eats berries and even shrimp, small fish and crabs, as well as beetles, crickets, and grasshoppers. The green broadbills, however, prefer fruit.

All species build the same type of unusual nest, which may reach a length of $6\frac{1}{2}$ feet (2 meters). It usually hangs from the tip of a branch in a shady forest glade, and it is almost always over a river or some other body of water. Its shape corresponds to that of a gigantic pear, with an elongated narrow part connecting it to the end of the branch. There is usually a large projection over the entrance. The nest is built of grass, leaves, moss, rootlets, and similar materials, and it is lined with green leaves. The nest exterior is often decorated with lichens and spider webs. Broadbills usually lay 2–4 eggs; the eggs are white, light red, or cream-colored, with spots of varying density. Nothing seems to be known about the duration of incubation, the fledgling period, or other details of the nest life in any of these species.

BROADCASTING. See **Radio Communication**; and **Television**.

BROADENING OF SPECTRAL LINES. A spectral line emitted by an atomic or nuclear system does not consist of a single frequency, but rather of a continuous group of frequencies, which may be very narrow in its extent. The inherent width of a line is known as its natural width. A spectral line may be additionally broadened by Doppler broadening and by collision, or pressure broadening. In the latter case, the lifetime τ of an excited state may be reduced during a collision, which in turn increases the energy level width, Γ, of the excited state through the relation, $\Gamma + h\tau$. Since the change in energy ΔE in the transition and the frequency of emitted radiation are related by $\Delta E = hv$, any broadening of the energy change results in a broadening of the frequency spectrum. See also **Doppler Broadening**.

BROCA, PIERRE PAUL (1824–1880). Broca was a French surgeon and anthropologist. He became a professor of surgical pathology at the University of Paris. His early research dealt with the histology of cartilage and bone, aneurisms, and infant mortality. In latter years, Broca studied the brains of aphasic patients. He became famous with his discovery in 1861 of the cerebral localization of speech while working with his patient, "Tan" who had a neurosyphilitic lesion in one side of his brain that controlled speech.

Broca was considered a pioneer in the study of physical anthropology. He developed many new measuring instruments for measuring the crania. He was interested in the anatomy of primates and described trephined skulls from the Neolithic.

J. M. I.

BROCHANTITE. A mineral composed of basic copper sulfate corresponding to the formula $Cu_4(SO_4)(OH)_6$, crystallizing in the monoclinic system in needle-like prisms, or forming druses or masses. Hardness, 3.5–4; specific gravity, 3.9; vitreous luster; color, green; streak, green; transparent to translucent.

Brochantite is a secondary mineral occurring in the oxidized zones with other copper minerals, and is found in the Ural Mountains, in Rumania, in Sardinia; Cornwall, England; Chile. In the United States this mineral has been found at Bisbee, Arizona, Utah, in the Tintic District and in Inyo County, California. Brochantite was named for Brochant de Villiers.

BROEBOE. See **Winds and Air Movement**.

BROMINE. [CAS: 7726-95-6] Chemical element, symbol Br, at. no. 35, at. wt. 79.904, periodic table group 17 (halogens), mp $-7.2\,^{\circ}C$, bp $58.8\,^{\circ}C$, density 3.12 g/cm^3 ($20\,^{\circ}C$). Bromine is one of the few elements that is liquid at standard conditions. The element volatilizes readily at room temperature to form a red vapor that is very irritating to the eyes and throat. Liquid bromine causes painful lesions upon contact with the flesh. Bromine has two stable isotopes ^{79}Br and ^{81}Br. Elemental bromine finds limited application as a chemical intermediate and as a sanitizing, disinfecting, and bleaching agent. Both the inorganic and organic compounds of the element find extensive commercial usage. Bromine was discovered in 1826 by Antoine-Jérôme Balard, who identified the element as a component of seawater bitterns. Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^5$. Ionic radius Br^- 1.97 A, Br^{7+} 0.39 Å. Covalent radius 1.193_5. First ionization potential 11.84 eV; second 19.1 eV; third 25.7 eV. Oxidation potentials $2Br^- \rightarrow Br_2(1) + 2e^-$, -1.065 V; $2Br^- \rightarrow Br_2(aq) + 2e^-$, -1.087 V; $Br^- + H_2O \rightarrow HBrO + H^+ + 2e^-$, -1.33 V; $Br^- + 3H_2O \rightarrow BrO_3^- + 6H^+ + 6e^-$, -1.44 V; $\frac{1}{2}Br_2 + 3H_2O \rightarrow BrO_3^- + 6H^+ + 5e^-$, -1.52 V; $\frac{1}{2}Br_2 + H_2O \rightarrow HBrO + H^+ + e^-$, -1.59 V; $Br^- + 6OH^- \rightarrow BrO_3^- + 3H_2O + 6e^-$, -0.61 V; $Br^- + 2OH^- \rightarrow BrO^- + H_2O + 2e^-$, -0.70 V.

Other important physical properties of bromine are described under **Chemical Elements**.

Bromine is only moderately soluble in H_2O (3.20 g/100 ml) but markedly so in nonpolar solvents, e.g., carbon tetrachloride, as is consistent with the covalent character of the Br—Br bond. It dissolves more readily in alkali bromide solutions due to the formation of the tribromide ion (Br_3^-), and in certain associated solvents, such as concentrated H_2SO_4 and ethyl alcohol. Its aqueous solution is more stable than that of chlorine, since the tendency of Br_2 to hydrolyze to unstable hypobromous acid and hydrogen bromide is less than the corresponding reaction for chlorine. Bromine exhibits in common with the other halogens a marked readiness to form singly charged negative ions, as would be expected from the fact that these atoms need only one electron to acquire an inert gas configuration. Its electron affinity (3.53 eV) is between that of chlorine and iodine. The bromides range in character from ionic to covalent compounds, many of them having bonds of intermediate nature. In addition to its negative univalence, bromine forms essentially covalent linkages with negative elements, in which it has positive valences 1, 3, and 5.

Bromine occurs as bromide in seawater (0.188% Br), in the mother liquor from salt wells of Michigan, Ohio, West Virginia, Arkansas, and in the potassium deposits of Germany and France.

Production. In the United States, nearly all bromine is derived from natural brines. The Arkansas brines which contain a minimum of 4000 ppm bromide account for over half of this production. Recovery is effected by a *steaming-out* process. After heating fresh brine, the solution is fed to the top of a tower. Chlorine and steam are injected at the bottom of the tower. The chlorine oxidizes the bromide and displaces one resultant bromine from solution. For brines of lower concentration, air instead of steam is used to sweep out the bromine vapors after chlorination.

Hydrogen Bromide and Hydrobromic Acid. HBr, is formed directly from the elements, effectively when catalyzed by sunlight, by heated charcoal or platinum, or more conveniently by hydrolysis of phosphorus tribromide. Treatment of bromides with H_2SO_4 yields mixtures of HBr and bromine. The H—Br bond is considered to be partly covalent. Hydrobromic acid is a strong acid in aqueous solution. Its salts are the bromides, all of which are water-soluble except those of copper(I), silver, gold(I), mercury(I), thallium(I) and lead(II), the divalent ions of the elements of the second and third transition series, and the salts of the heavy alkali ions with many bromo-complex anions, e.g., Cs_2PtBr_6, $RbAuBr_4$, etc. The main uses of HBr and hydrobromic acid are in the production of alkyl bromides (by replacement of alcoholic hydroxyl groups or by addition to olefins) and inorganic bromides.

Sodium Bromide. [CAS: 7647-15-6] This is a high-tonnage chemical and one of the most important of the bromide salts ($NaBr_2$). High-purity grades are required in the formulation of silver bromide emulsions for photography. The compound, usually in combination with hypochlorites, is used as a bleach, notably for cellulosics. The production of sodium bromide simply involves the neutralization of HBr with NaOH or with sodium carbonate or bicarbonate.

Calcium Bromide. [$CaBr_2$ 7789-41-5] Because of its ready solubility, calcium bromide forms solutions of high density which when properly formulated are finding increasing use as functional fluids in oil well completion and packing applications.

Lithium Bromide. [CAS: 7550-35-8] (anhydrous), [CAS: 13453-70-8] (hydride) LiBr finds use as a desiccant in industrial air conditioning systems and industrial drying agents.

Zinc Bromide. [CAS: 7699-45-8] $ZnBr_2$ is used as a rayon-finishing agent, as a catalyst, as a gamma-radiation shield in nuclear reactor viewing windows, and as an absorbent in humidity control. It too finds use in high density formulated functional fluids in oil well applications. Zinc bromide is prepared either by the direct reduction of bromine with zinc, or by reacting HBr with zinc oxide or carbonate.

Other Bromides. Aluminum bromide [CAS: 7727-15-3] is used as a catalyst and parallels $AlCl_3$ in this role. Strontium and magnesium bromides are used to a limited extent in pharmaceutical applications. Ammonium bromide is used as a flame retardant in some paper and textile applications; potassium bromide is used in photography. Phosphorus tribromide PBr_3 and silicon tetrabromide $SiBr_4$ are used as intermediates and catalysts, notably in the production of phosphite esters.

Hypobromous Acid and Hypobromites. Hypobromous acid HOBr results from the hydrolysis of bromine with H_2O and exists only in aqueous solution. The compound finds limited use as a germicide and in water treatment; also it can be used as an oxidizing or brominating agent in the production of certain organic compounds. Although hypobromous acid is low in bromine content, concentrated hypobromite solutions can be formed by adding bromine to cooled solutions of alkalis.

Bromic Acid and Bromates. Bromic acid [CAS: 7789-31-3], $HBrO_3$, can exist only in aqueous solution. Bromic acid and bromates are powerful oxidizing agents. Bromic acid decomposes into bromine, oxygen, and water. Many oxidizing agents, e.g., hydrogen peroxide, hypochlorous acid, and chlorine convert Br_2 or Br^- solutions to bromates. The decomposition reactions of bromates vary considerably. Lead(II) bromate and copper(II) bromate give the metal oxides and Br^-; silver, mercury(II) and potassium

bromates give the metal ion, Br^- and oxygen, while zinc, magnesium, and aluminum bromates give the metal oxide, Br_2 and oxygen.

Halogen Compounds. Bromine forms a number of compounds with the other halogens. Its binary iodine compounds are discussed under iodine; other interhalogen compounds of bromine include bromine monochloride, bromine monofluoride, bromine trifluoride, and bromine pentafluoride. The nonexistence of higher chlorides of bromine, differing from iodine, can readily be explained in terms of the oxidation potential of Br(III) and Br(V). The monochloride, bromine chloride, BrCl, exists in pure state only at very low temperatures in the solid form. Dissociation in the gas phase is approximately 40% at 25 °C and increases slowly with increasing temperature; less than 20% occurs in the liquid phase. With many substrates, bromine chloride reacts much more rapidly than does bromine itself to introduce bromine substituents. Bromine monofluoride, BrF, is also somewhat unstable, decomposing spontaneously at 50 °C to Br_2, BrF_3, and BrF_5. It has never been prepared pure since it is always in equilibrium with Br_2 and BrF_5. It is a gas at room temperature, reacting readily with water, phosphorus, and the heavy metals. Bromine trifluoride, BrF_3, is much more stable than the monofluoride. It is obtained directly from the elements at 10 °C, or by fluorination of univalent heavy metal bromides. It is a liquid, bp 127.6 °C, mp 8.8 °C. There is evidence (high Trouton constant) that it undergoes self-ionization to form BrF_2^+ and BrF_4^-. The former is found in the acidic addition products it forms with gold(III), antimony(V) and tin(IV) fluorides, BrF_2AuF_4, BrF_2SbF_6 and $(BrF_2)_2SnF_6$. The latter occurs in the tetrafluorobromates, such as $KBrF_4$ and Ba $(BrF_4)_2$. The solvent properties of BrF_3 are consistent with its indicated dissociation, i.e., reactions involving the two classes of compounds mentioned take place as if BrF_3 acts as a fluoride ion donor or acceptor as H_2O is a proton donor or acceptor in the H_2O system. For example, potassium dihydrogen phosphate, KH_2PO_4 gives KPF_6, a mixture of HNO_3 and B_2O_3 gives NO_2FB_4, etc. Bromine trifluoride fluorinates many of the metal halides and oxides. Bromine pentafluoride, BrF_5, is prepared from BrF_3 and fluorine. It is thermally stable. It is a very active fluorinating agent, converting to fluorides most metals, their oxides and other halides, and being hydrolyzed by H_2O probably to hydrofluoric and bromic acids.

The polyhalide complexes of bromine include $(PBr_4)(IBr_2)$ formed by reaction of phosphorus pentabromide and iodine monobromide, and dissociating in certain organic polar solvents to the ions PBr_4^+ and IB_2^-. Other polyhalides include NH_4IBr_2, , $[(CH_3)_4N][IBr_2]$, Cs[IFBr], Rb[IClBr], and Cs[IClBr]. Most of these compounds hydrolyze readily, ionize in polar nonreacting solvents to the corresponding polyhalide ions, and decompose on heating to give the metal halide of greatest lattice energy.

Oxides. In binary combination with oxygen, bromine forms at least three compounds. Bromine(I) oxide, Br_2O, is a dark brown solid that is stable only in the dark below −40 °C. It is prepared by passing dry gaseous bromine through dry mercury(II) oxide and sand. Bromine(I) oxide, in carbon tetrachloride at low temperatures, reacts with alkali hydroxide to give hypobromites. Bromine(IV) oxide, BrO_2, is obtained by reaction of the elements in a cooled electric discharge tube. It is yellow, and is stable only at low temperatures. The compound appearing in the older literature as tribromine octoxide, Br_3O_8, is actually bromine trioxide, BrO_3, or dibromine hexoxide, Br_2O_6 (cf. chlorine). It is obtained from the low temperature, low pressure reaction of ozone and bromine; it is stable only at low temperatures and is soluble in H_2O with decomposition. Bromine(VII) oxide may be present among the decomposition products of BrO_2, or BrO_3, but no other evidence for its existence has been found.

Organic Bromine Compounds. Commercially important organic bromine compounds include: (1) methyl bromide CH_3Br formed by reacting methanol with HBr or hydrobromic acid. The compound is a highly toxic gas at standard conditions. Because of its toxicity, it is used as a soil and space fumigant. In many organic syntheses, the compound is used as a methylating agent; (2) ethylene dibromide (1,2-dibromoethane) is used in combination with lead alkyls as an antiknock agent for gasoline. The compound also is used as a fumigant; (3) methylene chlorobromide (bromochloromethane) is a low-boiling liquid of low toxicity and is useful as a fire-extinguishing agent in portable equipment and aircraft; (4) bromotrifluoromethane is increasingly employed as a fire extinguishant in permanently installed systems protecting high-cost installations, such as computer rooms, where its low toxicity and especially its freedom from corrosivity are important considerations; (5) acetylene tetrabromide (1,1,2,2-tetrabromoethane) is made by adding bromine to acetylene. The compound is comparatively dense and finds use as a gage fluid and in specific gravity separations of solids. It is also used as part of the catalyst system for the oxidation of *p*-xylene to terephthalic acid; (6) tris(2,3-dibromopropyl) phosphate may be prepared by the reaction of phosphorus oxychloride with 2,3-dibromopropanol, or by the addition of bromine to triallyl phosphate. This viscous fluid was used as a flame retardant in a number of polymer systems, but has been displaced from most, or all, of these uses, because it is a mutagen and suspect carcinogen; (7) tetrabromobisphenol A is produced by the direct bromination of bisphenol A. The compound is used extensively as a flame retardant and usually is incorporated into the polymer backbone structure of epoxy resins, unsaturated polyesters, and polycarbonates; (8) tetrabromophthalic anhydride, made by the catalytic bromination of phthalic anhydride in fuming H_2SO_4, also finds use as a reactive flame retardant in the formulation of polyol systems (for polyurethane foams) and in unsaturated polyesters; (9) decabromodiphenyl ether, and others of the lower brominated diphenyl ethers, are finding increasing use as flame retardants in a variety of thermoplastic polymer systems; (10) vinyl bromide has also found major use in flame-retarding modacrylic textile fibers when introduced as a co-monomer in the synthesis of the polymer itself.

Alkanes and arenes, e.g., ethane and benzene, respectively, react with bromine by *substitution* of bromine for hydrogen (hydrogen bromide also formed) — ethane to yield ethyl bromide C_2H_5Br plus further substitution products; benzene, in the presence of a catalyst, e.g., iodine, phosphorus, iron, to yield bromobenzene C_6H_5Br plus further substitution products; toluene, under like conditions to benzene, to yield orthobromotoluene and parabromotoluene $CH_3C_6H_4Br$ plus further substitution products, but at the boiling temperature, in sunlight, dry, and in the absence of a catalyst, to yield alkyl side-chain substitution products, benzyl bromide $C_6H_5CH_2Br$, benzal bromide $C_6H_5CHBr_2$, and benzotribromide, $C_6H_5CBr_3$.

Alkenes, alkynes, and arenes, e.g., ethylene, acetylene and benzene, respectively, react (1) with bromine by *addition*, e.g., ethylene dibromide $C_2H_4Br_2$ (1,2), acetylene tetrabromide $C_2H_2Br_4$ 1,1,2,2, hexabromocyclohexane $C_6H_6Br_6$; also carbon monoxide yields carbonyl bromide $COBr_2$; (2) with hypobromous acid by *addition*, e.g., olefins form, for example, ethylene bromohydrin $CH_2Br \cdot CH_2OH$; (3) with hydrogen bromide by *addition*, to form, for example, ethyl bromide $CH_3 \cdot CH_2Br$ from ethylene. When the two olefin carbons have unequal numbers of hydrogens, the carbon to which one bromide or one hydroxyl attaches can be controlled by the reaction conditions.

Oxygen-function compounds, e.g., ethyl alcohol, acetaldehyde, acetone, acetic acid, react (1) with bromine, to form *bromo-substituted* corresponding or related *compounds*, e.g., ethyl alcohol or acetaldehyde to yield bromal $CBr_3 \cdot CHO$, acetone to yield bromoacetone $CH_2Br \cdot CO \cdot CH_3$; acetic acid to yield, at the boiling temperature, dry, and in the absence of a catalyst, monobromoacetic acid $CH_2Br \cdot COOH$, dibromoacetic acid $CHBr_2 \cdot COOH$, tribromoacetic acid $CBr_3 \cdot COOH$, the substitution taking place on the alpha-carbon (the carbon next to the carboxyl-group-COOH), (2) with phosphorus bromides, to form corresponding *bromides*, e.g., ethyl bromide C_2H_5Br, ethylidene dibromide CH_3CHBr_2, acetone bromide $(CH_3)_2CBr_2$, acetyl bromide CH_3COBr, (3) with hydrobromic acid, concentrated, alcohol forms the corresponding bromide.

Bromoform is made by reaction of acetone or ethyl alcohol with sodium hypobromite; carbon tetrabromide by reaction of CS_2 plus bromine Br_2 in the presence of iron, heated; or by one reaction of bromoform with aqueous hypobromite solutions. Use is made of the diazo-reaction to introduce bromine into aryl compounds.

Many of the bromo-compounds are used as reagents or as intermediate compounds in organic chemistry. When alkyl bromocompounds are treated (1) with NaOH dissolved in alcohol, hydrogen bromide is removed, e.g., ethyl bromide $CH_3 \cdot CH_2Br$ yields ethylene $CH_2{:}CH_2$, ethyl dibromide $CH_2Br \cdot CH_2Br$ yields acetylene CH⋮CH; (2) with magnesium or zinc and alcohol, bromine is removed, e.g., ethylene dibromide $CH_2Br \cdot CH_2Br$ yields ethylene $CH_2{:}CH_2$, acetylene tetrabromide $CHBr_2{:}CHBr_2$, yields acetylene CH⋮CH.

BRONCHIAL ASTHMA. A relatively common, obstructive lung disease, with an estimated 2.5% of the population symptomatic at any given time. Symptoms tend to range widely between patients and in any one patient. The severity of symptoms can spontaneously change rapidly in any particular patient. Although much has been learned concerning the relief of symptoms, treatment of a given patient may require a series of trials with available drugs before a reasonably effective combination of drugs can be identified. There is no known permanent cure for the disease, although some patients can be essentially symptom-less for fairly long periods, only to have a spontaneous flare-up of symptoms. Generally the physician will advise the asthma patient that treatment will be over the long term. Statistics indicate that about two-thirds of asthma-prone persons will develop before the age of 5 years. The time of onset of the disease ranges widely in the other third of cases. The incidence of bronchial asthma is nearly twice as high in men as in women. Largely a result of lack of attention and treatment, approximately 5000 deaths in the United States per year are attributable to bronchial asthma. Bronchial asthma, known for centuries, remains a poorly understood disease.

Much of the knowledge pertaining to the nature of bronchial asthmas has been gained from postmortem examinations of persons who have died of status asthmaticus. The lungs are over-distended. Airways from the trachea to the respiratory bronchioles are blocked by plugs of thick, tenacious mucus. Frequently bronchiectasis (chronic necrotizing infection of the bronchi and bronchioles, accompanied by purulent exudation and very enlarged air passages) and fibrosis (fibroid tissue) are present. Emphysema is not usually indicated. Close inspection of the plugs of mucus reveals shed epithelium (Curschmann's spirals), many eosinophils, and so-called Charcot-Leyden crystals, components that are also usually found in the sputum of living patients. A heavy infiltrate of eosinophils in the airways is a prominent feature. This has led some authorities in recent years to include *eosinophilia* (excess of eosinophils) as part of the formal definition of bronchial asthma. Eosinophils make up only 2–3% of the leukocytes in the blood. See Blood. Total blood eosinophil counts are usually found to be in excess of 300/mm^3 in untreated bronchial asthma patients. This involvement of the eosinophils may be a lead to a much better understanding of the etiology of bronchial asthma as research continues.

A major step forward in the understanding of bronchial asthma was made when it was recognized that this is not a single disease *per se*, but rather it is a group of disorders with different pathogenic mechanisms. Using this as a base, several types of bronchial asthma were identified: (1) Inherited immunological (IgE-mediated) asthma; (2) post-exercise asthma; (3) aspirin-induced asthma; (4) occupational asthma; and (5) bronchial asthma associated with system vasculitis. As more is learned of the general disease, of course, these types may be later reclassified.

IgE-Mediated Asthma. Immediate hypersensitivity (reactions which may appear in the short span of seconds to minutes) occurs as the result of interaction between an antigen and an antibody. These reactions occur in anaphylaxis (susceptibility to a drug protein or toxin or toxin resulting from infection), hay fever, hives, and allergic (extrinsic) asthma. Hypersensitivity is mediated by immunoglobulin IgE, once called the reaginic antibody. Usually only traces of IgE are found in the serum of normal persons, but in some persons (atopic) there is a higher level of IgE. In these persons, there is commonly found a family history of IgE-mediated disorders. See also **Immune System and Immunology**.

The present concepts of the pathogenesis of IgE-mediated asthma are far too complex to delineate here. However, it may be said that at least three changes in the bronchi occur to create bronchial obstruction — *bronchoconstriction*, caused by increased muscle tone in the bronchial smooth muscle; *edema* of the bronchial mucosa; and secretion of thick plugs of mucus. The alveolar ducts also usually become constricted. A number of specific substances, or classes of substances, have been identified in these processes — *histamine*, which is known to constrict bronchial smooth muscle and to cause edema of bronchial mucosa, apparently as the result of increasing the permeability of small bronchial veins; a substance identified as *SRS-A*, which acts more slowly than histamine and thus prolongs the effect of histamine; a substance known as *platelet-activating factor* (PAF), which releases histamine and serotinin from platelets; and a substance referred to as *eosinophilic chemotactic factor* (ECF-A), which apparently causes the migration of eosinophils into affected regions and thus the condition of eosinophilia previously mentioned. It has been hypothesized that possibly the eosinophils, which originate in the bone marrow and reach the lungs through the blood, may assist in inactivating SRS-A. There are also secondary mediators that participate in the process. These include prostaglandins and bradykinins.

Post-exercise Asthma. Rather than a specific type of bronchial asthma, as identified by some authorities, perhaps post-exercise asthma is better designated as an episode that may appear in certain other types of asthma. When exercise precipitates acute attacks of asthma, this generally indicates the patient is not receiving adequate treatment.

Aspirin-Induced Asthma. In certain individuals, aspirin and various benozic acid derivatives may induce asthma that will not respond to traditional therapy. Tartrazine, used in certain food colorings, also may be implicated. Treatment is avoidance of salicylates and aspirin.

Occupational Asthma. It is believed that a number of substances may induce asthma. Examples of substances that, when repetitively inhaled, may cause this type of asthma, include: animal dander, exhaust gases and particulates from wood and other fuel combustion processes, castor beans, formaldehyde, grain dusts, isocyanates, metal dusts (particularly nickel, platinum, tungsten, and vanadium), plastic-generated fumes, proteolytic enzymes used in some detergents, and textile and tobacco dusts, among others. Treatment is avoidance of exposure to these substances.

Bronchial Asthma Associated with Vasculitis. A person with chronic bronchial asthma may after a period develop systemic *vasculitis* (inflammation of a blood vessel). Small arteries and veins, particularly involving the lungs, peripheral nerves, and skin, may be affected. This condition is sometimes referred to as the *Churg-Strauss syndrome*.

Treatment of Bronchial Asthma. The principal pharmacologic agents used in the therapy of bronchial asthma include: (1) *Beta antagonists*, such as isoproterenol, salbutamol, and ephedrine, which are bronchodilators. These are available in inhaler, oral, and parenteral forms. (2) *Methylxanthine and its derivatives*, such as theophylline (aminophylline), which also are bronchodilators. These are available in oral and parenteral forms. (3) *Parasympatholytic agents*, such as atropine and S1080, which decrease acetylcholine output by the vagus nerve and thus, by a complex pathway, reduce alveolar constriction. These are available in inhaler and parenteral forms. (4) *Corticosteroids*, such as prednisone and beclomethasone. Although widely used, the mechanism of their action is poorly understood. They are available in oral, inhaler, and parenteral forms. (5) *Mast cell inhibitors*, such as cromolyn, which decreases release of mediators. These are available as inhalers.

Asthma Research Pathways. As pointed out by M.T. O'Hollaren and colleagues (Mayo Clinic and Mayo Foundation), "Risk factors for sudden respiratory arrest or death have included lability of the lower airways, lack of appreciation of the severity of airflow obstruction on the part of primary care physicians, and psychological factors, including emotional instability, depressive symptoms, and family dysfunction."

The investigators were aware of the implication of the common mold (*Alternaria altemata*) as a causative factor in asthma attacks in certain regions and during certain seasons, such as in the summer and fall months in the U.S. Midwest, where the mold was believed to have triggered a number of severe asthma attacks. A study group of patients was selected,

several of whom had a history of respiratory arrest and another group of persons who had chronic asthma but that had not suffered a respiratory arrest. Conclusions of the report: "Exposure to the aeroallergen *A. alternata* is a risk factor for respiratory arrest in children and young adults with asthma."

Bronchodilators are widely used by chronic asthmatics to maintain normal airways. Normally, a prompt improvement is achieved after the use of inhalers, which contain β_2 agonists (theophyllin). However, chronic asthma may lead to persistent airflow limitation, which may be the end result of long-lasting inflammation. To reduce this inflammatory condition, inhaled steroids sometimes are added if the asthma symptoms are not controlled adequately. Researchers (Helsinki University Central Hospital) posed the question, "If steroids are helpful later, perhaps they could be used initially?"

A trial study was made of over 100 patients. Conclusions of the study: Antiinflammatory therapy with inhaled budesonide (a corticosteroid) is an effective first-line treatment for patients with newly detected mild asthma, and it is superior to the use of terbutaline (a β_2 agonist) in such patients.

In 1991, a group of researchers at the Princess Margaret Hospital for Children, Perth, Australia, investigated the influence of family history (of asthma) and the presence of parental smoking on airway responsiveness in early infancy. As pointed out by S. Young and colleagues, "Airway responsiveness to inhaled nonspecific brochoconstrictive agents has been demonstrated in normal, healthy infants. However, it is unknown whether airway responsiveness is present from birth or if it develops as a result of subsequent insults to the respiratory tract. To investigate this question, we assessed airway responsiveness in 63 normal infants at a mean age of 4.5 weeks."

Conclusions: "This study indicates that airway responsiveness can be present early in life and suggests that a family history of asthma or parental smoking contributes to elevated levels of airway responsiveness at an early age."

In a study of respiratory arrest in near-fatal asthma, a group of investigators (Hospital Nacional Maria Ferrer, Buenos Aires) a basic question was asked: Is the near-fatal arrest the result of severe asphyxia or possibly because of cardiac arrhythmias? Conclusions: "It is concluded that at least in this group of patients, the near-fatal nature of the exacerbations was the result of severe asphyxia rather than cardiac arrhythmias. These results suggest that under-treatment rather than over-treatment may contribute to an increase in mortality from asthma."

In 1992, a report based upon data at the National Center for Health Statistics (U.S.) estimated that the cost of illness related to asthma in the United States during 1990 was $6.2 billion. Inpatient hospital services represented the largest single direct medical expenditure for the chronic condition, namely, $1.6 billion. The value of reduced productivity due to loss of school days represented the largest single indirect cost, approaching $1 billion. Although asthma often is considered to be a mild chronic illness treatable with ambulatory care, the study found that 43% of its economic impact was associated with emergency room use, hospitalization, and death. Nearly two-thirds of the visits for ambulatory care were physicians in three primary categories: (1) pediatrics, (2) family medicine or general practice, and (3) internal medicine. See Weiss reference.

This report, coupled with other reports of recent years, clearly indicate increasing morbidity and mortality due to asthma. As will be pointed out later in this article, researchers now are reevaluating therapies that essentially have been standard therapeutic procedures, seeking new drugs and therapies, and addressing much more intensely the underlying causes of the disease. Professionals in the field readily acknowledge that asthma remains poorly understood.

In the last few years, considerable knowledge has been gained pertaining to the demographics of bronchial asthma. The information contains a number of surprises and has been helpful toward the location of treatment centers and specializing physicians, but little light has been shed on the basic functionalities of bronchial asthma that could lead to improved care.

E.R. McFadden, Jr., and I.A. Gilbert (Case Western Reserve University of Medicine, Cleveland, Ohio) reported on a study in late 1992, that indicated four geographical areas in the United States that account for the highest mortality from asthma. These included New York City, Cook County (Chicago), Illinois, Maricopa County, Arizona, and Fresno County, California. A surprising 21.1% of all deaths from asthma occurred in New York City and Cook County, yet these places account for only 6.8 percent of the population 5 to 34 years of age that are at risk. Other age groups were not reported in the study. The rates of mortality are higher among nonwhites than whites in the population. The report also indicates that mortality from asthma has been increasing by a startling rate. In 1987, there were 4360 deaths from asthma in the United States, 31 percent more than the number in 1980.

In summary, the discovery of anything resembling a permanent cure for asthma is indeed well beyond the expectations of those professionals who are researching the field. See also **Respiratory System**.

Principal portions of this article were prepared by R.C. VICKERY, M.D.; D.Sc.; Ph.D. Blanton; Dade City, FL

BRONCHIECTASIS. An inflammatory or degenerative condition of the bronchi and bronchioles in which the tubes are dilated; usually associated with abscess formation. The two main symptoms of bronchiectasis are a persistent cough and the expectoration of large amounts of sputum, sometimes foul-smelling. The condition may follow the advent of such diseases as broncho-pneumonia, tuberculosis, or lung abscess. However, the disease occurs in some patients who have no history of any prior infection. Symptoms of advanced bronchiectasis include marked weight loss, fever, loss of appetite, and in most cases, extreme weakness. A person with this disease may live for years, although he is generally uncomfortable because of the foul odor of the sputum and feeling of general malaise. If the bronchiectasis is limited to one area of the lung, surgical removal may be advised. Prolonged administration of antibiotics, use of expectorants, steam-inhalation, postural therapy to assure efficient utilization of normal pathways of bronchial discharge, relocation to dry and warm climate are among corrective measures sometimes used.

BRONCHITIS. An inflammation of the mucous membrane of the tubes leading from the windpipe to the lungs (*bronchi*). The condition usually affects the larger bronchi. When the smaller bronchi are affected, the condition is more serious. When inflammation of the smallest bronchi (or *bronchioles*) occurs, the disease is actually bronchial pneumonia. Acute bronchitis is found most often in children under three years of age, in order people, but it can occur at any age. Factors contributing to the disease include occupational conditions, diet, and general health. It appears that residence in damp, foggy climates may be a contributing factor.

Acute bronchitis is a often termed "chest cold." The condition often develops after the common cold and includes chest discomfort, dry cough, fever, and loss of energy. The cough may become severe and produce mucus. Predisposing factors are exposure, chill, fatigue, malnutrition, and rickets. Physical and chemical irritants, such as tobacco smoke, strong acid fumes, ammonia, chlorine, sulfur dioxide, and bromine, may trigger the condition. The significant danger of acute bronchitis is the possible onset of pneumonia.

Generally, *chronic bronchitis* is a much more serious condition. Chronic bronchitis is now identified as one of the chronic obstructive lung diseases (COLD), which also include obstructive emphysema, bronchiolitis, cystic fibrosis, and Kartagener's syndrome, among others. Patients with this condition have a chronic cough and expectoration along with recurrent acute infections of the lower respiratory tract. The condition is especially prevalent during winter months. Chronic bronchitis usually develops over a period of years, with the tendency for an acute upper respiratory tract infection to be invariably followed by a persistent cough which hardly disappears before another episode commences. Usually, in the morning, the victim must devote considerable effort to expectoration of a thick, sticky sputum. Wheezing may be present. Later complications include shortness of breath. If left untreated, the disease may place a large strain on the heart, with resulting congestive heart failure, or an infection, such as influenza or pneumonia.

Major attention must be directed to the patient's general health. Every effort must be made to facilitate the raising of sputum and clearing of air passages. Expectorants, steam inhalation, and vasodilators are helpful. Mucolytic agents frequently are effective in loosening thick, tenacious sputum. In the instance of shortness of breath, bronchodilator aerosols may be used. In more severe cases, inhalation of oxygen is used. An important part of the therapy for bronchitis is avoidance of environmental irritants, with particular emphasis on cigarette smoking.

BRONCHOSCOPY. Internal visual examination of the bronchi by means of a tube-like instrument (bronchoscope), which contains a light. The bronchoscope is introduced into the mouth and passed through the throat into the bronchial tree.

BRONTIDE. A natural explosive noise, frequently unexplained. Brontides have been well documented and frequently are associated with seismic activity and in some cases as precursors to major earthquakes. Some explanations offered have included ground-to-air acoustic transmission from shallow earthquakes, as well as noises from the sudden eruption of gas from high-pressure sources in the ground. Frequently, what may appear to be a brontide will be a noise from distant thunder or artillery practice, as well as other anthropogenic causes, such as sonic booms. Brontides or natural booming noises have been reported since ancient times. Some noises have been given colloquial barries. These include the "Bansal guns" heard in the Ganges delta area; "Seneca guns" in New York State; *mispoefiers* ("fog belchers") off the coast of Belgium.

Recent attention to brontides was brought about in connection with mysterious noises noted off the eastern coast of North America during 1977 and 1978. Many thousands of persons reported these noises. Investigation by the U.S. Naval Research Laboratory accounted for about 70% of these booms a caused by supersonic aircraft. A study of Mitre Corporation concluded that the remaining booms most likely resulted from natural causes not satisfactorily explained. Possibly some were caused by *rock bursts*, i.e., the fracture of an exposed or near-surface rock face. Where no earthquake activity can be associated with brontides, anthropogenic causes are usually suspected even though no noise-making activities of the type are identified within hearing range. It is suggested that certain favorable combinations of atmospheric conditions can enable hearing sounds as much as 100 kilometers (62 miles). Some investigators have suggested that this may explain the Belgian mistpoeflers, i.e., they may be caused by thunder or artillery fire at a considerable distance, but within audio detection range because of favorable atmospheric conditions.

In terms of earthquake precursory brontide episodes, observations were reported in the vicinity of the South Carolina earthquake of 1886 at least a year prior to the earthquake. Stierman (1981) observes that field observations have shown that earthquakes too small to be felt sometimes produce loud booming noises. During aftershock studies near the Mojave Desert town of Landers, California and in the vicinity of Mammoth Lakes, California, booming sounds from earthquakes as small as magnitude 1 were transmitted from large-bedrock outcrops. Earthquakes near Fontana, California (January 8, 1980) and Berkeley, California (April 6, 1980) were reported heard rather than felt. Air waves associated with the great 1964 Alaska earthquake were recorded on microbarographs thousands of kilometers from the source. It was demonstrated that a significant part of the signal traveled as an airwave from the epicenter of the quake. Mikumo (1968) reported that the barographs records were distinctly different from records of large atmospheric explosions and that they were consistent with the hypothesis that the source of the pressure waves was a sudden vertical displacement of a large area of the earth's crust.

Gold and Sorter (1979) proposed that direct ground-to-air acoustic transmission from weak foreshocks do not account for all booming noises, but that rather, gas escaping from fractures in the earth may be responsible for many of the unexplained explosive, booming noises. Most specialists in the field generally agree that at least the two aforementioned (and possibly additional) causes may be involved for the noises which have not been fully documented or explained. For example, a Chinese seismologist who briefed Wallace and Ta-liang Teng (1980) on the sounds beginning a few months before the Sungpan-Pungwu earthquakes of 1976 stated that "many of the sounds were clearly not related to foreshocks, because good data from seismic records showed the absence of foreshocks at the time of the sounds. On one occasion, several seismologists ... were watching a seismograph when they heard sounds they believed to be earthquake sounds. The instrument did not record an event when they heard the sounds, but a minute on so afterward, the arrival of P waves was recorded." Gold and Soter (Letter to Editor, 1981) describe direct evidence for gas eruption in connection with the great Fort Tejon earthquake of 1857 in Southern California (Agnew and Sich, 1978)

Ambient Noise in the Ocean. L.A. Crum (National Center for Physical Acoustics) observed at a 1990 meeting, "There is a lot of ambient noise in the ocean and bubbles are very efficient generators of sound. It is our contention that a great deal of the sound in the frequency range from about 100,000 Hz down to 10 Hz is generated by bubbles." Investigations of sounds caused by oscillating bubbles, or scattered by quiescent bubbles, possibly may be used in the future for designing remote detectors of precipitation over the ocean and for monitoring a number of oceanic processes, including the exchange of gases between the ocean and the atmosphere. D.M. Farmer (Institute of Ocean Sciences, Sidney, B.C.) has pointed out, "There's a huge world of underwater sound — both natural and artificial — that provides a window on the ocean, which has not been exploited."

Wind-blown breaking waves trap significant volumes of air that, in turn, become thousands of tiny bubbles (measured in terms of microns in diameter). These bubbles become pulsating sources of sound near the ocean surface. Although such bubbles may radiate sound for just a few milliseconds before becoming passive, scientists speculate that these bubbles produce far more acoustic energy that is detectable under water than that caused by water impacting on water. The formation of bubbles and the noise that bubbles produce may be useful in oceanographic research for the measurement of climatic factors at the ocean-atmosphere interface as well as undersurface ocean currents.

BRONZE. See **Copper**.

BRONZE AGE. An archeological term to designate a cultural level that originally was the middle division of the so-called three-age system. The age is characterized by bronze technology. The term is principally of European interest, inasmuch as the age coincides with written history in Asian archeology and bronze was not used extensively in Africa and the Americas. It was preceded by the Stone Age and followed by the Iron Age.

BROOKITE. Brookite, composed of titanium dioxide, TiO_2, is an orthorhombic mineral of the same chemical composition as rutile and octahedrite. It was named for the English mineralogist H.J. Brooke. See also **Rutile**; and **Titanium Dioxide**.

BROOMCORN. Of the family *Gramineae* (grass family), genus *Sorghum*, *Sorghum vulgare* var. *technicum* var. A variety of tropical grasses, characterized by having an inflorescence in which the branches are very long and slender, growing in loose panicles. The plant is extremely drought resistant and so adapted for regions having an arid climate. The close-bunched stiff inflorescent-branches account for the principal use of broomcorn, i.e., the manufacture of brooms and whisk brooms, although this use has been much displaced by plastic materials. Some varieties of the sorghum grasses contain sweet juices, which can be made into a sweet syrup and which find uses like those of maple syrup. However, the syrup from any sorgo contains considerably more invert sugar. Sorghum molasses is also sold commercially.

BROWN CLOUD. See **Clouds and Cloud Formation**.

BROWN, HERBERT C. (1912–2004). An English-born chemist who was the recipient of the Nobel Prize for chemistry with Wittig, Georg in 1979. Via his work in organic synthesis, he discovered new routes to add substituents to olefins selectively. His early education was irregular and disjointed as a result of family circumstances and the economic depression of the 1930s. He eventually received his Ph.D. from the University of Chicago. The reduction of carbonyl compounds with diborane was the topic of his thesis. The bulk of his career was spent at Purdue University. http://www.chem.purdue.edu/faculty.htm

See also **Boron**.

BROWNIAN MOTION. The random movement observed among microscopic particles suspended in a fluid medium. The phenomenon was observed in 1827 with suspensions in liquids, colloids, by Robert Brown, English botanist, who is said to have attributed it to living organisms. Not until the kinetic theory was developed was it generally understood to be due to the thermal agitation of the suspending medium. A smoke particle floating in the air, for example, is battered on all sides by the high-speed air molecules. The resultant displacement is for the most part nearly zero, but there are statistical inequalities which now and then reach such magnitude as to produce motions visible in a high-powered microscope, and which result in an irregular migration of the particle. In fact, such particles may be regarded essentially as huge molecules, with mean square speeds of thermal motion proportionately smaller as their masses are larger than that of the true molecules of the surrounding medium. See also **Brown, Robert (1773–1858)**.

In a series of papers published from 1905 to 1908, Einstein successfully incorporated the suspended particles into the molecular-kinetic theory of heat. He treated the suspended particles as being in every way identical to the suspending molecules except for the vast difference of their size. He set forth several relationships that were capable of experimental verification and he invited experimentalists to "solve" the problem.

Fig. 1. Replica of plot made by Jean Baptiste Perrin (France) in 1912 of a microscopic particle suspended in water. The position of the particle was recorded at half-minute intervals. At the time, Perrin observed that "only a very meager idea of the extraordinary discontinuity of the actual trajectory" can be obtained in this experimental fashion.

Several workers undertook this task. The most notable of these was Perrin. Perrin's special success was due to his technique for preparing particles to suspend that were of uniform and known size. The uniformity was achieved by fractional centrifuging, and the size was established by noting that they could be coagulated into "chains" whose length could be measured and whose "links" could be counted. The microscopic observation of these uniform particles enabled Perrin and his students to verify the Einstein results and to make four independent measurements of Avogadro's number. See Fig. 1. These results not only established an understanding of Brownian movement, but also they silenced the last critics of the atomic view of matter.

Probably the simplest example of Perrin's experiments was his test of the Law of Atmospheres. If it is assumed that air is at rest and has the same temperature from ground level upward, it can be shown that the pressure (and concentration) of the air falls off exponentially with increasing altitude. For particles of mass m and density ρ suspended in a medium of density ρ at absolute temperature T, the ratio of the particle concentrations n_1 to n_2 at heights h_1 and h_2 is given by

$$\frac{n_1}{n_2} = \exp\left[-\frac{\mathrm{mg}(\rho - \rho')N_0(h_1 - h_2)}{\rho RT}\right]$$

where N_0 is Avogadro's number, g is the acceleration of gravity, and R is the universal gas constant. Although the concentration of air varies slowly with height, the concentration of the relatively heavy particles varied significantly over a height change of a few millimeters. By observing the concentration variation as a function of height, all quantities in the given equation were known except Avogadro's number, which could, therefore, be determined.

An exceptionally interesting and complete paper on Brownian motion was prepared in 1985 by B.H. Lavenda (University of Camerino, Italy). In a very workmanlike manner the author reviews the impact of the Brownian motion concept on other important topics of science, as previously mentioned, and continuing to the present time. In recent years, study of Brownian motion has led to the invention of mathematical techniques for the general investigation of probabilistic processes. For example, such techniques have been applied in the control of electromagnetic "noise," and they have contributed to the comprehension of the dynamics of star clustering, and the development and adaptation of ecological systems, not to mention studies of stock and commodity prices.

In another paper, R. Kuho (Keio University, Japan) illustrates in a rather technical and mathematical fashion the relationship between Brownian motion and non-equilibrium statistical mechanics. In this paper, the author describes the linear response theory, Einstein's theory of Brownian motion, coarse-graining and stochastization, and the Langevin equations and their generalizations.

BROWN, ROBERT (1773–1858). Robert Brown was a British botanist and explorer, who also observed the cell nucleus and "Brownian motion."

Brown was born in Montrose, Scotland, where his father was Episcopalian minister. In his boyhood he was friends with James Mill, the father of John Stuart Mill. At the age of 14 he entered Marischal College, Aberdeen, then in 1789 moved to Edinburgh University to read medicine. His interest predominantly lay in natural history, which he pursued eagerly in and outside the university. In 1795 he obtained a commission as assistant-surgeon in the Fifeshire regiment of fencible infantry, during which time he was introduced to Joseph Banks who soon afterwards offered him a place as naturalist on Captain Flinders' voyage to Australia. Brown accepted with alacrity. The voyage lasted from 1801 to 1805 and Brown made exceptionally good use of his time. He collected nearly 4000 plant species in Australia and Tasmania, many of which were new to science. See also **Plant Sciences (The History)**; and **Taxonomy (The History)**.

After his return he became librarian to the Linnean Society of London, dealing with the magnificent Banks library and herbarium, and was thus placed at the centre of London's botanical science. When Jonas Dryander died in 1810, Brown succeeded him as Banks' personal librarian, going to live in Banks' house in Soho Square and eventually inheriting it and the collections. In 1827, acting under the terms of Banks' will, Brown transferred himself, the books and plant specimens to the British Museum. In this second part of his life he was known to many as a canny museum man who indefatigably promoted botany as a professional science. He was undoubtedly the most famous British botanist of his day, acclaimed in Europe and highly regarded at home, and a mentor to many. Nevertheless, he fell out with John Lindley, of the Horticultural Society; and then ran into institutional rivalry with William Hooker at Kew.

Brown worked incessantly and meticulously, often with microscopes tailored to his own instructions, and made many important new observations on the fertilization and embryonic development of plants. But he disliked publication. He produced a widely admired, truncated account of the Australian plants, and several path-breaking microscopical studies, including those on the Asclepiadeae and Proteaceae, which indicated his great gift for experimentation and in understanding the natural system of classification. In other articles he described the pollen tubes and fecundation of orchids. For the most part, he was secretive about his discoveries. He had an irritating habit of incorporating his latest findings in whatever he was working on, regardless of its relevance.

While investigating pollen under a high-powered single-lens microscope in 1827, he observed the apparently spontaneous movement of particles, now known as Brownian motion. See also **Brownian Motion**. He published a short article on it 1828. Subsequently it has been established that Jan Ingenhousz was first to see this motion, and that the importance of Brown's observations were not appreciated by physicists until the term Brownian motion was coined by H.C. Bastian in 1871. George Eliot referred to it a year later in *Middlemarch*. Working on orchids in 1831, Brown noted the presence of a nucleus in every cell and cytoplasmic streaming. He also maintained a long-term interest in fossil botany and morphological studies.

Brown became a Fellow of the Royal Society in 1811. He was awarded an honorary degree from Oxford University in 1832 and the Copley medal (the highest honor of the Royal Society) in 1839.

JANET BROWNE, Wellcome Institute for the History of Medicine, London, UK

BROWN-SÉQUARD, CHARLES EDOUARD (1817–1894). Charles Brown-équard was a Mauritian-born British (later French) physiologist who defined the sensory pathways in the spinal cord, emphasized the importance of functional processes in the operation of the nervous system, showed experimentally that the adrenal glands are essential to life, and founded modern hormone replacement therapy by his use of organ extracts. See also **Adrenal Glands**.

The son of a French settler and Irish-American sea captain whom he never knew, Brown (later Brown-équard, when he added his mother's surname to his own) trained as a physician in Paris. His doctoral thesis (1846) and subsequent work indicated that sensory fibers cross in the spinal cord and are not confined to the posterior columns. His description of the neurological deficit that follows lateral hemisection of the cord (the Brown-Séquard syndrome) initially met with fierce opposition; after its widespread acceptance, he repudiated it and the associated belief that the sensory deficit resulting from cord lesions relates to interruption of a hard-wired system. Instead, he came to favor a more dynamic concept in which any sensory disturbance depends on the interplay of excitatory and inhibitory influences on the spinal segmental apparatus. His belief that discrete regions of the nervous system exert excitatory or inhibitory influences on more distant regions was disregarded during his lifetime but later validated experimentally by Sherrington. See also **Sherrington, Charles Scott (1857–1952)**.

Brown-Séquard used himself freely as an experimental subject, most notoriously in examining the effects of injected testicular extracts on his declining bodily functions, which he reported to the Biological Society in Paris in 1889. This work caused an uproar in scientific and lay circles, but led him to study the effects of administering extracts of other animal organs in different diseases of humans and thus marks the beginning of modern hormone replacement therapy. His approach was exploited by an opportunist fringe and his beliefs were distorted by the popular press, but his concept of chemical integrative mechanisms was eventually vindicated.

Brown-séquard was an imaginative and impetuous physiologist whose experimental work often failed to justify the sweeping conclusions that he reached but whose intuitive insight anticipated many important concepts that were developed in the years after his death. A restless and eccentric genius, he is said to have crossed the Atlantic Ocean more than sixty times, spending some 6 years of his life at sea. He was married three times, fathered three children, and founded three medical or scientific journals. He was a founder-physician (1859–1863) of the National Hospital for Nervous Diseases at Queen Square, London, and held chairs in several universities in Europe and North America, including the Medical College of Virginia (1854–1855), Harvard College (1864–1867), the Sorbonne (charé du cours 1869–1872) and the College de France (1878–1894), where he succeeded Claude Bernard as Professor of Medicine. He turned down chairs at many other institutions including the universities of Glasgow and Geneva. He was elected a fellow of the Royal Society of London (1860), the National Academy of the United States of America (1868) and the Academy of Sciences in Paris (1886).

BROWN-TAIL MOTH *(Insecta, Lepidoptera).* A European species, *Euproctis chrysorrhea*, related to the tussock moths of this continent. It was introduced into Massachusetts during the last century and together with the gypsy moth, another introduced species, has become an important pest in the New England states and the adjacent Canadian provinces, attacking shade and fruit trees. Spraying with control chemicals in the late summer has been found an effective method of control, as well as the collection and destruction of the winter nests in which the caterpillars hibernate.

The hairs of the larva are very irritating to the human skin.

BRUCELLOSIS. At one time, the common name for brucellosis was undulant fever or Malta fever. This disease, caused by infection with

the gram-negative *Brucella*, is transmitted from domesticated animals to humans. The three species of *Brucella* usually implicated are *B. melitensis* (from goats); *B. suis* (from hogs); and *B. abortus* (from cattle). In recent years, *B. canis* (from dogs) also has been implicated in a few cases of brucellosis. Prior to the initiation of mandatory milk pasteurizing regulations in a number of countries several years ago, the principal cause of brucellosis was the ingestion of raw milk and butter and cheese prepared from non-pasteurized milk. As recently as 1950, about 3500 cases of the disease were reported each year in the United States. The cases per year, as of the early 1980s, average about 200. The persons now at highest risk are workers in the meat packing and livestock industries. Less than 10% of cases now result from ingestion of milk products. Only a few of these can be attributed to products made in the United States.

The microorganism generally enters through the mucous membranes of the mouth and throat, or through breaks in the skin. The organism then reaches the lymphatics, traverses the lymph node barriers, and invades the bloodstream. After this, almost any organ of the body can become involved, although lesions are most frequently seen in the spleen, liver, lymph nodes, and bone marrow. However, the heart, lungs, joints, and prostate, among other organs, can be infected. The incubation period may range from a few days to several months. Symptoms of brucellosis include chills and fever, headache, loss of weight and appetite, and myalgia. There may be pain in the region of vertebrae, or acute arthritis may be manifested. Pregnancy may end in abortion. Untreated, the infection may produce complications, including osteomyelitis and localized nephritis.

Treatment is usually by tetracycline over a period of 3 weeks or longer. Trimethoprim-sulfamethoxazole also has been used. This treatment usually is quite successful. Of over 2000 cases reported since 1965, only 2 fatalities directly attributable to brucellosis have been reported. See also **Bacterial Diseases**.

BRUCITE. The mineral brucite is magnesium hydroxide corresponding to the formula $Mg(OH)_2$; iron and manganese may occasionally be present. The crystals are usually tabular rhombohedrons of the hexagonal system; it may also occur fibrous or foliated. Brucite has one perfect cleavage parallel to the prism base; hardness, 2.5; specific gravity, 2.39; luster, pearly to vitreous; commonly white but may be gray, bluish or greenish; transparent to translucent. Brucite is a secondary mineral found with serpentine and metamorphic dolomites. It has been found in Italy, Sweden, and the Shetland Islands; and in the United States in New York, Pennsylvania, Nevada and California. Brucite was named in honor of Archibald Bruce, an American physician.

BRUNTON COMPASS. This type of compass is specially designed for geologists and fitted with a clinometer and other devices for reading both horizontal and vertical angles.

Named after its inventor David W. Brunton (1849–1927), a U.S. mining engineer, the device enables the comparatively easy determination of the strike and dip of rock formations. The device is used primarily in sketching mine workings and in preliminary topographic and geologic surveys on the surface, such as determining stratigraphic thickness and vertical elevations.

BRUNT-VÄISÄLÄ FREQUENCY. The frequency N at which a displaced air parcel will oscillate when displaced vertically within a statically stable environment. Given as

$$N = \left(\frac{g}{T_v} \frac{\partial \theta_v}{\partial z} \right)^{1/2},$$

where $g = 9.8\ \mathrm{m\,s^{-1}}$ is gravitational acceleration, T_v is the average absolute virtual temperature, and $\partial\theta_v/\partial z$ is the vertical gradient of virtual potential temperature. Units are radians per second, although this is usually abbreviated as $\mathrm{s^{-1}}$. This frequency is not defined in statically unstable air and is zero in statically neutral air. The frequency of internal gravity waves in the atmosphere cannot exceed the local Brunt–Väisälä frequency. This frequency is also sometimes used as a measure of the stability within a statically stable environment. See also **Buoyancy Frequency**.

AMS

BRUSH (Electrical Machinery). A device for conducting current to or from a rotating part. The brush is stationary, and is held and guided by a fixed brush holder in which it slides freely. There may be several brushes side by side to form a single-brush set. The rotating member may be the commutator of a dc generator or motor, or it may be the slip rings of an ac motor or generator. Examples of brushes might also include those used in magnetos and static electricity machines.

Brush materials, commonly used include carbon, carbon graphite, graphite, resin-bonded graphite, metal graphite, and electrographitic substances. Important factors for designers in selecting brush materials are abrasiveness, coefficient of friction, contact drop, current capacity, hardness, ability to withstand high peripheral speeds, specific resistance, and transverse strength. Spring-leaf copper and copper gauze are rarely used except in special circumstances. Circuit connections to carbon brushes are made directly to the brush by means of short flexible cables from the external circuit because the contact surface between brush holder and brush is an unreliable conductor.

Brushes wear and must be replaced periodically. Also, their ends should fit commutators so as to make good contact over the entire brush surface. They may sometimes need periodic redressing with sandpaper in order to maintain the proper shape of contact. The most serious fault of a brush is the formation of electric arcs between the rotating member and the brush. This may be due to the condition of the brush, vibration of the brush in the holder, or improper setting of the brush. The position of the brushes on the commutator is adjusted so the coils or turns being shorted by the brushes will have a minimum voltage. This means that the coil sides will be in the position of minimum flux, which position will depend upon the load unless correction is applied. In modern machines interpole windings are used to compensate for the distortion of the field caused by the armature current so the brush position is opposite the center of the poles. In machines without some form of compensation the position will be to one side of this and is adjusted to give minimum sparking under normal load.

BRUXISM. Grinding of the teeth while sleeping is termed *bruxism*. When this is done without awareness while awake, the habit is referred to as *bruxomania*.

BRYONIA. A perennial herb (*Bryonia alba* L.) of the *Cucurbitacea* family that grows mainly in woods, thickets, and fields in central and southern Europe, western Asia, the Far East, and North Africa. An extract from the roots is used for flavoring liqueurs, bitters, and drugs. The extract contains resin, phytosterine, bryonol, enzymes, terpenes, fatty acids, protein substances, and glucosides.

BRYOPHYLLUM. Genus of the family *Crassulaceae* (orpine family). Several tropical plants have the unusual habit of reproducing by means of their leaves. If a mature leaf is removed from one of the plants and placed on damp sand, within a short time there appear in the notches of the leaf margin, tiny roots and, later, small green plants which soon become independent of the parent leaf. Infrequently the little plants appear in the notches while the leaf is still attached to the parent plant. The explanation of this uncommon habit is that, in the development of the leaf, certain cells in the leaf notches remain permanently embryonic. For reasons unknown, their development is inhibited so long as the leaf remains attached. Severing of the leaf removes this inhibition and the embryonic cells resume active development. See also **Asexual Reproduction**.

BRYOPHYTES. This subdivision of plants, comprising mosses and liverworts (or *Hepatics*), is a group having some 20,000 species. Most of these are terrestrial plants. The bryophytes inhabit a wide range of habitats, from dry barren rocks to submerged objects, but are most frequent where an abundance of moisture is assured. They are found on trunks and branches of trees, on the soil, and even on the leaves of some tropical plants.

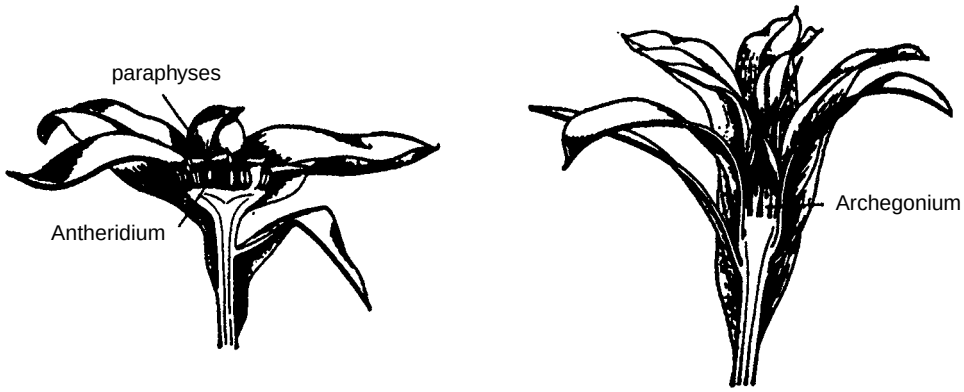

Fig. 1. (Left) The tip of a plant of *Mnium* that bears antheridia, cut lengthwise to show the antheridia. (Right) The tip of an archegonial plant of *Mnium*, cut lengthwise to show the archegonia.

The body of these plants is small and without much structural complexity. See Fig. 1. Rhizoids, slender outgrowths that serve mainly to attach the plant to its substratum and which serve only slightly as absorbing organs, are common. They may be single-celled or multicellular, but are colorless. The habit of the plant body is diverse. In many hepatics it is a thin flat thallus, one to several cells thick. Often the edge of the thallus is so lobed that it appears to be differentiated into a central stem and lateral leaves. In the mosses this differentiation is much greater. There is an erect central stem that bears many thin radiating leaves. However complex the structure may be, the cells of the plant-body of a bryophyte show very little differentiation. The central cells may be longer; other cells may have thicker walls; cells nearer the surface contain more chloroplasts, but there is never any real modification of cells to form vascular elements. The latter are entirely wanting in this group, thus the group is separated from the *Tracheophyta* in the classification of plants.

The sex organs of the bryophytes are highly developed objects, which distinguish this group very sharply from the lower plants, both algae and fungi. The antheridium, in which the sperm cells are formed, is a club-shaped multicellular body. The archegonium is a flask-shaped body, also multicellular. Antheridia and archegonia may be formed on the same plant or on different plants; often they appear at different times so that self-fertilization is largely prevented. The sperm, a biciliate actively motile cell, swims to the egg, which is located in the swollen basal portion of the archegonium. There a sperm unites with the egg to fertilize the latter and incite growth of a new generation. But the plant resulting from this fertilized egg is one entirely unlike the parent plant. Commonly it is a well-developed plant, but less conspicuous than the one on which it is usually entirely dependent for its food supply. When mature it forms a large mass of small spherical cells called spores, which are freed from the body in which they are formed and carried away by currents of air. On reaching a suitable environment, each spore germinates, and eventually forms a plant like that which bore the sexual organs. There is then in the bryophytes a very definite alternation of generations, a haploid sexual generation called the gametophyte, bearing male and female sex organs, and a diploid asexual generation called the sporophyte, in which haploid asexual spores are formed. The gametophyte is green and carries on photosynthesis. In most cases it is terrestrial. The sporophyte, however, depends on the gametophyte for its food supply and water.

Bryophytes are separated into two classes, the *Hepaticae* or liverworts and the *Musci* or mosses. Each class is subdivided into three orders, as follows:

Class I. *Hepaticae*.
- Order 1. *Merchantiales*.
- Order 2. *Jungermanniales*.
- Order 3. *Anthocerotales*.

Class II. *Musci*.
- Order 1. *Sphagnales*.
- Order 2. *Andreaeales*.
- Order 3. *Bryales*.

The liverworts are generally considered lower in the scale of evolution than the mosses. The thallus, or plant body, of the liverworts is prostrate and flat. When it forks, the two branches are equal, a method of branching known as dichotomous. In the second order of liverworts the thallus is so divided as to appear leafy, the order often being called the leafy hepatics. All liverworts have unicellular rhizoids borne on the lower side of the thallus by which they are anchored firmly to the substratum. The sex organs are borne embedded in the body of the thallus or in special outgrowths called gametophores, which rise from the thallus. The small sporophytes are dependent on the gametophyte for their nutrients. In these plants an asexual reproduction occurs by means of small masses of cells which develop from the gametophyte to which they are attached by a very slender stalk. These small bodies, called gemmae, are easily separated from the parent plant. They develop into a new gametophyte when they are carried by wind or water to a suitable environment.

The three orders of the liverworts form an interesting series, of increasing complexity. The *Marchantiales* include forms that have a prostrate thallus, often showing a structure of considerable complexity. The sporophyte is very simple. Growth of the thallus is by repeated divisions of a single apical cell which itself sometimes forms two such cells, whose continued divisions form a dichotomous branching of the thallus. As the thallus increases in length at the apical end, death of the cells occurs at the other end, so that the plant slowly grows ahead until in time a fork is reached and the two halves separate by progressive disintegration of the older portions.

One of the simplest members of this group is *Riccia*, a small plant found either floating on still waters or growing on wet mud. Some species are thick and fleshy, others are slender much-branded bodies, having a very evident median groove. See Fig. 2.

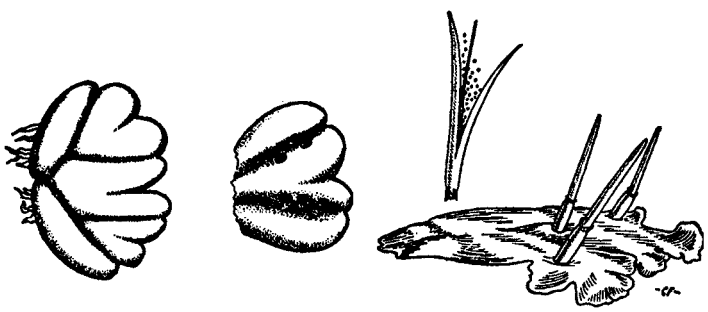

Fig. 2. (Left) Gametophytes of a liverwort, *Riccia*. The bodies embedded in the right-hand plant are sporophytes. (Right) *Anthoceros*, one of the horned liverworts. The "horns" are sporophytes. A portion of a sporophyte is shown separately to illustrate the method of liberation of spores.

From the lower surface single-celled rhizoids grow downward. From this surface also, thin scales or plates are developed, forming an overlapping row along the middle of the thallus. Both antheridia and archegonia are formed on the upper surface along the midrib. The antheridia have a wall a single cell in thickness, and contain many sperm mother cells, each of which divides to form two biciliate sperms. The archegonial wall is also a single cell in thickness, and encloses a row of six cells, four of which are the canal cells, the other two a ventral cell and an egg cell. When the latter is mature, the other five disintegrate, while at the same time the apical cells of the archegonium split apart, forming a canal through which the

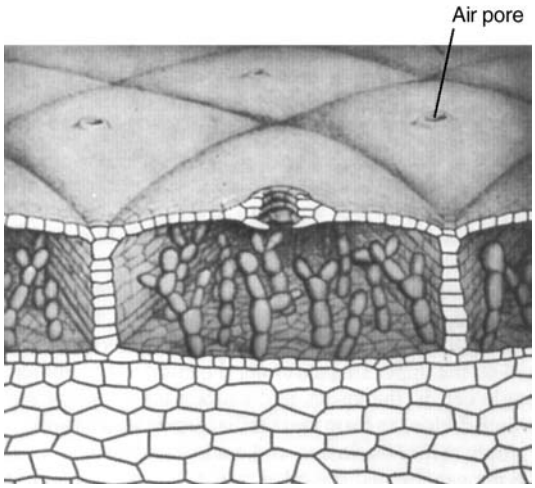

Fig. 3. *Marchantia*. Section through a thallus showing air chambers.

sperm swims to fuse with the egg. The sporophyte that develops from the fertilized egg remains embedded in the gametophyte thallus; when mature it is nearly all sporogenous tissue enclosed in a thin-walled capsule. A more complex member of this order is *Marchantia*. See Fig. 3. In this the gametophyte thallus is several inches long and from a half an inch to an inch (2.5 to 5 centimeters) broad. Its lower surface bears rhizoids and scales, or lamellae, quite like those of *Riccia*. The upper part of the thallus, just beneath the upper surface, contains a number of large chambers, each connected with the outside air by a large pore. Gemmae are produced in cup-like organs growing out of the upper surface of the thallus. The sexual organs in this plant are not formed in the thallus, but are borne on special erect branches called gametophores. Antheridia and archegonia are borne on different plants, the plants thus being dioecious. They are quite like the antheridia and archegonia of *Riccia*. The sporophyte is considerably larger than that of *Riccia*, with a well-developed foot attaching it to the gametophyte, a short thick stalk, which pushes the spore-containing capsule out from the tissues of the gametophore. Not only does this capsule contain large numbers of spores, but also, scattered among the spores, slender elongate cells called elaters, whose walls have spiral thickenings. These are affected by differences in humidity that cause the elater to twist about, apparently to stir up and loosen the spores. In *Marchantia* the gametophyte is very elaborately developed; the sporophyte, very simple.

In the second order of liverworts the thallus is so incised on its margins that it appears to bear two rows of small leaves. See Fig. 4. The *Jungermanniales* are small plants, many of them very delicate, growing in wet places, either on the ground or on rocks and tree trunks. Cellular differentiation in the thallus is very slight. In them the sporophyte is much more highly developed than in the first order. It has a long slender erect stalk, which bears the capsule. When the latter is mature, it splits into four valves, which spread apart and free the spores within. Members of this suborder also form a series more or less as do the *Marchantiales*. The third order, the *Anthocerotales*, is a small group containing three genera. In all of them the gametophyte thallus is of a very simple type, with no great cellular differentiation, and with the sex organs always embedded. In this order the sporophyte is a most interesting object, far advanced in comparison with those of the other liverworts. It is an erect, slender, more or less cylindrical object composed of a basal foot and a long capsule. The central portion of the capsule is a rod of sterile tissue called the columella. Around it is the sporogenous tissue. The spores are formed in zones alternating with narrow bands of sterile tissue. Outside the sporogenous tissue is a wall of sterile tissue composed of chlorophyll (see **Pigmentation (Plants)**) containing cells. The epidermal portion of this wall contains many stomata (see **Stomate (or Stoma)**). The basal portion of the sporophyte, just above the foot, is composed of meristematic cells, which by their divisions cause the capsule to elongate. When mature this capsule splits into two valves which pull apart, resembling horns. These plants, with their very simple gametophyte and very elaborate sporophyte, contrast strikingly with the *Marchantiales*. In fact, the sporophyte is so advanced that some botanists place this order in a separate class, the *Anthoceratae*.

The liverworts are of no economic importance, but are of interest because they suggest what may have been the habit of those plants that first left the water and grew on land. They have never become independent of water, since it must be present if fertilization is to occur.

The number of mosses known is much larger than the number of liverworts. See Fig. 5. Mosses are found in many different regions, being much more abundant than liverworts, and able to grow under a wide range of environments. They are found in greatest abundance in moist shaded regions where they often cover an extensive area. Other species grow on the trunks of trees, often well above the ground, where they are exposed for long periods of time to desiccation. In tropical forests, mosses often clothe not only the trunks but also the branches of trees with a thick green covering; they may even succeed in growing on the thick evergreen leaves that characterize many tropical trees. Some species of mosses grow well on the exposed surfaces of barren rocks. A few are equatic, living entirely submerged in running water throughout their existence.

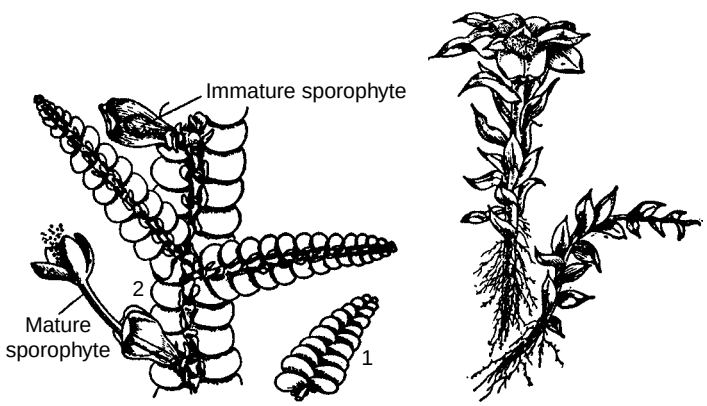

Fig. 4. (Left) *Porella*, a leafy liverwort: (1) a branch seen from the upper side; (2) a portion of a plant seen from the lower side; sporophytes are also visible, attached to archegonial branches, each partially enclosed in a perianth. (Right) *Mnium*, a common genus of mosses.

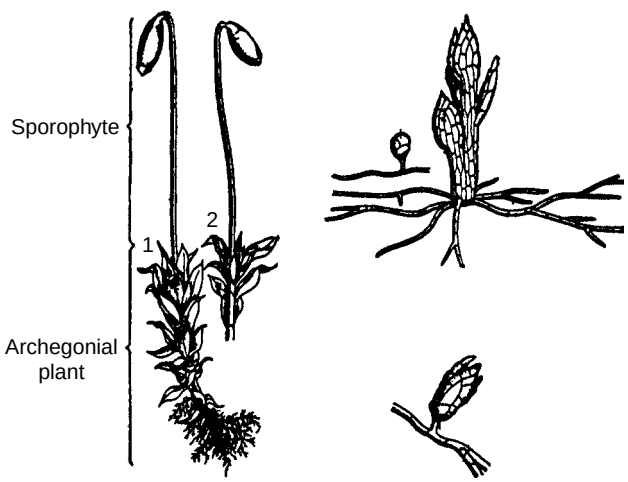

Fig. 5. (Left) (1) The sporophyte of a moss-*Mnium* attached to the gametophyte; (2) the same, the gametophyte being cut away to show the enlarged venter of the archegonium. (Right top) Moss protonema, showing the production of those buds which become the upright, leafy shoots. (Right bottom) The bud of a moss *Mnium*.

Usually moss plants are small (often tiny), and seldom exceed a few inches in length. A few genera, such as *Fontinalis*, which grows in water, and several tropical members, grow to lengths of 10–15 inches, which is very unusual in this group. Moss plants show a much higher development than hepatics. Usually the gametophyte, the part ordinarily seen and called a moss, has a very distinct, often erect stem, which bears many small radiating leaves. In each leaf there is generally a fairly evident midrib. There are many rhizoids growing from the lower part of the stem and attaching the plant to the ground. The rhizoids of mosses are longer than those of liverworts and are multicellular. There is no true vascular system in any moss, though the cells of the central portion of the stem are often much longer and more slender than those surrounding them. The sexual

organs of mosses are very similar to those of hepatics and are borne at the tips of the stem or branches. Biciliate sperms are formed which must have water in which they can swim to the egg. The fertilized egg gives rise to a sporophyte which is much more highly organized than that of liverworts but still entirely dependent on the gametophyte. The basal portion of the sporophyte is the foot, a mass of cells in close contact with those of the gametophyte. Above the foot there is a stalk which in most mosses is very long and slender. It bears at its top a capsule or spore-bearing sac. This capsule has a very specialized structure. The axis of the capsule is a mass of sterile tissue called the columella. Around this the sporogenous tissue occurs, in turn surrounded by a wall many cells thick and with large cavities within it. The basal part of the capsule is also a mass of sterile tissue, often considerably swollen, known as the apophysis. The apical portion of the capsule is very complex. Over its surface is the operculum, a layer of cells, which completely covers it and which falls off like a lid when mature. Beneath this and distinct from it is the peristome, which, when mature, splits into a number of slender teeth which react to changes in humidity, rolling back when dry and closing together when wet. Surrounding the developing capsule and remaining around it for some time is a loose jacket of cells in no way connected with it. This is the calyptra, formed from cells of the gametophyte which were originally cells of the archegonal wall.

The ripe spores of mosses are shaken out through the apical opening and scattered by currents of air. On germinating, these spores do not give rise to a new moss plant directly. Instead they form a slender branching filamentous structure called a protonema which very much resembles certain kinds of algae. There are two types of cells composing the protonema: one contains many chloroplasts and so carries on photosynthesis: the other lacks chloroplasts and forms colorless rhizoids that grow downward and attach the protonema to the soil. A peculiarity of the protonema is the cross-walls between cells: they are commonly diagonal to the long axis of the filament rather than at right angles. From the cells of the protonema short erect branches ending in small buds are formed. These buds develop into erect moss plants. The life history of a moss plant shows a very distinct alternation of generations. In addition there is the juvenile phase of the gametophyte, the protonema.

The first order of mosses, the peat- or bog-mosses, contains the single genus *Sphagnum* with many species of worldwide distribution, always growing in low, wet bogs. See Fig. 6. These mosses are considered very primitive. The gametophyte has an erect stem from which arise numerous branches, all of two kinds, either spreading, or pendent against the stem. The many leaves are small and but a single cell in thickness. Some of the cells are small and elongated, forming a fine anastamosing network in the leaf. These are living cells containing chloroplasts. The openings of the network are filled by very large inflated cells with thin walls and no protoplasm. Large pores in the walls of these dead cells permit free passage of water into the cell cavity. The small sporophyte has a spherical capsule, which is black or dark brown, and a very short stalk. The sporophyte is borne at the end of a specialized structure called a pseudopodium which lifts the sporophyte above the tuft of branches at the top of the gametophyte. The protonema of *Sphagnum* is a small flat thallus resembling that of the *Anthocerotales*.

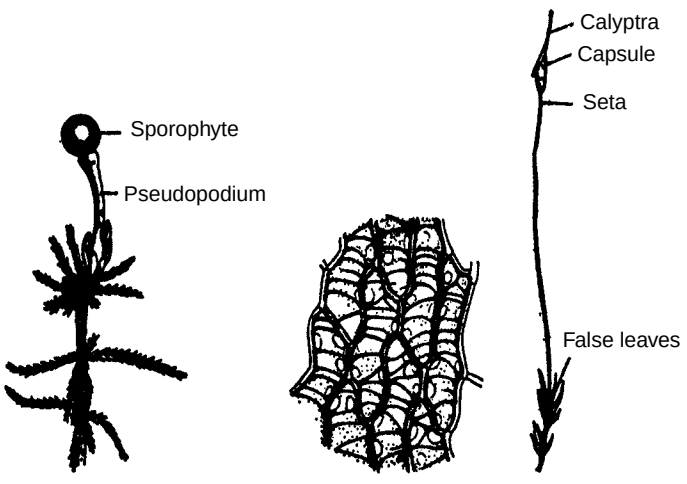

Fig. 6. (Left) *Sphagnum* sporophyte attached to a leafy plant. (Middle) A portion of a leaf or *Sphagnum*, the peat moss. Surface view. (Right) Individual plant of *Bryum*. Leafy axis bearing young sporophyte, with calyptra on top.

Peat-mosses are the only members of the Bryophyte group which have any commercial value. Growing slowly for long periods of time, they gradually accumulate in the wet bogs in which they are found. Gradually the lower parts amass, together with such debris as may have accumulated, forming a compact mass known as peat, and used as fuel. The ability of the large hollow cells of the leaf of *Sphagnum* to absorb and retain large quantities of water leads to the extensive use of *Sphagnum* moss as a material in which to pack live plants for shipment. For this reason also, and because *Sphagnum* is naturally a sterile substance, harboring few bacteria, certain species have been used as surgical dressings, especially in times of great need.

The *Andreaeales* is a small group of small mosses growing on the surfaces of siliceous rocks. They are unimportant.

Most mosses belong to the third order, the *Bryales*, which are the true mosses.

As a group the Bryophytes are of little importance. They are recognized as primitive plants that develop from some simple ancestral forms from which they have gradually diverged independently along several different lines. The existing forms do not form a single series, representing stages in the development of the most advanced forms, nor are they plants from which the higher plants have taken their origin. In this group the gametophyte appears in its most advanced form.

B-STATION. In loran, the designation applied to the transmitting station of a pair, the signal of which always occurs more than half a repetition period after the next succeeding signal and less than half a repetition period before the next preceding signal from the other station of the pair, designated an A-station.

BTU (BRITISH THERMAL UNIT, BTU). A unit of energy defined as that quantity of heat required to raise the temperature of one pound of water by one degree Fahrenheit; it is equal to 252.1 calories or 1055 joules.

In the United States, the term "BTU" is used to describe the heat value (energy content) of fuels, and also to describe the power of heating and cooling systems, such as furnaces, stoves, barbecue grills and air conditioners. When used as a unit of power, BTU *per hour* is understood, though this is often confusingly abbreviated to just "BTU".

It is also still occasionally encountered in the UK, in the context of older heating and cooling systems. In most other areas, it has been replaced by the SI unit of energy, the joule (J).

Conversions. One BTU is approximately:

- 1.054-1.060 kilojoule
- 252–253 cal (calories, small)
- 0.252–0.253 kcal (kilocalories)
- 778–782 ft·lbf (foot-pounds-force)

Other conversions:

- In natural gas, by convention 1 MM Btu (1 million Btu, sometimes written "mm BTU") = 1.054615 GJ. Conversely, 1 gigajoule is equivalent to 26.8 m^3 of natural gas at defined temperature and pressure.

Associated Units

The BTU per hour (BTU/h) is the unit of power most commonly associated with the BTU.

- 1 watt is approximately 3.41 BTU/h
- 1000 BTU/h is approximately 293 W
- 1 horsepower is approximately 2540 BTU/h

- 1 "ton of cooling", a common unit in North American refrigeration and air conditioning applications, is 12,000 BTU/h. It is the amount of power needed to melt one short ton of ice in 24 hours.
- 1 *therm* is defined in the United States and European Union as 100,000 BTU –but the U.S. uses the $BTU_{59°F}$ whilst the EU uses the BTU_{IT}.
- 1 *quad* (short for quadrillion BTU) is defined as 10^{15} BTU, which is about one exajoule (1.055×10^{18} J). Quads are occasionally used in the United States for representing the annual energy consumption of large economies: for example, the U.S. economy used about 94.2 quads/year in 1997. See also http://rredc.nrel.gov/tidbits.html.

The BTU should not be confused with the Board of Trade Unit (B.O.T.U.), which is a much larger quantity of energy (1 kWh, or about 3412 BTU).

BUBBLE. See **Brontide**; and **Foam**.

BUBBLE BURSTING. See **Meteorology**.

BUBBLE CAP. See **Distillation**.

BUBBLE CHAMBER. A vessel filled with a transparent liquid so highly superheated that a moving ionizing particle initiates boiling in the liquid along its path. The superheating is produced by a sudden reduction of the pressure on the liquid below that at which the liquid boils. During a brief period the liquid will then boil where a disturbance is created by a charged particle but not elsewhere, so that tracks of bubbles in the liquid show the paths of charged particles. The tracks are recorded on stereo photographs in the same way as with a cloud chamber. See also **Cloud Chamber**. Bubble chambers are key instruments used in particle-physics experiments and may measure up to 12–15 feet (3.6–4.5 meters) in diameter.

Bubble chamber photographs store a large amount of data that must be extracted by first scanning the film for events that may satisfy the requirements of a particular experiment. For simple interactions, computer-guided pattern recognition methods may be applied in conjunction with human intervention and interrogation, combining the scanning and subsequent measuring processes. More often, the scanned film is transferred to measuring machines of varying complexity where positions of bubble images are measured with commensurate accuracy. As an example, on a flying-spot digitizer, a light spot, 15 micrometers in diameter, scans a photograph in a few seconds. A bubble image causes a signal in a photomultiplier, which is compared with time pulses similarly produced by a grating scanned by a synchronized light spot, locating the image with respect to fiducial marks. Hundreds of events per hour can thus be measured with excellent precision. In the spiral reader, a fine slit spirals over the photograph, again producing light signals. A flying-image digitizer will scan many different portions of a photograph simultaneously so that thousands of events can be processed per hour. The processing of bubble chamber data requires large amounts of computer time, on-line for scanning and measuring equipment, and off-line for spatial reconstruction of events from the three or more stereoscopic views, for kinematic fitting and selection of probable events, and finally for interpretation of results.

BUBO. An inflamed, swollen lymph gland, particularly in the region of the armpits and groin.

BUBONIC PLAGUE. This disease, caused by infection with the gram-negative, short, thick coccobacillus *Yersinia pestis*, is transmitted by fleas from rats to humans. Recent research has indicated that rabbits and domesticated dogs and cats may also harbor the microorganism. In the Old World in times past, the disease was commonly called *Black Death*. The brown rat, *Rodentia norvegicus*, is a great traveler and is the prime means of spread of bubonic plague, even though it does not make contact with humans. The rat frequents city sewers and docks and, when it dies, fleas leave its carcass and frequently infect the black rat, *R. rattus*, which lives in close proximity to humans and their dwellings. Rat plague is seasonal and spreads during the period when fleas are most numerous.

Humans can also become infected directly from wild rodents by handling them during trapping and skinning, but such cases are sporadic and few in number. Infected, semi-domestic rodents may introduce the infection to rural villages and cause small outbreaks of the disease. With much better control over rats, the incidence of the disease decreased. Bubonic plague is seldom seen in many of the countries in temperate climates and with advanced sanitation. Local outbreaks can occur in the United States, particularly in the region from the Pacific States eastward to Kansas.

The bacteria is present in the bloodstream of animals having the disease. Thus, a flea biting a diseased rat obtains some of the bacteria, which multiply to form a plug in the flea's gullet. This plug causes the flea to regurgitate some bacteria into the next rat it bites. When the rat dies of the plague, the fleas leave the dead animal in search of a new host. If a rat cannot be found, the flea will bite another animal or a person. If the disease is left untreated, mortality ranges from 25 to 50%.

At the site of the bite, a trivial, hardly noticeable pustule will form, but within a short period, the regional lymph node will enlarge. A very marked inflammatory reaction will involve surrounding tissue, producing a bubo. The inflamed region will be tender and usually very painful. In bubonic plague, entry of the microorganism into the bloodstream occurs early — hence the need for very early diagnosis and commencement of therapy. Incubation period of the disease extends from 2 to 10 days. Associated with the bubo and surrounding tenderness will be fever, increasing to high fever and chills, prostration, and septic shock within just a few days. A common complication is pneumonia, which progresses at exceptionally fast rates in patients and can cause respiratory failure and death within a matter of hours.

Diagnosed patients should be placed in isolation. Traditional treatment is antimicrobial therapy with large doses of intramuscular streptomycin. Tetracycline and chloramphenicol are sometimes used, as well as combined therapy with trimethoprim and sulfamethoxazole. For immunizing persons with high risk to bubonic plague exposure, a killed vaccine is available.

The Great Plague. In recent years medical historians have reconstructed the path of the bubonic plague of 1345–1352, which engulfed much of Europe, the Near East, and the coast of North Africa. In an excellent article (1988), McEvedy (St. Bernard's Hospital, London), describes the probable origin of the great plague as being somewhere along the Trans-Asian Silk Road of those times. The first signs of the disease were noted in 1346 at Saray (on the Volga River) and at Astrakhan, where the Volga runs into the Caspian Sea. These cities were caravan stations along the Silk Road. However, the connection was not associated with the movement of silk, but rather with the use of the road by trappers for transporting marmot fur to Western buyers. Prior to the massive outbreak, there had been reports of hunters who suffered or perished from the disease. (The marmot is closely related to the rat, which generally is considered the host of the flea that carries the disease.)

At Kaffa, on the northern shore of the Black Sea, the furs were transferred to sailing ships, which then transported the infected cargo to Constantinople and then southward across the Mediterranean to Alexandria, hence spreading the disease to Cairo, Gaza, Beiruit, Damascus, and Aleppo, located along the eastern shore of the Mediterranean. Other ships went northward from Constantinople around the Grecian Islands and north toward the Adriatic shores of the Balkans, while other ships went west around Italy to deliver furs to Pisa, Genoa, and other Italian cities. The disease progressed westward from Sicily to Tunis and along the North African coast. Once the disease was well established in Italy, it spread northward through Germany and France and finally reached the Scandinavian countries, the British Isles, and Ireland. Large cities, such as London, were particularly adversely affected. It is noteworthy that Milan was the only large city to escape, probably because of its distance from seaports.

After ravaging northern Europe, it swung eastward, entering Poland in 1351 and Russia in 1352.

McEvedy suggests that sailing vessels were an ideal means of spreading the disease in a comparatively short time. "The holds of these ships were generally crawling with rats and when the crew slept, the rats took over, running through the rigging and dropping fleas onto the decks below. The cycle of infection, from flea to rat and rat to flea, would be maintained until the rat population was so reduced by the disease that it no longer could sustain the fleas and the bacteria they were carrying. Hungry fleas then sought other sources of blood and quickly turned to the human population."

It has been estimated that 75% of the population of the cities and towns in the path of the plague were infected. Of those infected, about 50% died within a 15-day period.

BUCHNER, EDUARD (1860–1917). Eduard Buchner was a German biochemist who discovered cell-free fermentation and began the modern study of enzymes and biochemistry.

Buchner was born on 20 May 1860 at Munich where his father was Professor of Forensic Medicine and Obstetrics in the university. After graduating from the Realgymnasium at Munich, Buchner served in the field artillery. He then studied chemistry at the Technische Hochschule in Munich, but abandoned his studies in 1880 due to financial problems. In 1884, assisted by his elder brother Hans, a bacteriologist, he returned to chemical studies under Adolf von Baeyer. His first organic synthesis was of *diazoacetic ester* with his friend Theodor Curtius. At the same time Buchner also studied botany in Karl von Nägeli's laboratory at the Institute for Plant Physiology, under the supervision of his brother Hans. He became interested in alcoholic fermentation and in his first paper on this subject he concluded that yeast cells can cause fermentation with or without the presence of air, in opposition to Pasteur's description of fermentation as "la vie sans l'air." See also **Baeyer, Johann Friedrich Wilhelm Adolf von**.

Buchner gained his doctorate in 1888 and in 1890 was appointed teaching assistant to Baeyer, who, in 1891, procured funds to enable Buchner to establish a small laboratory for fermentation chemistry. At Hans's suggestion, he attempted to rupture yeast cells, which are very small and tough, to obtain their fluid. He was unsuccessful and the supervisory Board of his laboratory decided that it was a waste of time and ordered him to discontinue these experiments. The decision arose from contemporary disputes between mechanists and vitalists. The former included Berzelius, Liebig and Wöohler, all of whom regarded fermentation as a chemical process brought about by *enzymes*, water-soluble biological catalysts working outside the cells. Others, including Berthelot, Mayer, Nägeli and Pasteur, had observed fermentation only in the presence of living yeast cells. They regarded it as the product of *ferments* existing inside living cells and operating only in the presence of a *life force*.

The interruption of his fermentation studies led Buchner to concentrate on preparative organic chemistry and he published nearly fifty papers on the preparation of organic nitrogen compounds using diazoacetic ester. In 1893 Buchner succeeded Curtius as Head of Analytical Chemistry at the University of Kiel, and in 1896 he became Professor of Analytical and Pharmaceutical Chemistry at the University of Tübingen. On vacation in Munich where Hans, now a professor, was a member of the Board of Directors at the Hygienic Institute, Buchner returned to his fermentation studies. At the suggestion of his brother's assistant, Martin Hahn, he succeeded in rupturing yeast cells by pulverizing them with sand and diatomaceous earth and then, wrapping the mixture in canvas, he squeezed out the fluid using a hydraulic press. Finding that this fluid readily decomposed, he added a concentrated solution of sucrose in an effort to preserve it. When the mixture began to froth and produce carbon dioxide and alcohol, Buchner realized that fermentation had occurred in the absence of living cells. He had shown that fermentation is caused by the catalytic action of cellular enzymes and not, as the vitalists insisted, by the action of a *life force*. Buchner published his first papers on 'Alkoholische Gärung ohne Hefezallen' (alcoholic fermentation without yeast cells) in 1897.

In the following year he moved to Berlin as Professor of General Chemistry and Director of the Institute for the Fermentation Industry at the College of Agriculture. His continued studies of the active agent in yeast juice, which he called *zymase*, showed that it was a chemical substance and caused fermentation without the aid of living matter. The physiologist Max Rubner and the biochemist Hans von Euler-Chelpin argued that the fermentation was due to fragments of living yeast cells, which had passed through the filter, but Buchner refuted this by showing that zymase still caused fermentation even in conditions known to kill yeast cells. He examined the chemical properties of the fluid and found that it contained other enzymes besides zymase. He also suggested that lactic acid, methylglyoxal, glyceraldehyde and dihydroxyacetone were intermediates in alcoholic fermentation. Some of these have since been identified. The first comprehensive account of Buchner's work, *Die Zymase-Gärung*, written in collaboration with his brother Hans and Martin Hahn, was published in 1903 and Buchner's achievements were recognized by the award of the Nobel Prize for Chemistry in 1907. After this he accepted posts at the Universities of Breslau (1909) and Würzburg (1911) and persevered with investigations into the nature of zymase and the intermediate reactions and products of the fermentation process, though elucidation of the chain of reactions involved was due to other workers. See also **Euler-Chelpin, Hans Karl August Simon von (1873–1964)**; and **Rubner, Max (1854–1932)**.

As a pioneer of biochemistry Buchner showed some important characteristics. He was an open-minded and imaginative thinker and persisted in his work despite criticism and the rejection of his ideas by the scientific community of his day. He developed new, simple techniques and showed keen powers of observation. His scientific methodology allowed him to establish his conclusions by eliminating other interpretations through careful experimental techniques. Buchner's contribution to the foundations of biochemistry was invaluable. He refuted the vitalist theory of fermentation and established the study of enzymology. His discovery of cell-free fermentation showed that biochemical processes depend on the interplay of chemistry, physics and biology; it opened up an important natural function, which occupied many biochemists for nearly half a century and led to modern ideas on intermediary metabolism. Buchner's zymase is now known to consist of at least fourteen enzymes, each of which catalyses a specific stage in the fermentation of sugar to form carbon dioxide and alcohol. Perhaps the most important legacy of Buchner's work was the development of the modern fermentation industry, which provides foods and drinks, organic products for the chemical and agricultural industries and antibiotics and other important biological substances for medicine and research. See also **Biochemistry (The History)**; **Fermentation**; and **Harden, Arthur (1865–1940)**.

BUCKEYE AND HORSE CHESTNUT TREES. Members of the family *Hippocastanaceae* (horse chestnut family); these trees are of the genus *Aesculus* and are of several species. These trees are deciduous shrubs or trees with compound leaves. Important species include:

Baumann's horse chestnut	*Aesculus hippocastanum "Baumannii"*
California buckeye	*A. californica*
Common horse chestnut	*A. hippocastanum*
Damask horse chestnut	*A. carnea "Plantierensis"*
Dwarf buckeye	*A. parviflora*
Indian horse chestnut	*A. indica*
Japanese horse chestnut	*A. turbinata*
Ohio buckeye	*A. glabra*
Painted buckeye	*A. sylvatica*
Red buckeye	*A. pavia*
Red horse chestnut	*A. carnea*
Sweet buckeye	*A. flava*
Yellow buckeye	*A. octandra*

The preferred geographic regions for some of the foregoing species are obvious from their common names. The common horse chestnut is found in Greece and Albania and grows to a height of about 120 feet (36 meters).

TABLE 1. RECORD BUCKEYE TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
Bottlebrush buckeye (1993) (*Aesculus parvillora*)	34	86.4	14	4.27	20	6.1	Virginia
Ohio buckeye (typ.) (1994) (*Aesculus glabra var. galbra*)	151	384	148	45.1	48	14.6	Kentucky
Painted buckeye (1999) (*Aesculus sylvatica*)	12	30.5	27	8.23	15	4.57	Georgia
Red buckeye (1994) (*Aesculus pavia*)	95	241	58	17.7	48	14.6	Virginia
Yellow buckeye (1995) (*Aesculus actandra*)	229	582	136	41.5	53	16.2	Tennessee

[1]From the "National Register of Big Trees," American Forests (by permission).
[2]At 4.5 feet (1.4 meters).

The Damask horse chestnut is a backcross between *A. hippocastanum* (three-fourths) and *A. carnea* (one-fourth). The dwarf buckeye is found in the southeastern United States and grows to a height of about 15 feet (4.5 meters) and is shade tolerant. The Indian horse chestnut is found in the northwestern Himalayas and grows to a height of about 100 feet (30 meters). The Ohio buckeye (Ohio is called the Buckeye State) is found in the central and southeastern portions of the United States. The tree grows to a height of about 30 feet (9 meters). The red buckeye grows in the southern regions of the United States and reaches a height of about 20 feet (6 meters) and thus can be called a shrub or small tree. The red horse chestnut reaches a height of about 70 feet (21 meters). The sweet buckeye is found in the southeastern United States and reaches a height of about 90 feet (27 meters). Record buckeyes as reported by American Forests are listed in Table 1.

The wood of the American horse chestnut (Ohio buckeye) is dense, whitish in color, and is used for making furniture. It is particularly suited for the construction of artificial limbs. The kernel of this chestnut is poisonous.

Budding of the buckeye is described under **Bud**.

BUCKINGHAM PI THEORY. A systematic method of dimensional analysis, whereby variables that are relevant to a particular atmospheric situation are formed into dimensionless groups called Pi groups. See also **Dimensional Analysis**.

Because the number of dimensionless groups equals the original number of variables minus the number of fundamental dimensions present in all the variables, this analysis reduces the degrees of freedom for the physical situation and can be used to guide the design of measurement programs. Buckingham Pi theory is often used in similarity theory to identify the relevant dimensionless groups. Fundamental dimensions are length, mass, time, temperature, electric current, and luminous intensity. All other dimensions can be formed from combinations of these fundamental dimensions.

AMS

BUCKLEY GAGE. A very sensitive pressure gauge, based on measurement of the amount of ionization produced in a gas by a specified current.

BUCKMINSTERFULLERENE (BUCKYBALLS). Spherical aromatic molecule (C_{60}) with a hollow truncated-icosahedron structure, similar to a soccer ball. First reported in the mid-1980s. Capable of enclosing ions or atoms in a host-guest relationship. See also **Carbon**.

BUCKTHORN SHRUBS AND TREES. Of the family *Rhamnaceae* (buckthorn family), there are several species of shrubs, and infrequently sizeable trees. They are characterized by alternate, toothed leaves, small flowers, and, in some species, thorns. Table 1 of record buckthorns in the United States attests to the fact, however, that some species and specimens can attain relatively significant proportions.

The Carolina buckthorn may be classified as a tall shrub or small tree, ranging in height between 10 and 30 feet (3 to 9 meters). The bark is a dark brown, reasonably smooth. This species of buckthorn does not have thorns. The leaves are large, elliptical, dark green, smooth, and only slightly pointed. The red-to-purple fruit is a little over-$\frac{1}{4}$ inch (0.6 centimeter) in diameter, is of a sweetish taste, and contains three seeds. This shrub prefers wet lowlands and swampy areas, as may be found from Long Island southward to Florida, along the Ohio River valley, and as far west as Texas.

The alder buckthorn or glossy buckthorn ranges from 5 to 8 feet (1.5 to 2.4 meters) in height and was introduced into North America from Europe. The leaves are small, pale olive green, elliptical, and toothless. The fruit

TABLE 1. RECORD BUCKTHORN TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
Carolina buckthorn (1982) (*Rhamnus caroliniana*)	23	58	43	13.1	18	5.5	Tennessee
Carolina buckthorn (1974) (*Rhamnus caroliniana*)	41	104	27	8.23	23	7.01	Virginia

[2]At 4.5 feet (1.4 meters).

contains three seeds and is black, about-$\frac{1}{4}$ inch (0.6 centimeter) in diameter. The shrub is reasonably local to swamps on Long Island and in northern New Jersey, although as Table 1 indicates, is found in the Midwest as well.

BUCKWHEAT *(Fagopyrum esculentum; Polygonaceae).* Aside from the grasses, buckwheat is the only plant used to any extent as a cereal in the United States. It is an erect branching plant from one to four feet tall, with a small root system and a smooth rather weak stem at each node of which is borne a single heart-shaped leaf. The inflorescence is a many-flowered raceme, the individual flowers being white or pink-tinged. The calyx lobes, five in number, are colored; there is no corolla. There are eight stamens and a single one-celled ovary, which bears three curved styles. Cross-pollination is brought about by the numerous insect visitors attracted by the pleasant fragrance of the flowers. The mature fruit is a triangular brown or black achene. The single seed within contains an abundance of white endosperm high in starch content.

Buckwheat is an Asiatic plant that is cultivated in widely scattered regions. It grows well in cool climates, on poor soils, and where the growing season is short. It matures early, producing flowers from 3–5 weeks after planting.

The plant is used as a green manure, being turned under to enrich the soil. Pancake flour is made from buckwheat seeds. The grain is also used as food for poultry and other domestic animals, either whole or divested of the hulls. Buckwheat flowers are a source of honey.

BUD. In botany, a bud is an undeveloped shoot and normally occurs in the axil of a leaf or at the tip of the stem. Once formed, a bud may remain for some time in a dormant condition, or may develop into a shoot immediately.

The buds of many woody plants, especially in temperate or cold climates, are protected by a covering of modified leaves, called scales, which tightly enclose the more delicate parts of the bud. Many bud scales are covered with a gummy substance, which serves as added protection. When the bud develops, the scales may enlarge somewhat but usually drop off, leaving on the surface of the growing stem a series of horizontally elongated scars. By means of these scars one can determine the age of any young branch, since each year's growth ends in the formation of a bud, the development of which causes the appearance of an additional group of bud scale scars. Continued growth of the branch causes these scars to be obliterated after a few years so that the total age of older branches cannot be determined by this means.

In many plants scales are not formed over the bud, which is then called a naked bud. The minute undeveloped leaves in such buds are often excessively hairy. Such naked buds are found in shrubs like the Sumac and Viburnums and in herbaceous plants. In many of the latter, buds are even more reduced, often consisting of undifferentiated masses of cells in the axils of leaves. A head of cabbage (see **Brassica**) is an exceptionally large terminal bud, while Brussels sprouts are large lateral buds.

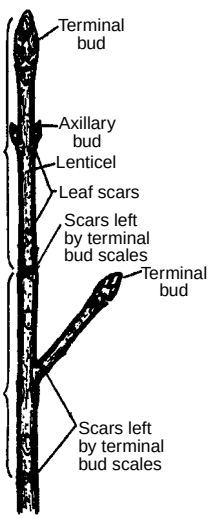

Fig. 1. Twig of buckeye (*Aesculus glabra*), showing two years of growth.

Since buds are formed in the axils of leaves, their distribution on the stem is the same as that of leaves. There are alternate, opposite and whorled buds, as well as the terminal bud at the tip of the stem. In many plants buds appear in unexpected places: these are known as adventitious buds.

Often it is possible to find in a bud a remarkable series of gradations of bud scales. See Fig. 1. In the Buckeye, for example, one may observe a complete gradation from the small brown outer scale through larger scales which on unfolding become somewhat green to the inner scales of the bud, which are remarkably leaf-like. Such a series suggests that the scales of the bud are in truth leaves, modified to protect the more delicate parts of the plant during unfavorable periods. See Fig. 2.

Fig. 2. A series of stages in the growth of a bud of buckeye (*Aesculus glabra*).

In zoology, a bud may be defined briefly as an outgrowth from the body that develops into a new individual. See **Budding**; **Adventitious Buds**; and **Plant Growth Modification and Regulation**.

BUDAN THEOREM. Let $P(x) = 0$ be a polynomial of degree n with real coefficients and suppose that one wishes to locate its real roots. Choose a and b which are real numbers such that $a < b$ and neither of which is a root of the polynomial. Let V_a denote the number of variations of sign of $P(x), P'(x), P''(x), \ldots, P^{(n)}(x)$ for $x = a$, after vanishing terms have been deleted, and similarly V_b is the number of variations for $x = b$. Then $V_a - V_b$ is either the number of real roots $P(x) = 0$ between a and b or it exceeds the number of these roots by a positive even integer. A root of multiplicity m is here counted as m roots.

BUDDE EFFECT. The increase in volume of halogens, especially chlorine and bromine vapor, on exposure to light. It is a thermal effect, due to the heat from recombination of atoms.

BUDDING. This term is used to designate a process of asexual reproduction in which the young are formed as outgrowths of the parent body. See **Conjugation**. It is limited to animals or plants of relatively simple structure. In this process a portion of the wall of the parent cell softens and pushes out. The protuberance thus formed enlarges rapidly while at this time the nucleus of the parent cell divides. One of the resulting nuclei passes into the bud. Presently the bud becomes cut off from its parent cell and the process is repeated. Often the daughter cell starts to bud before it becomes separated from the parent, so that whole colonies of adhering cells are formed. Eventually cross walls cut off the bud from the original cell.

The term budding is also applied to a process of embryonic differentiation in which new structures are formed by outgrowth from preexisting parts.

A third use of the term budding is discussed in the entry on **Grafting and Budding**.

BUD MOTH *(Insecta, Lepidoptera).* This insect is an economic pest, notably on apple, pear, and pecan, and occurs throughout the United States. The apple and pear bud moth (*Tmetocera ocellana*) adult is a gray color, with a pale-beige band on forewings. The larva is brown, with black head, and ranges up to $\frac{1}{2}$-inch (12 to 13 millimeters) in length. The insect eats buds, blossoms, and leaves and spins webs around them. This reduces fruit production by causing injury to terminal shoots and thus encouraging bushy growth rather than fruit production. Organic phosphorus compounds have been found to be effective against this pest. Non-insecticide control methods also can be effective. Young trees should be examined for bud moth damage in May. Dead, brown leaves are evidence of infestation

by this pest. Nests can be destroyed by removal from trees, or they can be crushed on the tree to kill the enclosed caterpillars or pupae. Several parasites and predators, such as *Trichogramma* (minute wasps) and ground beetles help to control this insect. Birds also feed on the caterpillars. Mud dauber wasps sometimes store them in their shells where they are used as food for their grubs.

The pecan bud moth (*Proteopteryx deludana*) is closely related in appearance and action and frequents pecan trees, upon which infestations can be quite damaging. Treatment is similar to that described for apple and pear. For pecan, chemical insecticides are most effective when applied just as the last of the petals are falling. A repeat application may be required.

BUFFALO CARPET-MOTH *(Insecta Coleoptera)*. More properly known as the carpet beetle but misnamed through the similarity of habits of its larva and those of the clothes moths.

The true carpet beetle is an introduced European species, *Anthrenus scrophulariae*, whose larva eats woolen materials of all kinds as well as furs and feathers. The adult is a compact oval insect about one-eighth inch long and marked with brickred, black and white, and the larva is a brown hairy grub. A number of other species, native to North America, have the same habits and may be equally troublesome. The adults frequent flowers and eat pollen, hence they may migrate readily to houses. They are important pests in museums.

In the home, good housekeeping methods are usually an adequate safeguard against these pests. In special cases fumigation is necessary to destroy them but as a rule the use of sprays now supplied commercially for application to clothing and other fabrics is the only unusual measure required.

BUFFER (Chemical). When acid is added to an aqueous solution, the pH (hydrogen ion concentration) falls. When alkali is added, it rises. If the original solution contains only typical salts without acidic or basic properties, this rise or fall may be very large. There are, however, many other solutions that can receive such additions without a significant change in pH. The solutes responsible for this resistance to change in pH, or the solutions themselves, are known as *buffers*. A weak acid becomes a buffer when alkali is added, and a weak base becomes a buffer upon the addition of acid. A simple buffer may be defined, in Brønsted's terminology, as a solution containing both a weak acid and its conjugate weak base.

Buffer action is explained by the mobile equilibrium of a reversible reaction:

$$A + H_2O \rightleftharpoons B + H_3O^+$$

in which the base B is formed by the loss of a proton from the corresponding acid A. The acid may be a *cation*, such as NH_4^+, a *neutral molecule*, such as CH_3COOH, or an *anion*, such as $H_2PO_4^-$. When alkali is added, hydrogen ions are removed to form water, but so long as the added alkali is not in excess of the buffer acid, many of the hydrogen ions are replaced by further ionization of A to maintain the equilibrium. When acid is added, this reaction is reversed as hydrogen ions combine with B to form A.

The pH of a buffer solution may be calculated by the mass law equation

$$pH = pK' + \log \frac{C_B}{C_A}$$

in which pK' is the negative logarithm of the apparent ionization constant of the buffer acid and the concentrations are those of the buffer base and its conjugate acid.

A striking illustration of effective buffer action may be found in a comparison of an unbuffered solution, such as 0.1 *M* NaCl with a neutral phosphate buffer. In the former case, 0.01 mole of HCl will change the pH of 1 liter from 7.0 to 2.0, while 0.01 mole of NaOH will change it from 7.0 to 12.0. In the latter case, if 1 liter contains 0.06 mole of Na_2HPO_4 and 0.04 mole of NaH_2PO_4, the initial pH is given by the equation:

$$pH = 6.80 + \log \frac{0.06}{0.04} = 6.80 + 0.18 = 6.98$$

After the addition of 0.01 mole of HCl, the equation becomes:

$$pH = 6.80 + \log \frac{0.05}{0.05} = 6.80$$

while, after the addition of 0.01 mole of NaOH, it is

$$pH = 6.80 + \log \frac{0.07}{0.03} = 6.80 + 0.37 = 7.17.$$

The buffer has reduced the change in pH from ±5.0 to less than ±0.2.

Figure 1 shows how the pH of a buffer varies with the fraction of the buffer in its more basic form. The buffer value is greatest where the slope of the curve is least. This is true at the midpoint, where $C_A = C_B$ and $pH = pK'$. The slope is practically the same within a range of 0.5 pH unit above and below this point, but the buffer value is slight at pH values more than 1 unit greater or less than pK'. The curve has nearly the same shape as the titration curve of a buffer acid with NaOH or the titration curve of a buffer base with HCl. Sometimes buffers are prepared by such partial titrations instead of by mixing a weak acid or base with one of its salts. Certain "universal" buffers, consisting of mixed acids partly neutralized by NaOH, have titration curves that are straight over a much wider pH interval. This is also true of the titration curves of some polybasic acids, such as citric acid, with several pK' values not more than 1 or 2 units apart. Other polybasic acids, such as phosphoric acid, with pK' values farther apart, yield curves having several sections, each somewhat similar to the accompanying curve. At any pH, the buffer value is proportional to the concentration of the effective buffer substances or groups. See also **pH (Hydrogen Ion Concentration)**.

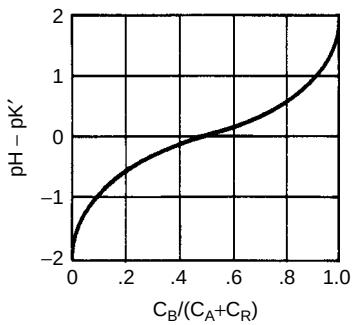

Fig. 1. The pH of a simple buffer solution. Abscissas represent the fraction of the buffer in its more basic form. Ordinates are the difference between pH and pK'.

Table 1 gives approximate pK' values, obtained from the literature, for several buffer systems.

TABLE 1. REPRESENTATIVE BUFFER SOLUTIONS

Constituents	pK'
H_3PO_4; KH_2PO_4	2.1
HCOOH; HCOONa	3.6
CH_3COOH; CH_3COONa	4.6
KH_2PO_4; Na_2HPO_4	6.8
HCl; $(CH_2OH_3)CNH_2$	8.1
$Na_2B_4O_7$; HCl or NaOH	9.2
NH_4Cl; NH_3	9.2
$NaHCO_3$; Na_2CO_3	10.0
Na_2HPO_4; NaOH	11.6

Buffer substances which occur in nature include phosphates, carbonates, and ammonium salts in the earth, proteins of plant and animal tissues, and the carbonic-acid-bicarbonate system in blood. See also **Acid-Base Regulation (Blood)**.

Buffer action is especially important in biochemistry and analytical chemistry, as well as in many large-scale processes of applied chemistry. Examples of the latter include the manufacture of photographic materials, electroplating, sewage disposal, agricultural chemicals, and leather products.

BUFFING. A finished process for producing a lustrous surface, usually on sheet metal. Buffing is usually effected by using a buffing wheel composed of layers of cloth sewed together to which a cake abrasive is periodically applied.

BUFFON, GEORGES LOUIS (1707–1788). Buffon was a French natural philosopher most famous for his work *Histoire Naturelle*, in which

he proposes a sequential history of the origin of the Earth and animals. Georges-Louis Buffon received his early education at the Jesuit College des Godrans in Dijon, demonstrating a keen interest in mathematics. He then studied law but soon moved to Angers to the university where he first encountered Newton's *Principia* (1687).

His early works were on a modest scale, on timber and forestry, but brought him admission to the Académie Royale des Sciences in 1734. He then produced two important translations which heralded the introduction of English mechanical philosophy into French science: *Vegetable Staticks* by Stephen Hales (French translation, 1734), and Newton's work on fluxions, over which Newton and Leibniz had argued for priority (French translation, 1740).

Buffon was appointed director of the Jardin du Roi, a prestigious establishment of museums, gardens and menageries in Paris. His interests turned to geology, chemistry and natural history, leading him towards the great publishing project of his *Histoire Naturelle* (1749–1804). This work was matched in grandeur of scale only by the other vast undertaking of eighteenth-century France, the *Encyclopédie of Diderot and D'Alembert*. In this *Histoire Naturelle* Buffon described the whole of the natural world from the origin of the Earth through to humankind and civilization, breaking off only where the encyclopedists began. It was completed after his death, running to 36 volumes, plus others published separately by collaborators during his lifetime and afterwards.

Like the *Encyclopédie*, the *Histoire Naturelle* was a banner for enlightenment thought. At all points Buffon took an enlarged, synthetic view of the subject. In the first volume he discussed the nature of scientific inquiry, separating this from religious concerns and rejecting the idea of God's intervention in nature. In another, his "Discours sur la manière d'étudier et de traiter l'histoire naturelle," he addressed contemporary issues in classification and roundly criticized Linnaeus's system. Buffon claimed that organisms do not fall into clear-cut categories as Linnaeus's scheme required: nature was a seamless web of individuals upon which human beings impose schemes and labels. In subsequent volumes he leaned more to the view that classification should follow the natural, structural groupings of organisms. On the basis of breeding experiments undertaken for him at the Jardin, and at Montbard, he proposed that a species was best understood as a set of animals that could produce offspring together. In this respect, Buffon became the first to put forward the breeding criteria on which modern definitions depend. Buffon, however, believed species could crossbreed far more widely than supposed, suggesting there were only 38 basic breeding 'families', as demonstated by the easy interbreeding between jackals, wolves and dogs, and zebras, donkeys and horses. See also **Linnaeus, Carl (Linné) (1707–1778)**.

Buffon's theory of inheritance stipulated that the particles of living matter were moulded into the correct shape by a 'moule intérieur', a process similar to epigenesis. He was convinced that spermatozoa were merely aggregates of living particles found also in the female secretions or were 'parasites' of the testes.

Much of his fame rests on his theory of the Earth given in volume II (1749). In this he emphasized the notion of the Earth's long historical development and that animals and plants had changed over time according to the environment. After conducting experiments on cooling spheres he proposed that the Earth was much older than previously thought, some 75 000 years, later extending this to 3 million years, a marked contrast to the fixed biblical timescale then broadly believed. The earth went through successive stages which he called 'epoques', roughly corresponding with the biblical eight 'days' of creation. Animals first appeared in the fifth epoch, just before the continents emerged from the primaeval ocean (sixth epoch). He attributed their origin to spontaneous generation rather than divine creation. While rejecting the Garden of Eden and Noah's flood, he nevertheless left the door open for those who wished to read a more obviously Christianized version into his proposals. Fossils, for him, represented the remains of the first animals on earth, which became extinct as conditions changed.

Buffon also proposed that animals moved over the globe from their point of origin and deviated from the original form by adapting to local conditions. In this way, the land took up its current appearance where continents have animals special to each area; for example, each has its own form of big cat. Modern biogeographers have christened this particular observation 'Buffon's law'. He included a discussion of human races diverging from one ancestral stock, suggesting that native American Indians had deviated or 'degenerated' from the original form, becoming smaller in stature according to the conditions in the New World.

Through these writings and his domination of leading scientific institutions, Buffon's influence was as direct and powerful as that of his monarch, Louis XVI. His Histoire was translated into many different languages, making him the most widely read scientific author of the day, equaling Rousseau or Voltaire.

BUG *(Insecta, Hemiptera)*. Insects with sucking mouth parts usually arising near the front of the head, with antennae usually long but with few joints, and with wings, when present, thicker at the base and membranous at the tip, overlapping when folded to form a more or less conspicuous X on the back. The bugs are so diverse that no concise definition can be generally adequate. The term bug is not synonymous with insect.

In general terms, the head of a bug is usually triangular and smaller than the remainder of the body. The antennae are short, usually with 5 to 13 or more joints, and located below the eyes. When folded, the wings conceal most of the bug's body. The legs are slender and long. There are usually 11 segments to the abdomen.

There are about 50,000 living and fossil species. The oldest known fossil insect (Protocimex silurica) was obviously a bug. Parts of a wing were found in Sweden in the Upper Ordovician beds. For major families of bugs, see **Hemiptera**.

BUHRSTONE. Relatively porous, calcareous, and siliceous sand-stones with sharp or angular grains.

BULB (Botany). A thick short stem that grows many thick leaves in which food reserves are stored. In many bulbs the leaves are closely wrapped together, forming a compact body called a tunicated bulb, as is the case in the onion. In other bulbs the fleshy leaves are loosely arranged to form a scaly bulb, such as the Easter lily. Bulbs are particularly common in monocotyledonous plants, and aid the plants greatly in surviving long dry seasons. Commonly the term bulb is erroneously applied to any fleshy underground plant part, regardless of its nature, so that rhizomes, corms and tubers are all popularly classed as bulbs. The dahlia "bulb," for instance, is really a fleshy root.

BULBIL. In some plants, there occur small reproductive bodies called bulbils, or sometimes, bulblets. An example is found in the small black objects growing in the axils of the leaves of tiger lilies. These are actually buds in which the scales are very much swollen. When mature, the whole body falls to the ground and, under favorable conditions, puts out roots and, in time, grows into a new plant. Similar bodies are found in the familiar onion sets and in several sedges. Serving the same purpose are the small globose bodies that develop on the leaves of several species of ferns, as, for example, *Cystopteris bulbifera*. All of these kinds of bodies represent one method of vegetative propagation.

BULBUL *(Aves, Passeriformes)*. Birds of several species found in Africa and the Oriental region, related to the babblers. They are said to be melodious singers.

The bulbul is a thrush-like bird, small, with brilliant plumage. The sexes are quite alike in plumage. The crest of the head is black. There are red spots below each eye. The throat and breast are white, with some brown on the back and wings. The tail is tipped with white. The under tail coverts are red. The bulbul attains a length of about 7 inches (18 centimeters). Diet consists of fleshy fruits, berries, and insects.

BULIMIA NERVOSA. See **Diet**; and **Eating Disorders**.

BULKHEAD. A bulkhead is a partition or a transverse strengthening frame. Ships' bulkheads are the important transverse partitions that subdivide the hold into separate water-tight compartments, being built from

the keel to the bulkhead deck. They must be not only water-tight, but have sufficient structural strength to resist the bursting pressure to which they will be subjected when one bulkhead space is filled with water, while the adjacent one is empty.

In construction, any wall used to restrain fluid or semi-fluid pressure, such as that resulting from water or saturated earth in foundation excavations, is called a bulkhead or bulkhead wall.

BULKING AGENTS (FOODS). See **Bodying and Bulking Agents (Foods) and Sweeteners**.

BULL. The male of certain animals, as domestic cattle, the bull elephant, and the bull alligator.

BULLFINCH *(Aves, Passeriformes)*. Birds of northern Europe and Asia, related to the grosbeaks. The bullfinch is a favorite cage bird in Europe and can be trained to whistle. The male is plump with rich rose-colored plumage on breast and gray on back. The tail, wings, and head are covered with glossy black feathers.

BULLFROG *(Amphibia, Salientia; Rana)*. Large frogs, closely related to the more familiar grass frogs and leopard frogs. The bullfrogs reach a length of 8 inches (20.3 centimeters). The flesh of the bullfrog is delicious.

BUMBLEBEE *(Insecta, Hymenoptera)*. Stoutly built hairy bees of moderate to large size. Some species are colonial, building nests on the surface of the ground, while others live as parasites in the nests of other bumblebees.

Unlike the honeybee, bumblebees are not permanently colonial in temperate regions. Only the queen lives through the winter. When she emerges from hibernation in the spring she builds a nest or occupies an abandoned nest of a bird or mouse, and in it makes waxen cells in which she lays eggs and a waxen honey pot in which to store surplus food. She feeds her young until they mature, and only when they emerge as worker bees does the colony take on an organization like that of the honeybee. In the fall, males and queens appear and the colonies break up. The queens mate before hibernating. Most authorities include all of these bees in the genus *Bombus*.

The parasitic bumblebees, making up the genus *Psithyrus*, enter the nests of other bumblebees and lay their eggs to be cared for by the hosts. Their chief structural difference is the lack of pollen-gathering organs in the females.

Bumblebees are important in the cross-fertilization of red clover and other deep-throated flowers.

BUMPINESS. See **Meteorology**.

BUNA AND ROLLS. See **Bakery Processes, Yeast-Raised Products**.

BUNDLE. Also often called vascular bundle or fibrovascular bundle. In most vascular plants the vascular tissues are arranged in the form of a cylinder. In many cases, notably in woody plants, this cylinder is a solid mass of cells. But in many plants, particularly in herbaceous dicotyledons and monocotyledons, the vascular tissues occur in strands, which are more or less distinctly separated from one another, and are called vascular bundles. See Fig. 1. Such bundles appear as discrete objects when seen in a cross section of the stem. See Fig. 2. However, they really form a continuous conducting system which extends from a single bundle in the root through the stem and into the leaves and other parts, and becomes an elaborate system of interconnecting parts. See Fig. 3.

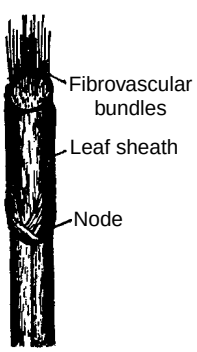

Fig. 1. Portion of corn stem (*Zea mays*), with the vascular bundles protruding, illustrating the structure of a typical monocotyledonous stem.

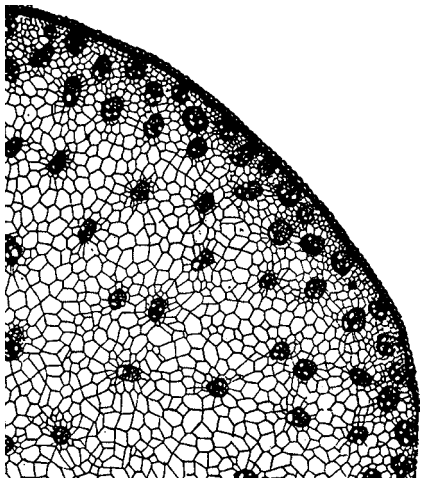

Fig. 2. Cross section of corn stem showing the distribution of fibrovascular bundles in a typical monocotyledon.

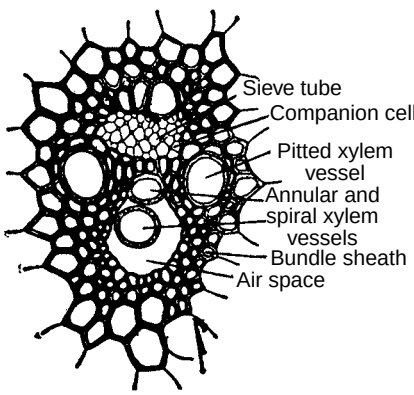

Fig. 3. Cross section of a single fibrovascular bundle of corn, *Zea mays*.

In the axis of the plant, each bundle consists of masses of xylem and phloem cells, which may appear in various arrangements; frequently, the xylem and phloem cells appear in radially adjoining masses, forming a collateral bundle; less frequently, one kind of cells is surrounded by cells of the other kind, forming a concentric bundle; in roots a third arrangement is found; the xylem occupies the center of the single bundle, nearly surrounded by strands of phloem. In cross section the xylem of the young root (see Fig. 4) is in the form of a cross with four or five arms (dicotyledons), or many arms (monocotyledons), and the phloem strands occupy the positions between the radiating arms of the xylem. Such bundles are called radial bundles.

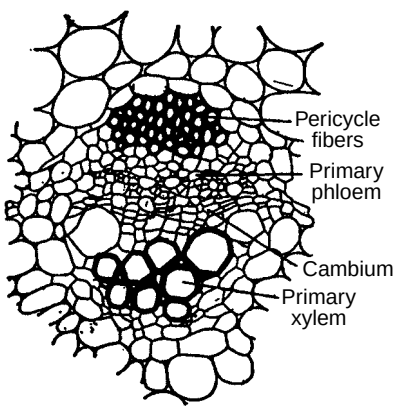

Fig. 4. Cross section of a single fibrovascular bundle of a young sunflower stem.

While a bundle consists normally of associated masses of xylem and phloem cells, in many plants there appears with them strands of fibers whose presence may give protection to the bundle, and additional rigidity to the stem. Because of the frequent occurrence of such fibrous masses as part of a bundle, the term fibrovascular bundle has been used to describe them. In many plants the fibrous cells form a mass on the outer side of the bundle, between it and the surface of the stem, while in other plants, particularly in monocotyledons, the fibers form a sheath completely encircling the bundle.

Bundles are often described as open or closed. Open bundles are those in which cambium cells are found, so that by the repeated division of the cambium cells, the size of the bundle constantly increases. Closed bundles are those in which no cambium occurs, they being composed entirely of primary tissues and so once formed remain constant in size.

BUNSEN, ROBERT WILHELM (1811–1899). Born in Germany, Bunsen is remembered chiefly for his invention of the laboratory burner named after him. He engaged in a wide range of industrial and chemical research, including blast-furnace firing, electrolytic cells, separation of metals by electric current, spectroscopic techniques (with Kirchhoff), and production of light metals by electrical decomposition of their molten chlorides. He also discovered two elements, rubidium and cesium.

BUNTING *(Aves, Passeriformes)*. Birds related to the finches and sparrows, including the British yellowhammer, not to be confused with the North American woodpecker, which bears this name, the ortolan, and the snow bunting. In North America the indigo bunting, *Passerina cyanea*, is the most widely distributed species, ranging over the eastern half of the country and sometimes to western Texas. The lazuli, varied, painted, and lark buntings are characteristically western birds. The painted bunting, *Passerina ciris*, is also called the nonpareil (meaning no parallel — no equal). This is one of very few birds with red feathers underneath. The head is blue with red along its back. The wings and tail are brown.

Buntings are among the best of songbirds. Some sing while in flight and during their courting dance. Most species are monogamous. The females incubate the eggs. The male assists in feeding the young sometimes feeding the female while she is on the nest. The nest is well constructed, of a cup-like shape, usually located in trees, but sometimes in structures. Some buntings construct roofs over their nests.

The buntings are extremely abundant. In 1951, it was estimated that about 70 million Bramblings (*Fringilla montifringilla*) ranged into Switzerland to establish a new roosting area close to Thun.

Many authorities treat the buntings, cardinals, sparrows and allied species as one complex family (*Fringillidae*).

BUOY. A buoyant object, usually attached to a specific location on the bottom of the sea or to some submerged object. Buoys are used by navigators to locate channels, dangerous rocks or shoals, for mooring positions, to mark submerged wrecks, and for a variety of other purposes. Various countries have devised their own systems of shapes and colors for coding buoys. In addition to the traditional uses of buoys as visual navigation markers, modern applications include: (1) buoys equipped with electronic and acoustic transmitters, to serve as location markers for ships equipped with suitable receivers; (2) buoys that support research equipment, often electronically transmitting data in connection with oceanographic and meteorological research and reporting; and (3) buoys equipped with receiving and transmitting gear as part of a communications link. In some applications, the buoy may be completely submerged, with a floating marker immediately above the submerged location.

BUOYANCY. The familiar lifting effect of a fluid upon a body wholly or partly submerged in it known as buoyancy, or buoyant force, was first closely studied by the Greek philosopher, Archimedes, in the third century B.C. What is now known as the "principle of Archimedes" states that the buoyant force is equal to the weight of that body of the fluid that the submerged body displaces, and it may be treated as a single force acting vertically upward, through the center of gravity of the displaced fluid (center of displacement). This statement applies whether the submersion is partial or complete. The principle readily follows from the consideration that, if the submerged body were withdrawn and the resulting cavity allowed to fill with the fluid, the latter would be in equilibrium under the joint action of its own weight and the external forces formerly exerted by the surrounding fluid upon the submerged body.

If the buoyant force equals the weight of the submerged body and acts through its center of gravity, the body will be in equilibrium. This might be true if the body had exactly the same mean density as the fluid. It would then remain at rest when completely submerged at the proper level. A balloon, for example, may rise to a certain height and remain suspended or drift along horizontally. But a solid body completely submerged in a liquid does not come so readily to stable equilibrium, because of the very slight compressibility of liquids, the presence of highly compressible gases in pores of the body or in bubbles clinging to it, and the unequal coefficients of expansion of the body and the liquid.

If, however, the body has a lower mean density than the liquid, it will "float," partly submerged to a level, and in a position with reference to the vertical, determined by the Archimedes principle. An important phase of flotation, especially in ship design, is the degree of stability. This may be expressed in terms of the position of the "metacenter." When a boat is tipped very slightly in a given plane, the center of displacement shifts to one side. There is one point of the boat, called the metacenter, which remains vertically above the center of displacement. This point must be higher than the center of gravity, as the resulting couple then tends to restore the boat to its normal position; if it is lower, the boat is unstable and will capsize. The height of the metacenter above the center of gravity (metacentric height) is a measure of the stability in the given vertical plane. It is in general different for different planes; for example, a boat has a transverse and a longitudinal metacenter and metacentric height, corresponding, respectively, to its rolling and its pitching. Thus one may usually change seats in a rowboat without danger, while an equal shift across the boat might overturn it. For buoyancy of fishes, see **Fishes**.

BUOYANCY FREQUENCY. In a continuously stratified fluid, the natural frequency of the vertical oscillation of fluid parcels.

It is also called the *Brunt–Väisälä frequency*. Explicitly, the squared buoyancy frequency is

$$N^2 = -(g/\rho)d\rho/dz,$$

in which g is the acceleration due to gravity and (z) is density as a function of height z.

AMS

BUOYANCY LENGTH SCALE. A measure of the suppression of vertical turbulent motions by statically stable air. Defined as:

$$l_B = \frac{\sigma_w}{N},$$

where σ_w is the standard deviation of vertical velocity, and N is the Brunt–Väisälä frequency. It is a useful length scale for the stable boundary layer.

AMS

BUOYANCY SUBRANGE. For a statically stable atmosphere, the portion of the turbulence kinetic energy spectrum at wavelengths longer than thosex in the inertial subrange, where buoyancy causes the spectral energy S to change with the -3 power of wavenumber k:

$$S(K) \propto N^2 k^{-3}$$

where N is the Brunt–Väisälä frequency.

In conditions of strong static stability, turbulent motions are strongly suppressed in the vertical and have characteristics similar to gravity waves.

AMS

BUOYANCY VELOCITY. A vertical velocity scale w_B for convective boundary layers, that is related to the buoyant driving force for convection and the depth z_i of the mixed layer:

$$wB = \left[\frac{gz_i}{T_{vML}}(\theta_{vsfc} - \theta_{vML})\right]^{1/2},$$

where g is gravitational acceleration, T_{vML} and θ_{vML} are the average absolute virtual temperature and average virtual potential temperature in the mixed layer, respectively, and θ_{vSfc} is the virtual potential temperature of the surface skin. It is related to the Deardorff velocity, $w*$, by $w_B \approx 13w*$. See also **Deardorff Velocity**.

AMS

BURBLE. A separation or breakdown of the laminar flow past a body; the eddying or turbulent flow resulting from this. Burble occurs over the upper surface of an airfoil when the angle of attack has been increased to the point where the air stream no longer follows the profile of the airfoil but breaks away from it. Burble may occur also over the lower surface of an airfoil at high values of negative angles of attack. The space between the airfoil and the detached air stream is filled with eddying, burbling air, and the lift is largely lost. The airfoil is then said to have reached the burble point. This is synonymous with "stalled" in wing terminology.

BURDEN (Instrument). Any circuit or device being measured will be somewhat altered by the instrument used for the measurement. Some amount of power must be transferred between the circuit and the test device in order to obtain a measurement. This characterizes the test instrument as part of the load seen by the device being tested. The power that is transferred to and from the test instrument is termed the *instrument burden*.

In circuits with limited power supplying capabilities, this loading effect, or burdening, by the test instrument will result in erroneous readings. The test instrument chosen must, therefore, exhibit characteristics that will minimize this burdening and thus produce more dependable results. The concept of instrument burden applies to all forms of measurement and also covers cases involving transient energy transfer.

The problem of instrument burden occurs frequently in applications that require direct reading meter movements. Frequently, the meter requires a significant amount of power for its operation. This may represent a large portion of the available power in the circuit being tested and consequently will result in incorrect test results as shown in Fig. 1.

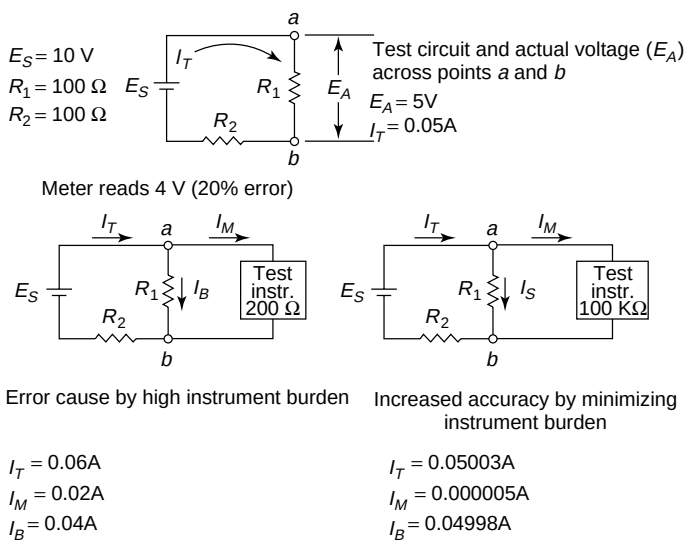

Fig. 1. Effect of instrument burden on measurement accuracy.

BURETTE. A long, slender, graduated glass tube used in volumetric analysis, particularly titrations. An average-size burette will contain 50 milliliters of reagent and will be graduated down to tenths of a milliliter. The amount of reagent required to effect a given reaction, such as neutralization of an acid with a base, is determined by taking the difference between the starting and ending readings of the graduations. So that the end-point can be determined with maximum precision, the bottom portion of the burette is in the form of a tapered, narrow tip, such that the exiting droplets are quite small. Flow of reagent from the burette is controlled by a ground glass stop cock which is an intimate part of the total glass assembly. For laboratories where numerous titrations requiring the same reagent are made routinely, a so-called automatic burette is available. Essentially, this simplifies the reagent refilling operation.

Other types of microanalytical apparatus, such as chromatography, have replaced manual titration methods, particularly where a procedure can be tooled for making tens of thousands of similar determinations automatically.

BURGA. See **Winds and Air Movement**.

BURGER NUMBER. A dimensionless number, Bu, for atmospheric or oceanographic flow expressing the ratio between density stratification in the vertical and the earth's rotation in the horizontal:

$$Bu = \left(\frac{NH}{\Omega L}\right)^2 = \left(\frac{Ro}{Fr}\right)^2 = \left(\frac{R_D}{L}\right)^2,$$

where N is the Brunt-Väisälä frequency, Ω is the angular rotation rate of the earth, H is the scale height of the atmosphere, L is a horizontal length scale of typical motions, Ro is the Rossby number, Fr is the Froude number, and R_D is the Rossby deformation radius. See also **Brunt-Väisälä Frequency**; **Froude Number**; and **Rossby Number**.

Bu is often of order one for many atmospheric phenomena, meaning that both stratification and rotation play nearly equal roles in governing vertical and other motions in the fluid.

Cushman-Roisin, B.: *Introduction to Geophysical Fluid Dynamics*, Pearson Education, Upper Saddle River, NJ, 1994.

AMS

BURGERS VECTOR. A vector representing the displacement of the material of the lattice required to create a dislocation. As usually defined, the Burgers vector must always be a translation vector of the lattice. The Burgers vector may be determined by comparing a path around a dislocation in the crystal with a corresponding path in a perfect part of the lattice. The difference gives the Burgers vector, which describes the magnitude and direction of slip.

BURGESS SHALE. In the Burgess Shale are preserved in exquisite detail complete communities of invertebrates that lived on the seafloor 505 million years ago (Ma), soon after the Cambrian evolutionary explosion. Burgess Shale fossils are extraordinarily important for the light they shed on early animal life and its subsequent evolution.

Location

The main site of the Burgess Shale is high in the Canadian Rocky Mountains, at an approximate elevation of 2,400 meters (7,874feet), on the west side of Fossil Ridge between Wapta Mountain and Mount Field in Yoho National Park, British Columbia, Canada.

The Burgess Shale itself is a sedimentary rock formation about 200 meters (656 feet) thick, composed of dark grey, brown-weathering shale, with minor layers of limestone. It outcrops intermittently along a northwest–southeast trend paralleling the continental divide over a distance of at least 60 kilometers (37 miles) to the southeast from Fossil Ridge. Although it is now 800 kilometers (497 miles) inland from the west coast, half a billion years ago the Burgess Shale animals lived in 80 meters (262 feet) of water on the seafloor adjacent to a submarine limestone cliff, now called the *Cathedral Escarpment*, that was the western edge of the continental platform. A shallow limestone platform stretched 60 kilometers (37 miles) to the east, at least as far as Castle Mountain in Banff National Park where the Stephen Formation, which covers the platform, outcrops. This was near to the Middle Cambrian oceanic shoreline. Paleogeographic maps locate it near the equator.

Fauna and Flora

About 150 animal species have been described from the Burgess Shale [Briggs, et al.:]. Another 20 or so await description. Two phyla, sponges and arthropods, comprise about half of all animals. The sponges, mostly demosponges, although glass and calcareous sponges are also present, are represented by about 35 species. They occur in large numbers on some bedding planes, where the fossils associated with them indicate that they provided shelter, especially for trilobites, and elevated sites for onychophorans to reach out for prey into the water column. The sponges were therefore important for the microenvironments that they provided locally in the community. The largest animal group present, both in numbers and variety, is that of the arthropods, with about 50 species. All three extant arthropod classes –crustaceans, chelicerates (Fig. 1 and uniramians –are represented, as well as the extinct trilobites, the newly recognized predatory dinocarids [Collins, ref.], marine onychophorans, and a significant number still to be classified in any arthropod class. The most common arthropod present, the small *Marrella*, is represented by over 15,000 specimens, followed by the crustacean, *Canadaspis*, with a few thousand, and *Burgessia* and *Waptia* with a few hundred to a thousand each. Other notable arthropods include *Odaraia*, with two large eyes, a tubular carapace and a triple-fluked tail; the earliest known goose

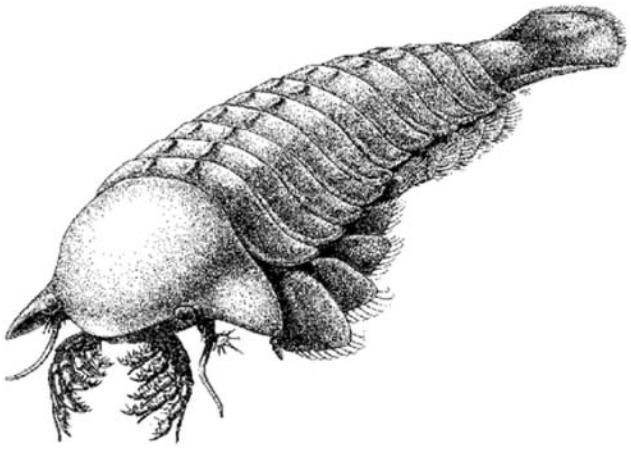

Fig. 1. The earliest known chelicerate, *Sanctacaris*.

barnacle, *Priscansermarinus*, and fish-like forms such as *Plenocaris*. See also **Entoprocta**; **Porifera**; and **Trilobita (Trilobites)**

The most recognizable fossil arthropods are the trilobites, with their mineralized shells, although two forms, *Naraoia* and *Tegopelte*, had nonmineralized exoskeletons. The most common trilobites are *Ogygopsis*, *Olenoides* (some with antennae and limbs preserved), the very small *Ptychagnostus*, used for international correlation, and the equally tiny *Pagetia*, used for local correlation. See also **Arachnida**; and **Crustacea**.

The most remarkable arthropods present are the marine onychophorans and the predatory dinocarids. The discoverer of the Burgess Shale, Charles D. Walcott, Secretary of the Smithsonian Institution, described the first of the marine onychophorans, *Aysheaia*, as an annelid in 1911. Soon after, Charles Schuchert of Yale University wrote to Walcott pointing out its similarity to extant terrestrial onychophorans. At that time, this was the first onychophoran known from the fossil record, and a marine one. Since then, one of the strangest Burgess Shale animals, *Hallucigenia*, after its original orientation was turned upside down, has been identified as another marine onychophoran. Three or four more remain to be described. See also **Annelida**; **Arthropoda (Arthropods)**; and **Onychophora**.

Recognition of the dinocarids, the largest predators known from Cambrian seas, was a long time coming. The claw was described in 1892, but identified as a headless body of a shrimp; the jaws were described in 1911 as a jellyfish; and a poorly preserved body was identified in 1911 as a sea-cucumber. It was not until an almost complete dinocarid, with most of its parts in place, was found in 1967 and first described in 1982, that a reasonable reconstruction of one of these animals was made. At least three dinocarids, all with circular jaws and 32 radiating teeth, have been recognized in the Burgess Shale. The largest, *Anomalocaris*, may have been a meter (3 ft) in length (Fig. 2).

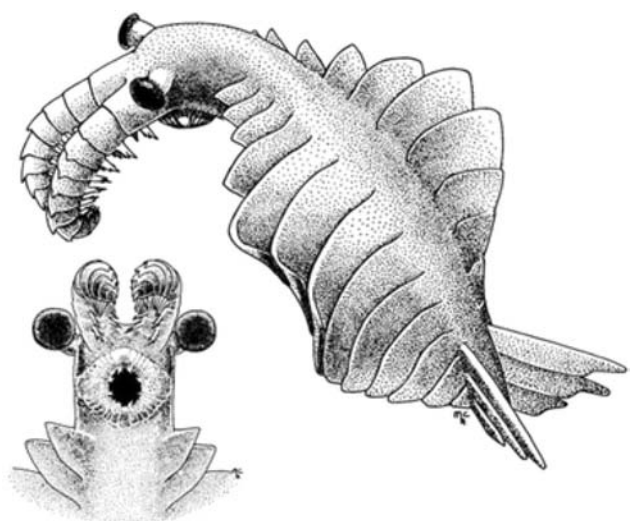

Fig. 2. The dinocarid predator, *Anomalocaris*.

The phyla next in numbers and variety are the echinoderms, priapulids, polychaetes and brachiopods. Echinoderms include the earliest known crinoid, *Echmatocrinus*, at least two eocrinoids, an edrioasteroid, a ctenocystoid, and two or more sea-cucumbers. One free-swimming sea-cucumber, *Eldonia*, is particularly common at two levels in the Burgess Shale, suggesting that it swam in schools. There are probably as many different kinds of priapulid (penis worm) found in the Burgess Shale as are present in the sea today. The most common, *Ottoia*, looks very much like today's *Priapulus*, and was also carnivorous. The remains of mollusks and trilobites have been found in the gut of *Ottoia*. The largest priapulid, *Louisella*, grew to up to 15 centimeters (6 inches) in length. Others, such as *Selkirkia*, lived in a tube. See also **Brachiopoda**; **Echinodermata**; **Mollusca**; and **Mollusks**.

Among the polychaetes, the aphroditid *Wiwaxia* is the most common, followed by the typical bristleworms *Canadia* and *Burgessochaeta*. Brachiopods include both articulate and inarticulate species. Cnidaria include an anemone, *Mackenzia*, a sea-pen, *Thaumaptilon*, and a jellyfish still to be described. Three ctenophores were described recently [Morris, and Collins, ref.]. They are all of the beroid type, without tentacles. Two had 24 comb rows, whereas the third had 80, i.e., all had comb rows in multiples of 8.

Mollusks and mollusk-like animals are represented by the hyolithids, having a conical shell with a lid, and two kinds of monoplacophoran, *Scenella* and *Helcionella*. The chordate, *Pikaia*, still to be described properly, occurs in two communities. Hemichordates and a chaetognath remain to be described.

Lastly, there are a number of forms that do not seem to fit into any living phylum. Those already described include *Amiskwia*, identified by Walcott as a chaetognath; *Banffia*, a tubular, worm-like animal with a terminal mouth; *Odontogriphus*, a flatworm-like animal with semicircular jaws; *Nectocaris*, an animal with both arthropod and chordate characters; and *Dinomischus*, a tulip-like animal with 18 'petals'. Other unknowns await description.

Compared to the fauna, the flora present in the Burgess Shale is meagre. Cyanobacteria and red, green and calcareous algae are all listed. However, the only ones of consequence are the tubular green alga, *Margaretia*, and organic sheets and bundles of filaments of the cyanobacteria, *Morania* and *Marpolia*, respectively. See also **Algae**.

Taphonomy

Whittington, [1971] proposed the currently accepted concept of most of the Burgess Shale animals living on or near the seafloor next to a submarine cliff, the Cathedral Escarpment, and being overwhelmed periodically by mudflows traveling along the bottom. This would both kill and bury the animals. There are few signs of decay or scavenging, which, along with the presence of pyrite on the bedding planes, indicate an environment low in oxygen. Subsequent to burial, the fossil remains were flattened and lithified. The reflectivity of the clay minerals present in the shale, along with the conversion of organic material to graphite, indicates that the Burgess Shale was subject to pressure and heating to approximately 280 °C (536 °F) [Butterfield, ref.], presumably during tectonic activity in the area. Fortunately, because of their location, the fossils in the main Burgess Shale locality were in the "stress shadow" of the submarine cliff of the dolomitized Cathedral Formation, and were preserved from destruction during tectonism.

Mode of Preservation

The fossils of the Burgess Shale are justly famous because of the preservation of their soft tissues and nonmineralized skeletons. For a long time, it was thought that they were composed of aluminosilicates of digenetic origin [Morris, ref.]. Recently, elemental mapping of specimens of the arthropods *Marrella* and *Alalcomenaeus* from the Burgess Shale has demonstrated that the more labile tissues were replaced by clay minerals during authigenesis, whereas the more decay-resistant structures such as polychaete sclerites and setae, priapulid cuticles and the sea-cucumber gut were preserved and/or changed to graphite [Orr, et al.:].

Evolutionary Significance

Walcott's first descriptions of Burgess Shale fossils in 1911 and 1912 created a sensation, because they demonstrated that so many animal groups were present in Cambrian seas. Previously, many animal groups, particularly those without mineralized skeletons, had been found only in much younger rocks, or had no fossil record at all. Hence the first effect

of Walcott's description was to put back in time the first appearances of many animal groups, and to demonstrate that most animal phyla were present in the world's oceans soon after what is now called the Cambrian explosion less than 40 million years before. At the time, Walcott classified all of the Burgess Shale animals in existing groups. Significant differences from their living descendants were attributed to their being "primitive." Overall, Walcott visualized the Burgess Shale community to be much like marine communities in the sea today, without the vertebrates. This view of Burgess Shale animals and Cambrian life in general, persisted until the 1970s. In 1966 and 1967, the Geological Survey of Canada reopened the Burgess Shale quarries, and initiated a restudy of the Burgess Shale fossils, to be undertaken by a team of graduate students and research assistants at Cambridge University, headed by Harry Whittington. As the research progressed, the perception began to develop that some of the fossils could not easily be classified in animal groups alive today. Finally, Whittington declared that the five-eyed *Opabinia* could not be classified as an arthropod, as Walcott had thought, but was of "unknown affinities." Description of other unclassifiable forms followed, particularly those by Simon Conway Morris. Stephen Jay Gould, of Harvard University, chronicled the change in perception by Whittington and his team in his 1990 bestseller *Wonderful Life, The Burgess Shale and the Nature of History*. Gould took the change further, by suggesting that the eight Burgess Shale "weird wonders" that could not be classified in existing phyla, belonged to animal phyla that had become extinct since the time of the Burgess Shale. This in turn demonstrated the role of contingency, mostly mass extinctions, in drastically reducing the number of animal phyla since the Cambrian. Indeed, humans are lucky to be alive, because if the Burgess Shale chordate *Pikaia* and its descendants had not survived, we would not have evolved.

In the years following Gould's book, four of the eight "weird wonders" have been classified in extant phyla, apparently reducing the effects of contingency. However, additional unclassifiable forms have since been found in the Burgess Shale and in two slightly older localities in southwest China (the Chengjiang fauna), and northwest Greenland (the Sirius Passet fauna), so the apparent effects of contingency are as great as ever. Simon Conway Morris joined the debate in a book, *The Crucible of Creation* (1998), in which he criticized Gould's view of contingency, and proposed instead that, owing to biological "convergence," human-like animals would have evolved no matter what happened to *Pikaia* and its descendants.

Research on the fossils of Cambrian communities with soft-bodied remains is still proceeding actively, especially from the Burgess Shale and the Chinese and Greenland localities. Fossils of animals such as phoronids, water bears and tongue worms have now been found in Cambrian rocks, filling in the gaps of existing phyla known from the Cambrian period. There seems little doubt that essentially all animal phyla were present in Cambrian seas. Moreover, the presence of so many Burgess Shale animals in the slightly older Chengjiang fauna demonstrates that the last pulse of the Cambrian explosion was over by 520 million years ago. This was then followed by 15–20 million years when the Burgess Shale/Chengjiang fauna spread throughout the world's oceans. As in the Burgess Shale, the animals of the fauna lived in distinct communities, each dominated at the top of the food chain by a major predator. In most cases, this was one of the fearsome dinocarids.

BURN. When body tissue is exposed to excessive heat, corrosive substances, or radiation, the destroyed areas are termed *burns*. It was estimated by the Atlanta Centers for Disease Control in 1990 that each year 2.5 million people in the United States seek medical care for burns. Of these persons, approximately 100,000 patients are hospitalized, and, of these, 12,000 burn victims die of their injuries. Burn treatment and care have progressed markedly during the past few decades. Prior to World War II, a 50% mortality rate in healthy young adults was the general rule where 30% (or somewhat less) of the body area had been burned. In the early 1990s, the mean burn size associated with a 50% mortality rate in most burn treatment centers ranges from 65 to 75% of the body-surface area. These impressive advances are attributed mainly to a better understanding of the fundamental pathophysiology of burn injuries, which have led to the change and improvement of nearly all treatment techniques.

Even with these improvements, however, burn injuries are second only to motor vehicle accidents as the principal cause of accidental death.

The principal tissue involved often is the skin, but severe burn injuries may penetrate deeper into the body and affect other tissues, such as nerves and bones, blood vessels, etc. In addition to possible damage to underlying organs, in the burn area the body is deprived of its protection against the external environment and, consequently, exposure to bacteria, fungus, and other microorganisms is ever present until the burn area can be protected by other means, including the application of artificial skin. Every effort must be made to keep the patient in highly sterile surroundings and to administer antibiotics for the prevention of infection. Further, the victim must be given drugs to relieve the severe pain that usually accompanies burns. Other factors that disturb the equilibrium of normal body functions must receive immediate attention. Loss of body fluids is an immediate danger and, if not alleviated, can lead to kidney failure, which in times past was frequently, fatal, and still remains a threat.

As pointed out by E.A. Deitch (Division of Burns and Trauma, Louisiana State University Medical Center), progress has continued at a rapid pace in recent years, "In large part because of the increasing availability of genetically engineered molecules, important advances have been made in understanding the basic biology of the burn wound as well as the systemic modulatory effects of the burn-induced inflammatory response. The knowledge that many of the systemic as well as local effects of a burn are mediated by the activation, production, or release of endogenous mediators is beginning to open a new chapter in the care of burn victims."

Care of a burn patient can be divided into three steps: (1) evaluation, (2) systemic therapy, and (3) wound care.

Initial evaluation includes the evidence of respiratory distress or smoke-inhalation injury. Pulmonary dysfunction after burns is a common cause of death. Inhalation injuries are revealed by the findings of soot, mucosal edema, hemorrhage, or ulcerations in the tracheobronchial tree through the use of fiberoptic bronchoscopy. The cardiovascular system must be evaluated. A determination should be made of the percentage of body area that has been burned. Burn depth must be determined. The patient also must be evaluated for other (non-burn) injuries, not an uncommon occurrence.

Systemic therapy includes intubation where respiratory distress is found or is strongly suspected. Supplemental oxygen is provided. Administration of the required body fluids continues over at least an 8-hour period. These are special fluids developed in accordance with years of experience and include Ringer's lactate solution based upon the Parkland formula. A nasogastric tube for gastric decompression will be used. A catheter should be used for monitoring urinary output.

Wound care involves cleaning the burns and gently removing all devitalized tissue with aseptic techniques. Topical antimicrobial agents are applied to all second-degree and third-degree burns. The burns are covered with closed dressing. At all times, the patient must be kept warm. Ice or cold dressing should not be applied because of the risk of hypothermia.

The most feared threat to the survival of burn victims is infection. Burn-wound sepsis and pneumonia may occur. As pointed out by E.A. Deitch, "Since the local mechanical defenses of the skin and respiratory tract are the systems injured most frequently in burn victims, it is not surprising that

the burn wound and the lungs are the most common foci of fatal infection. Although the originating foci of fatal infection can be identified in most patients, in an increasing number of patients with bacteremia, no source of infection can be identified." Recent studies indicate that the primary reservoir for these bacteria may be the intestine.

Classification of Burns. When a burn is caused by a hot liquid, steam, or other hot vapors, it may be termed a *scald*. Usually in this type of burn, the skin is reddened and becomes tender, in what medically may be called a *first-degree* burn. In a *second-degree* burn, the skin is blistered; in a *third-degree* burn, there is extensive tissue damage; some tissue may be charred and fully destroyed. This classification is not precise and is no longer preferred by professionals in the field.

When a burn is severe, the tissue may slough away, a condition known as *eschar*. In extremely severe burns, even the fat, muscles, and bone underlying the entire thickness of the skin also may be damaged. In first- and second-degree burns, the major factor of consideration is the extent of area damaged, determining the type and whether or not medical attention is required. A third-degree burn always requires professional medical attention.

Advances in Burn Therapy. An early breakthrough in burn care appeared in the 1960s with the introduction of water-soluble antibiotic ointments. These ointments can be applied directly to the wound, whereupon the drug is easily absorbed. A range of different antibiotics is used. A main thrust in burn therapy is that of closing the wound as fast as possible. Traditionally, to close a burn wound, surgeons scrape away dead tissue in the burn area, a process that may involve multiple procedures. Prior to the introduction of "artificial" skin, a skin graft would then be made, usually obtaining healthy tissue from the patient. In very severe cases, healthy skin in a sufficient amount may not be available and thus a skin donor, preferably a relative, is sought. As with other transplants, rejection of the donor skin may occur. Skin from cadavers also may be used, but such skin is generally in short supply and rejection may also occur. Heterografts of skin from animals (typically pigs) also have been used, but this skin will only serve as a covering for a week or less after application. While this temporary procedure may prevent infection and loss of fluids, later would scarring and substantial disfigurement may result.

Artificial skin has been envisioned by burn surgeons for many years as possibly the ideal solution for would covering. In the late 1970s, researchers at the Massachusetts Institute of Technology developed an artificial skin, which was first applied to a severely burned patient in late 1981. The patient, with nearly 80% of body surface burned and destroyed, received the artificial skin. The procedure was successful. After several months of therapy, the patient appeared much as before the accident. The artificial skin had prevented fluid loss and infection and, over a relatively long period of recovery, the skin performs like normal skin without disfigurement. The procedure has since been used in scores of cases.

The technology of preparing artificial skin is well beyond the scope of this encyclopedia. Briefly, one method is comprised of two basic steps, one for each of the skin's layers — the epidermis and the dermis. In step one, fibroblasts (connective tissue) from the patient or test animal are combined with collagen (a complex protein found in skin, tendon, and bone) in a nutrient medium. In the medium, the ingredients condense to a fraction of their original volume in a period of several days. The collagen fibers come close together and form a strong and flexible sheet of tissue. The sheet takes the form of the container in which it was cast. This substance thus becomes the *dermal* equivalent of skin. In a second step, a few epidermal cells are taken from the uppermost layers of a patient's healthy skin, then separated from one another by using appropriate enzymes. These are then sprinkled over the dermal equivalent. The cells proliferate and form islands and then a sheet of cells. The result is a two-layered "skin" which can be grafted to the damaged area. Reports show that there is essentially no limit to the size of the skin that can be produced. Sheets up to two square meters in area have been prepared from a single small biopsy.

Once a burn patient is well on the way to recovery, the long-term prospects must be confronted. Scarring is nearly always a problem. Cosmetic surgery has accomplished much by way of restoring faces and hands. Scar tissue is also reduced by covering the burn wound early and preventing infections. As new skin grows over a wound, it contracts, sometimes locking joints or distorting the face by pulling skin down from the eyes. Early rehabilitation, including simple exercises, can contribute much toward alleviating these problems.

First aid measures for burns, where immediate professional medical assistance is not available, are well covered in literature available from the American National Red Cross.

Radiation Injury. Although usually categorized as radiation burns, such injuries are quite different from thermal burns. The specific effects of radiation injury depend not only upon the exact area of the body exposed, but also upon the fact that certain kinds of tissue are more susceptible to injury than others. In humans, sensitivity of tissues to radiation decreases in the following order: (1) lymphoid tissue and bone marrow; (2) epithelial tissue, such as the testes and ovaries; (3) salivary gland; (4) skin; (5) mucous membranes; (6) endothelial cells of blood vessels and peritoneum; (7) connective tissue; (8) muscle, bone, and nerve tissue. It is in this order, therefore, that the specific effects of exposure to ionizing radiation might be expected to appear and do the most harm. See also **Bone**.

Blood changes are among the earliest to appear, and may occur as the result of doses of radiation that produce no other effect. If the white blood cells manufactured in the lymphatic tissue do not decrease in number within 72 hours following exposure, no serious dose of radiation has usually been received. Increase in the number of lymphocytes is often the first sign of recovery from radiation sickness. It has been recognized that leukemia, a malignant disease in which there is a considerable increase in the numbers of white blood cells, may be induced by overexposure to x-rays. The incidence of leukemia in radiologists is reported to be nine times as high as it is in other physicians. Careful studies of the incidence of leukemia among the population of cities suffering from an atomic blast indicate a significant increase in this disease among survivors. See **Blood**.

BURNER. A principal component of combustion equipment. While there are specialized burners for disposing of various kinds of waste, the usual meaning of the term applies to the burning of fuels with air to generate heat — as in the case of burning a fuel in a boiler furnace for the purpose of generating steam. See also **Boiler (Steam Generator)**; and **Combustion**.

Oil and Gas Burners

Burners are normally located in the vertical walls of the furnace. The burners introduce the fuel and air into the furnace to sustain the exothermic chemical reactions for the most effective release of heat. That effectiveness is judged by the following factors:

1. The rate of feed of the fuel and air shall comply with the load demand on the boiler over a predetermined operating range.

2. The efficiency of the combustion process shall be as high as possible with the minimum of unburned combustibles and minimum excess air in the products.

3. The physical size and complexity of the furnace and burners shall be as small as possible to minimize the required investment and to meet

the limitations on space, weight, and flexibility imposed by the service conditions.

4. The design of the burners, including the materials used, shall provide reliable operation under specified service conditions, and shall assure meeting accepted standards on maintenance for the burners and furnaces in which they are installed.

5. Safety shall be paramount under all conditions of operation of burners, furnace, and boiler, including starting, stopping load changes, and variations in the fuel.

The normal use of a steam generator requires operation at different outputs to meet varying load demands. The specified operating range or "load range" for a burner is the ration of full load on the burner to the minimum load at which the burner must be capable of reliable operation.

Combustion air is generally delivered to the burners by fans. It is necessary to supply more than the theoretical air quantity to assure complete combustion of the fuel in the combustion chamber (furnace). The amount of excess air provided should be just enough to burn the fuel completely in order to minimize the sensible heat loss in the stack gases.

Continuity of service is enhanced by designing the furnace and arranging the burners to minimize slagging and fouling of heat-absorbing surfaces for the normal range of fuels burned.

Maintenance costs of the burner are minimized by (1) the least exposure to furnace heat, and (2) provision for replacement or repair of vulnerable parts while the unit continues in operation.

Burner Types. The most frequently used burners are the circular type. Fig. 1 shows a single circular register burner for gas and oil firing; Fig. 2 shows a circular type dual register burner for firing oil or pulverized coal. The circular type dual register burner was developed for nitrogen oxides (NO_x) reduction. The maximum capacity of the individual circular burner ranges up to 300 million Btu/hour (1 Btu = 0.2520 kilogram-calories), dependent upon the atomizer used.

In both circular and cell burners the tangentially disposed "doors" built into the air register provide the turbulence necessary to mix the fuel and air and produce short, compact flames.

While the fuel is introduced to the burner in a fairly dense mixture in the center, the direction and velocity of the air, plus dispersion of the fuel, completely and thoroughly mixes it with the combustion air.

Oil Burners. In order to burn fuel oil at the high rates demanded by modern boiler units, it is necessary that the oil be atomized, that is, dispersed into the furnace as a fine mist, somewhat like a heavy fog. This exposes a large amount of oil particle surface for contact with the combustion air to assure prompt ignition and rapid combustion. There are many ways of atomizing fuel oil. The two most popular ways, steam or air, and mechanical atomizers are discussed below.

Natural Gas Burners. The variable-mix multi-spud gas element (Fig. 1) was developed for use with circular-type burners for obtaining good ignition stability under most conditions, such as the two-stage combustion technique and vitiated air (by gas recirculation) to the burner.

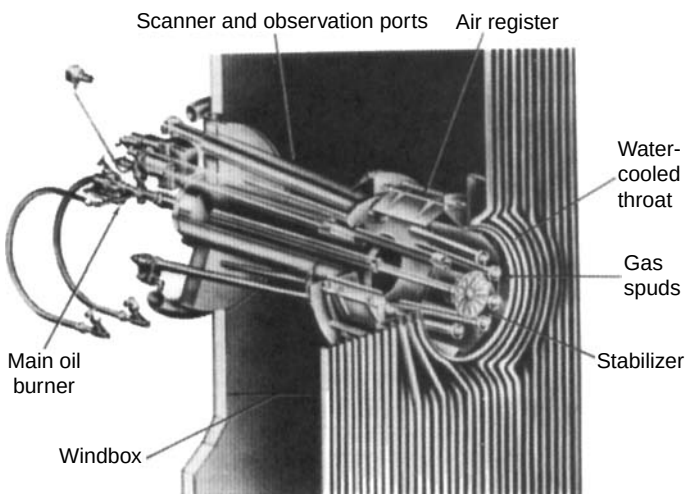

Fig. 1. Circular register burner with water-cooled throat for oil and gas firing. (*Babcock & Wilcox.*)

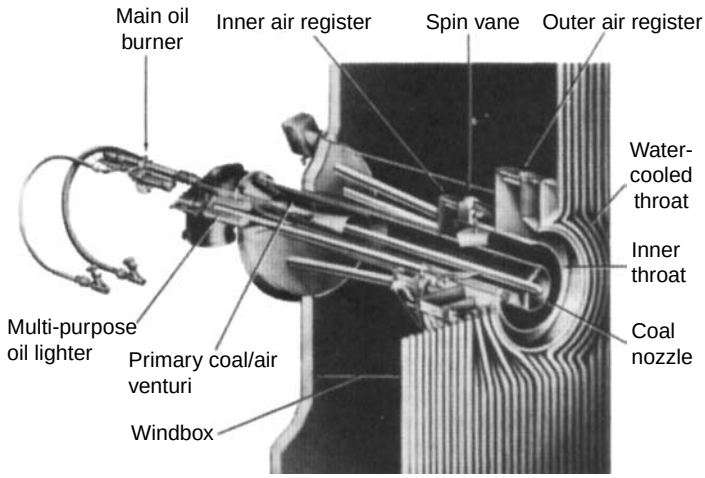

Fig. 2. Circular-type dual register burner showing location of burner components. (*Babcock & Wilcox.*)

Burner for Other Gases. Many industrial applications utilize coke oven gas, blast furnace gas, refinery gas or other industrial by-product gases. With these gases the heat release per unit volume of fuel gas may be very different from that of natural gas. Hence, gas elements must be designed to accommodate the particular characteristics of the gas to be burned. Also burners must be designed with reference to ignition stability and load range factors which govern in each case. Other special problems may be introduced by the presence of impurities in industrial gases, such as sulfur in coke oven gas, and entrained dust in blast furnace gas.

Lighters (Ignitors) and Pilots. Equipment is available for boiler units, ranging from the smallest to the largest, that allows the boiler operator to ignite the main fuel by the simple expedient of pressing a button. This equipment ranges from spark devices that ignite fuel oil directly, to gas or light oil equipment, in itself spark-ignited, which is used for ignition of the main streams of gas and fuel oil. These devices are available with control equipment that ranges from the simplest push button requiring observation of ignition by the operator at the burner, to a fully "programmed" starting sequence, complete with interlocks and flame-sensing equipment, all remotely operated from the boiler control room.

Usually the ignition device is energized only enough to assure that the main flame is self-sustaining. With the fuel normally used in oil or natural gas burners, ignition should be self-sustaining within one or two seconds after the fuel reaches the combustion air. On a fully automated burner it is customary to allow 10 to 15 seconds "trial for ignition" so that the fuel can reach the burner after the fuel shut-off valve on the burner is opened.

Burner Pulsation. One of the mystifying problems associated with gas burners and, to a much less degree, with oil burners, is that of burner pulsation. It appears to result from certain combinations of combustion chamber size and configuration coupled with some characteristic of the burners, perhaps too perfect mixing of fuel and air at the burner. When one or more burners on a large unit start to pulsate, it may become alarmingly violent, at times shaking the whole boiler. Making an adjustment of only one burner may start or stop pulsation. At times only minor burner adjustments eliminate the pulsation. In other instances, it is necessary to alter the burners. This may involve modifying the gas ports, impinging gas streams on one another, or using some other device that effectively alters the mixing of the gas with the air.

Coal-Burning Systems

Historically in the United States, more than three-fourths of the mined tonnage of bituminous coal and lignite has been used to generate steam for electrical power. A high percentage of the coal used for the generation of steam is burned in pulverized form.

Selection of Coal-Burning Equipment. Selection of equipment for a particular installation consists of balancing the investment, operating characteristics, efficiency, and type of coal to be used — with the objective of achieving the most economical installation. Almost any coal can be burned successfully in pulverized form or on some type of stoker. The capacity

limitations imposed by stokers have been overcome by the development of pulverized-coal and cyclone-furnace firing. These improved methods also provide: (1) the ability to use coal, from fine particles up to those 2 inches (5 centimeters) in maximum size; (2) improved response to load changes; (3) an increase in thermal efficiency, because of lower excess air for combustion and lower carbon loss than with stoker firing; (4) a reduction in labor required for operation; and (5) an improved ability to burn coal in combination with oil and gas.

Pulverized-Coal Systems

The function of a pulverized-coal system is to pulverize the coal, deliver it to the fuel-burning equipment, and accomplish complete combustion in the furnace with a minimum of excess air. The system must operate as a continuous process and, within specified design limitations, the coal supply or feed must be varied as rapidly and as widely as required by the combustion process.

A small portion of the air required for combustion (15 to 20% in current installations) is used to transport the coal to the burner. This is known as primary air.

In the direct-firing system, primary air is also used to dry the coal in the pulverizer. The remainder of the combustion air (80 to 85%) is introduced at the burner and is known as secondary air.

The two basic equipment components of a pulverized-coal system are:

1. The pulverizer which pulverizes the coal to the fineness required.
2. The burner which accomplishes the mixing of the pulverized-coal-primary-air mixture with secondary air in the right proportions and delivers the mixture to the furnace for combustion.

Other necessary requirements are:

3. Hot air for drying the coal for effective pulverization.
4. Fan(s) to supply air to the pulverizer and deliver the coal-air mixture to the burner(s).
5. Coal feeder to control the rate of coal feed to each pulverizer.
6. Coal and air conveying elements.
7. Pyrites reject system.
8. Measuring and control elements.

Two principal systems — the bin system and the direct-firing system — have been used for processing, distributing, and burning pulverized coal. The direct-firing system is the one being installed almost exclusively today.

Direct-Firing System. The bin system has been superseded by the direct-firing system because of improvements in safety conditions, plant cleanliness, greater simplicity, lower initial investment, lower operating cost, and less space requirement.

The pulverizing equipment developed for the direct-firing system permits continuous utilization of raw coal directly from the bunkers where coal is stored in the condition in which it is received at the plant. This is accomplished by feeding the raw coal directly into the pulverizer, where it is dried as well as pulverized, and then delivering it to the burners in a single continuous operation.

Components of the direct-firing system (Fig. 3) are as follows:

1. Raw-coal feeder.
2. Source (steam or gas air heater) to supply hot primary air to the pulverizer for drying the coal.
3. Pulverizer fan, also known as the primary-air fan, arranged as a blower (or exhauster).
4. Pulverizer arranged to operate under pressure (or suction).
5. Coal-and-air conveying lines.
6. Burners.

Two direct-firing methods are in use: (1) the pressure type, which is the more commonly used; and (2) the suction type.

In the pressure method, the primary-air fan, located on the inlet side of the pulverizer, forces the hot primary air through the pulverizer where it picks up the pulverized coal, and delivers the proper coal-air mixture to the burners. Where a separate air heater is provided, the fan operates on cold air, forcing the air first through the air heater and then the pulverizer. In either event, the coal is delivered to the burners by a fan operating entirely on air, so that the entrained dust passes through the fan. One pulverizer generally furnishes the coal for several burners. With the pressure method, it is usual to supply each burner with a single conveying line direct from the pulverizer, thus eliminating the expense of a distributor.

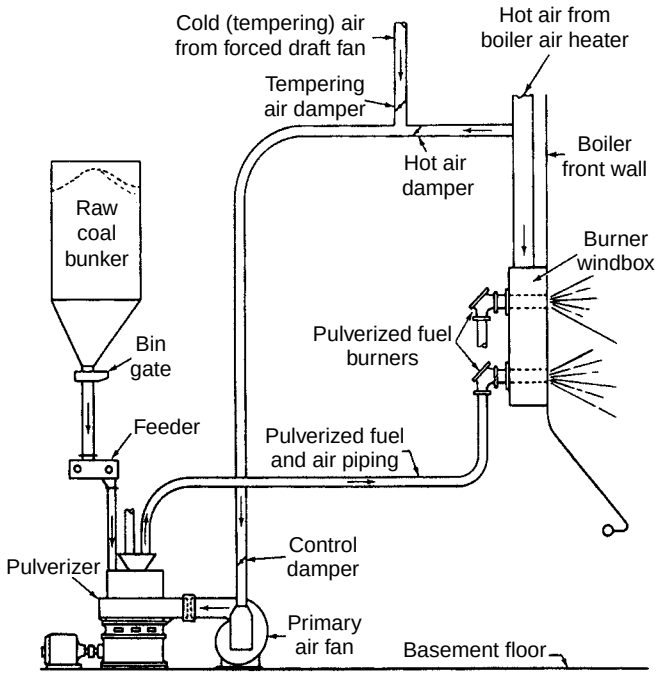

Fig. 3. Direct-firing system for pulverized coal. (*Babcock & Wilcox.*)

The feeding of coal and air to the pulverizer is controlled by either of two methods: (1) the coal feed is proportioned to the load demand, and the primary-air supply is adjusted to the rate of coal feed; or (2) the primary air through the pulverizer is proportioned to the load demand, and the coal feed is adjusted to the rate of air flow. In either case, a predetermined air-coal ratio is maintained for any given load.

Types of Pulverizers. The reduction of materials to a fine-particle size for countless uses is a very old art. Coal-pulverizing equipment is based, generally, on rock and mineral-ore grinding machinery. The principles involved in all pulverizing machinery are grinding, (1) by impact; (2) by attrition; (3) by compression; or (4) by a combination of two or more of these methods. Most pulverizers involve ball-and-race or roll-and-race designs. Other types include bowl mills, tube mills, and impact mills. Pulverizer requirements may be summarized by:

1. Rapid response to load change and adaptability to automatic control.
2. Continuous service for long operating periods.
3. Maintenance of prescribed performance throughout the life of pulverizer grinding elements.
4. A wide variety of coals should be acceptable.
5. Ease of maintenance with the minimum number and variety of parts, and space adequate for access.
6. Minimum building volume required.

Exhausters and Blowers. Primary air is required for conveying the pulverized coal to the burners. In the direct-firing system the primary air is supplied through pulverizers. With a pressure system, the primary-air fan handles clean air and is not subjected to abrasion by the pulverized coal. In this case a high-efficiency fan can be used since the conditions permit an efficient rotor design and high tip speed.

With a suction system, the fan or exhauster must handle pulverized-coal-laden air. To comply with the National Fire Protection Association requirements, the exhauster housing must be designed to withstand an explosion with the fan. Furthermore, since the exhauster is subject to excessive wear, the design is limited to a paddle-wheel type of heavy construction and hard-metal or other protective-surface coatings. All of these construction features are detrimental to the mechanical efficiency of the fan.

Pulverized-Coal Burning Equipment

As for oil and gas, the burner is the principal equipment component for the firing of pulverized coal, and much of the discussion concerning the

burning of oil and gas is basically applicable to pulverized coal. However, the use of solid fuel in pulverized form presents additional problems in the design of boilers and furnaces.

As oil must be atomized to expose a large amount of oil particle surface to combustion air, so coal must be pulverized to the point where particles are small enough, i.e., surface is sufficiently large per unit of mass to assure proper combustion.

In the direct-firing system, coal is dried and delivered to the burner in suspension in the primary air, and this mixture must be adequately mixed with the secondary air at the burner.

Burner Types. As with oil and gas, the most frequently used burners are the circular type. A circular dual register type burner is shown in Fig. 4. Circular single register burners are also used. Either of these burners is designed for firing pulverized coal only. They can be used singly or in multiples. The dual register type was developed for NOx reduction. However, either of these burner types can be equipped to fire any combination of the three principal fuels. It is to be stressed, however, that combination pulverized coal firing with oil in the same burner should be restricted to short emergency periods. It is not recommended for long operating periods due to possible coke formation on the pulverized-coal element.

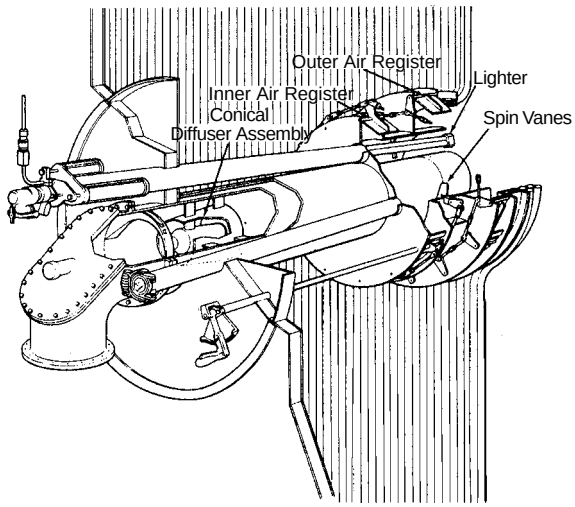

Fig. 4. Circular dual register pulverized-coal burner. (*Babcock & Wilcox*.)

Excess Air. Pulverized coal requires more excess air for satisfactory combustion than either oil or natural gas.

One reason for this is the inherent maldistribution of coal both to individual burner pipes and to the fuel discharge nozzles. The minimum acceptable quantity of unburned combustible is usually obtained with 15% excess air as measured at the furnace outlet at high loads. This allows for the normal maldistribution of both primary-air-coal and secondary air. Higher excess air values may be necessary to avoid slagging or fouling of the heat absorption equipment.

In the design of the burner and furnace of a pulverized-coal-fired unit, consideration must be given to the burner arrangement and furnace configuration to minimize slagging or fouling from coal ash. Increasing excess air will permit most designs to perform satisfactorily but this can be an uneconomical long-time substitute for good basic design.

In general, the pulverizer-burner combination can operate satisfactorily from full load to approximately 40% of full load with all pulverizers and burners in service. In some installations a pulverizer and set of burners, in addition to the number actually required, is provided to assure availability of the boiler unit in case of unscheduled outage of a pulverizer. Where spares are provided, it is generally most economical to operate with the greatest number of burners and pulverizers in service consistent with the capacity demand on the unit. Although the use of this excess equipment raises the minimum load that can be obtained without cutting out pulverizers and burners, other benefits offset this disadvantage.

It is easier to pick up load with an operating pulverizer than to bring an idle unit into service. Also, at high loads on a boiler unit the burner elements in idle burners deteriorate quickly because of radiant heat. Air that is admitted through idle burners to reduce over-heating does not enter into the combustion reaction but is excess air which lowers the boiler efficiency.

Cyclone Furnace. The introduction of pulverized-coal firing in the 1920s was a major advance, providing advantages over stoker firing. As of the late 20th Century, pulverized-coal firing was highly developed and remained the most effective way to burn many types of coal, particularly the higher grades and ranks. However, since about 1940, the cyclone furnace has been developed and is now widely used.

The cyclone furnace is applicable to coals having a slag viscosity of 250 poises at 1427 °C or lower, provided the ash analysis does not indicate excessive formation of iron or iron pyrites. With these coals, cyclone-furnace firing provides the benefits obtainable with pulverized-coal firing, plus the following advantages: (1) reduction in fly ash content in the flue gas; (2) saving in the cost of fuel preparation, since only crushing is required instead of pulverization; and (3) reduction in furnace size.

The cyclone furnace is a water-cooled horizontal cylinder in which fuel is fired, heat is released at extremely high rates, and combustion is completed. Its water-cooled surfaces are studded, and covered with refractory over most of their area. Coal crushed in a simple crusher, so that approximately 95% will pass a four-mesh screen, is introduced into the burner end of the cyclone. About 20% of the combustion air, termed primary air, also enters the burner tangentially and imparts a whirling motion to the incoming coal. Secondary air with a velocity of about 300 feet/second (90 meters/second) is admitted in the same direction tangentially at the roof of the main barrel of the cyclone and imparts a further whirling or centrifugal action to the coal particles. A small amount of air (up to about 5%) is admitted at the center of the burner. This is known as "tertiary" air.

The combustible is burned from the fuel at heat release rates of 450,000 to 800,000 Btu/cubic foot/hour (1 Btu = 0.2520 Calorie) and gas temperatures exceeding 1649 °C are developed. These temperatures are sufficiently high to melt the ash into a liquid slag, which forms a layer on the walls of the cyclone. The incoming coal particles are thrown to the walls by centrifugal force, held in slag, and scrubbed by the high-velocity tangential secondary air. Thus, the air required to burn the coal is quickly supplied, and the products of combustion are rapidly removed.

The gaseous products of combustion are discharged through the water-cooled re-entrant throat of the cyclone into gas-cooling boiler furnace. Molten slag in excess of the thin layer retained on the walls continually drains away from the burner end and discharges through the slag tap opening to the boiler furnace, from which it is tapped into a slag tank, solidified, and disintegrated for disposal.

The cyclone furnace is capable of burning successfully a large variety of fuels. A wide range of coals varying in rank from low volatile bituminous to lignite may be successfully burned and, in addition, other solid fuels, such as wood bark, coal chars, and petroleum coke, may be satisfactorily fired in combination with other fossil fuels. Fuel oils and gases are also suitable for firing.

Stokers. A successful stoker installation requires the selection of the correct type and size for the fuel to be used and the desired capacity. Also, the associated boiler unit should have the necessary instruments for the proper control of the stoker. The grate area required for a given stoker type and capacity is determined from allowable rates established by experience.

Mechanical stokers can be classified in four main groups, based on the method of introducing fuel to the furnace: (1) Spreader stokers; (2) underfeed stokers; (3) water-cooled vibrating-grate stokers; and (4) chain-grate and traveling-grate stokers.

BURNET, FRANK MACFARLANE (1899–1985). Frank Burnet was born in Traralgon, Victoria, Australia in 1899. He was educated at state schools and Geelong College and the University of Melbourne where he received the MBBS degree in 1922 and the MD in 1923. He worked in pathology at the Royal Melbourne Hospital, an institution that was to

play a critical role in his career. During this time, he was appointed a candidate researcher and administrator of the clinical research unit, the Walter and Eliza Hall Institute of Medical Research. His first research was on agglutinin reactions in typhoid fever in 1923. To further his education and skills in bacteriology, Burnet departed for London to serve as a Beit Fellow at the Lister Institute (1926–1927) and received a PhD in 1928 from the University of London. He worked as a fellow in virus research in London at the National Institute for Medical Research, Hampstead, from 1932 to 1933. On returning to Australia, he became Assistant Director of the Hall Institute in Melbourne in 1934 and was appointed Director from 1944–1965. Burnet was elected to fellowship in the Royal Society in 1942. Prior to 1957, his research addressed mainly viral and rickettsial diseases with special emphasis on influenza virus. He made significant contributions in the fields of virology and theoretical immunology. He maintained an active interest in infectious diseases and considered them from an ecological perspective. His book first entitled *Biological Aspects of Infectious Disease* and later changed to *Natural History of Infectious Disease* was a popular classic and appeared in four separate editions from 1940 to 1972. See also **Influenza**.

Burnet first became interested in immunology in 1928 when he discovered staphylococcal toxin and demonstrated the presence of antitoxins in the blood sera of patients. Subsequently, he demonstrated variations among strains of both influenza and poliomyelitis viruses. He found that both viruses and bacteria were capable of mutation and selection. He discovered that a bacteriophage could replicate together with the bacterial genome for generations (lysogeny). His eclectic laboratory experience served him well in formulating clever hypotheses in experimental biology. His monographs became classics, such as the one published in 1941 that offered an alternative to the template or instructive theory of antibody formation. In Burnet's concept, the antigen did not serve as a template for the shaping of proteins but impressed itself into adaptive enzymes that would order amino acids into an appropriate configuration. This adaptive enzyme concept represented an early explanation of substrate induction of an enzyme which was later explained as derepression and exposure of the associated gene to messenger RNA. This theory had the Lamarckian requirement that an acquired characteristic had to be inherited but it did account for immunological memory and augmented responses. Nevertheless, his monograph challenged the prevailing views of immunochemists of no less prominence than Linus Pauling, a Noble laureate and friend of the eminent immunochemist Karl Landsteiner. At a meeting in 1944 between Burnet and Pauling in the USA, Burnet could not be persuaded to change his views. With important research on transplantation and immunological tolerance taking place in the 1940s during World War II and thereafter, the template instructionist theory of antibody formation could not account for the new findings. See also **Landsteiner, Karl (1868–1943)**; and **Pauling, Linus Carl (19011994)**.

Burnet and F. Fenner at the Walter and Eliza Hall Institute were beginning to take a view of antibody (Ab) production different from that proposed by chemists adhering to the template theory of Ab synthesis. The second edition of their monograph, entitled *The Production of Antibodies*, published in 1949, contains an exposition of their developing concepts. Burnet advocated but later abandoned a self-marker hypothesis to explain Ab synthesis.

The template theory of Ab production that had been popular with chemists and prevailed for so many years could no longer explain new biological revelations that included immunological tolerance. And it had never explained the anamnestic (memory) immune response. The *coup de grace* to this hypothesis was the observation that mature Ab synthesizing cells contained no antigen (Ag). Burnet proposed lymphoid cells genetically programmed to synthesize one type of Ab.

N. K. Jerne proposed a natural selection theory of Ab formation in 1955 based on various Ab populations. Substituting replicating cells for the Ab populations, David W. Talmage published a cell selection theory in 1956. He communicated his ideas to Burnet in Australia who had independently formulated a similar concept. Clearly acknowledging Talmage's contribution, Burnet named his own version of the cell selection hypothesis the "clonal selection theory of acquired immunity."

Burnet postulated the presence of numerous Ab-forming cells, each capable of synthesizing its own predetermined Ab. One of these cells, after having been selected by the best fitting Ag, multiplies and forms a clone of cells that continue to synthesize the same Ab. Provided that one accepted the existence of very many different cells, each capable of synthesizing an Ab of a different specificity, all known facts of Ab formation were easily accounted for. An important element of the clonal selection theory as proposed by Burnet was the hypothesis that the many cells with different Ab specificities arise through random somatic mutations, during a period of hypermutability, early in the animal's life. Also early in life, the "forbidden" clones of antibody-forming cells (i.e. the cells that make Ab to the animal's own Ags) are destroyed after encountering these autoantigens. This process accounted for an animal's tolerance of its own Ags.

Ag would have no effect on most lymphoid cells but would selectively stimulate those cells already synthesizing the corresponding Ab at a low rate. The cell surface Ab would serve as receptor for Ag and proliferate into a clone of cells producing Ab of that specificity. Burnet introduced the "forbidden clone" concept to explain autoimmunity. Cells capable of forming Ab against a normal self Ag were "forbidden" and eliminated during embryonic life. Since that time various modifications of the clonal selection hypothesis have been offered.

Burnet suggested a concept of "clonal deletion" as a means to eliminate precursor lymphocytes capable of reacting with self antigens before birth. This concept provided for the permanent removal of self-reactive lymphocytes with the possibility that so-called "forbidden clones" might develop by spontaneous mutation in the later life of the individual. Therefore, tolerance to some self antigens is maintained even when the Ag is removed, whereas tolerance to other self antigens may be terminated. Thus, natural tolerance or unresponsiveness could result from the elimination of immunocompetent cell clones specific for self antigens, or clones of immunocompetent cells rendered unresponsive by early exposure to self-antigenic determinants.

Peter Medawar and associates tested Burnet and Fenner's concept in their transplantation experiments in mice and by 1953 had provided sufficient evidence to confirm Burnet's clonal selection hypothesis. Medawar introduced the term acquired immunological tolerance. For this work, Burnet and Medawar were awarded the Nobel Prize for Medicine or Physiology in 1960. Although Burnet retired officially in 1965, he continued as a research fellow in the Department of Bacteriology at the University of Melbourne until his death. His concepts were pivotal in shaping modern immunological thought. See also **Medawar, Peter Brian (19151987)**.

BURNING INDEX. See **Meteorology**.

BURNING RATE (symbol r). The velocity at which a solid propellant in a rocket is consumed.

Burning rate is measured in a direction normal to the propellant surface and is usually expressed in inches per second.

BURNISHING. A surface-hardening or surface-finishing process for metals, effected by the application of a roller or blunt rod under pressure to the surface. It is used for gear-tooth finishing to some extent. The work is rotated between three hardened and ground burnishing gears. Burnishing will not correct errors but serves to compress the surface of the teeth and provides a slight surface hardness. As a finishing operation prior to hardening, it can also be used to remove burrs and bruises.

BURROWING. The habit of living underground and also the preparation of runways and living quarters beneath the surface. Many animals such as wolves, not specially developed for burrowing, prepare burrows or dens for the birth of their young and for hiding places. Others are normally at home in the ground and come to the surface only under certain

conditions; here examples range from the worms, of which the earthworm is particularly well known, to highly specialized mollusks, insects, and vertebrates.

The less specialized burrowing animals cut away the earth by means of structures not associated with this use, such as the claws of reptiles, birds, and mammals, while in many of the more specialized forms these parts are highly developed and modified and other special adaptations are evident. The earthworm merely eats its way through the earth, and some insects are capable of burrowing into the tissues of plants in the same way. The shipworm, a mollusk, has the valves of the shell adapted for cutting burrows into wood.

The moles are highly developed for burrowing by the powerful build of the fore-limbs and by their large claws, and are further adjusted to life underground by their fine moisture-resisting fur. The poorly developed eyes are also correlated with conditions underground, since these animals rarely enter the light.

Mole crickets are in some ways like the moles. Their front legs are broadened and provided with claw-like processes and the body is covered with a downy vesture that repels moisture.

Burrowing offers the animal greater safety than can be enjoyed on the surface of the earth, since no predator can compete with the highly developed burrowing animal on equal terms below the surface.

BURROWS-WHELLER TRANSFORMS. See **Data Compression**.

BURSA AND BURSITIS. A small sac of connective tissue, usually interposed between joints, lined by synovial membrane and filled with fluid, which reduces friction. Bursae function as lubricating buffers between moving parts, the tendons and bone, or bone and joint capsule, or between skin and bony structures. There are approximately 1,000 bursae in the human body. Bursitis is inflammation of the bursae, usually caused by overuse of a joint, trauma, or infection. Bursitis may be acute or chronic. The acute form is disabling, the involved area being swollen, tender, and very painful in motion. The bursal sac is often distended with fluid in chronic bursitis. Occasionally an acute calcium deposit also is present. The shoulder joint (acromial and subdeltoid bursae), the elbow (olecranon bursa), and the knee (prepatellar bursa) are common sites for bursitis. Treatment usually is confined to immobilization of the affected area, followed by gradually progressing exercises. In chronic cases, patients should analyze their postural habits, note activities that may constantly irritate a specific joint, and make remedial changes. For example, shoulder bursitis may be prevented by avoiding long periods of leaning on one arm or resting an arm over a car windowsill for extensive periods.

Septic bursitis usually follows an injury and is caused by *Staphylococcus aureus* infection. There is considerable swelling, pain, and often, mild fever. This condition is usually seen in the olecranon (elbow) or prepatellar (knee) bursas and occurs most frequently in men. For moderate cases, oral antibiotics and/or needle aspiration may be sufficient therapy.

BURST. In cosmic ray studies a burst is an exceptionally large electric pulse observed in an ionization chamber, signifying the simultaneous arrival or emission of several or many ionizing particles. Such an event may be caused by a cosmic ray shower or by a spallation disintegration of the type that can produce a star. In communications a burst is a sudden increase in signal strength of waves being received by ionospheric reflection.

BURSTER. See **Winds and Air Movement**.

BUSH-CRICKET *(Insecta, Orthoptera).* Crickets of several species, most of which are found chiefly in shrubby vegetation.

BUSHING. In mechanical terminology, to bush is to reduce the size of a hole. A bushing is a hollow cylinder used as a renewable liner for a bearing or a drill jig.

A bushing is also a pipe fitting employed to reduce the size of pipe to a smaller size. When pipe is employed to contain electrical wires, the open end from which the wires emerge is often capped by a bushing, which substitutes a smoothly rounded surface for the sharp edges of an unbushed conduit. The sharp edges would tend to abrade the insulation on the wires.

In electrical work, where a conductor at high voltage emerges from one insulated condition to another, an intermediate support must be provided. An electrical bushing is needed to provide the support and insulation between the conductor and the supporting surface. For example, where the conductor leaves the insulated interior of a transformer case, a bushing is provided to support the terminal where it passes through the case, and to insulate the voltage difference between the terminal and the grounded case. A bushing is also required at terminals of oil circuit breakers, and at potheads where the conductors of a multiconductor cable are separated and brought out from the cable sheath for external connections. To obtain sufficient dielectric strength for very high voltage bushings without having the physical dimension of the bushing become excessive, the oil-filled bushing or the condenser-type bushing was developed. The condenser bushing is made of thin layers of tin foil wound between concentric layers of insulation. It is possible in this way to give uniform potential drop through the thickness of the bushing.

BUTADIENE. [CAS 106-99-0] $CH_3CH{:}C{:}CH_2$, 1,3- butadiene (methyl-allene), formula weight 54.09, bp $-4.41\,^{\circ}C$, sp gr 0.6272, insoluble in H_2O, soluble in alcohol and ether in all proportions. Butadiene is a very reactive compound, arising from its conjugated double-bond structure. Most butadiene production goes into the manufacture of polymers, notably SBR (styrene-butadiene rubber) and ABS (acrylonitrile-butadiene-styrene) plastics. Several organic syntheses, such as Diels-Alder reaction, commence with the double-bond system provided by this compound.

Butadiene came into prominence as an important industrial chemical during World War II as the result of the natural rubber shortage. Originally, butadiene was made by the dehydrogenation of butylenes. Later, the naphtha cracking for ethylene and propylene, with a byproduct C_4 stream, created another source of butadiene. The basis for one butadiene recovery process is the change in relative volatility of C_4 hydrocarbons in the presence of acetonitrile solvent. The latter makes the separation easier. The C_4 mixed charge goes to an extractive distillation column where it is separated in a solvent environment into a solvent-butadiene stream and a byproduct butane-butylenes stream (overhead). The acetonitrile is recovered from the butane-butylenes. Butadiene is stripped from the fat solvent, after which it goes to a postfractionator for recovery as a 99.5% pure product.

Other solvents used in the extractive distillation include *n*-methyl pyrrolidone, dimethyl formamide, furfural, and dimethyl acetamide.

BUTANE. See **Organic Chemistry**.

BUTENANDT, ADOLF FRIEDRICH JOHANN (1903–1995). Butenandt studied chemistry and biology at the University of Marburg (1921–1924), then took a doctorate under Adolf Windaus at Göttingen (1927). He remained at Göttingen as a laboratory course assistant until his appointment as Professor of Organic Chemistry at the Danzig Institute of Technology in 1933. In 1936 he became Director of the Max Planck Institute for Biochemistry, overseeing its moves from Berlin to Tübingen (1945) and to Munich (1956). He was Professor of Physiological Chemistry from 1945 until his retirement in 1972.

Butenandt's work was mainly in the field of sex hormones, a subject that he took up at the recommendation of Windaus. In the summer of 1929 he isolated the first pure sex hormone, oestrone (discovered independently by Edward Doisy), from the urine of pregnant women. In 1931 Butenandt isolated the male hormone androsterone from urine, and in 1934 progesterone was obtained from pigs' ovaries. The determination of their chemical structures was simplified by the realization that they were related to steroids; this opened the way to their synthesis from cholesterol. Later, his work extended to insect hormones and pheromones. In 1939 Butenandt shared the Nobel Prize in Chemistry with Leopold Ruzicka but, like Richard Kuhn, was forced by Nazi law to decline it. See also **Doisy, Edward Adelbert (1893–1986)**; Kuhn, Richard (1900–1967); and **Ruzicka, Leopold Stephen (1887–1976)**.

As Director of the Institute, and President of the Max-Planck Society (1960–1972), Butenandt contributed much to the postwar rebuilding of German science.

BUTTERFISHES *(Osteichthyes)*. Members of the suborder *Stromateoidea*, these fishes are characterized by a peculiar anatomy, i.e., they incorporate an expanded and muscular esophagus, which may feature ridges, papillae, and, in some instances, teeth. Butterfishes of the family *Stromateidae* are premium food fishes. The *Poronotus triacanthus* is a 12-inch (0.3-meter) species that inhabits the American Atlantic shores. The 10-inch (25-centimeter) California pompano (*Palometa simillima*) is found on the American Pacific coast. In actuality, however, this species is *not* a pompano, which is a member of the family *Carangidae*, along with jacks, cavallas, and scads. Quite often, younger butterfishes will be found under large floating jellyfish, such as the Portuguese man-of-war. The presence of pelvic fins distinguishes the nomeids from other butterfishes. An example is the *Nomeus gronovi*, a man-of-war fish (3 inches long; 7.5 centimeters), found throughout tropical waters. Almost always, this fish will be located among the trailing tentacles of the giant jellyfishes. The squaretail (*Tetragonurus cuvieri*) is a third species of butterfish distinguished by very tough, practically irremovable scales. It is also widely distributed in deep tropical and temperate waters.

BUTTERFLY *(Insecta, Lepidoptera)*. An insect with four large wings, usually completely covered with scaly vesture. See Figs. 1 and 2. Distinguished from most other members of the order (moths and skippers) by the terminal club of the antennae.

Butterflies are found to some extent in most all regions where flowers are in abundance, but their greatest occurrence is in the tropics. There are five major families of butterflies: (1) *Hesperiidae* — small, found worldwide, but particularly in the United States; (2) *Papilionidae*, a large family of beautifully-marked insects; (3) *Lycaenidae*, a large family of comparatively small butterflies; (4) *Lemoniidae*, a strikingly beautiful family of butterflies that occur in the tropics; and (5) *Nymphalidae*, of very ancient origin and the largest of all families of butterflies. The largest numbers of butterflies are members of the last three mentioned families.

Fig. 2. Monarch butterfly.

Fig. 1. Giant swallowtail butterfly.

In wing-tip spread, butterflies measure from as small as one-fourth inch to 12 inches. The bodies are slender and long. Particularly as seen in bright sunlight, butterflies are gaily colored. The wings are scaled, the scales overlapping. The name of their order (*Lepidoptera*) means "wings with scales." The wings are folded together and erect when at rest. Some butterflies can change the color of their wing spots when in danger. The two antennae are nearly hair-like and knobbed. Some butterflies have tiny brushes on their forelegs, which they use for cleansing their eyes. Some species migrate to warm climates in winter. Unlike moths, butterflies do not spin cocoons.

As pointed out by Kingsolver (see reference), some investigators in their studies of butterfly behavior have been looking at how the butterfly meets its needs for energy, how it flies, and how it maintains a thermal equilibrium by adapting an engineering perspective in their research work. In this way, the functional meaning of taxonomic categories can be uncovered. The taxonomic categories can, in some instances, be shown to differ in specific functional characteristics, as the genera *Pieris* and *Colias* have shown to differ in basking posture and wing pigmentation. Because characteristics such as wing pigmentation are genetically determined, the system of constraints also gives insight into the evolutionary relations among organisms. For example, the engineering analysis makes it possible to tell how much a mutation adding a third pigment to the wing of a *Colias* butterfly would affect the range of habitats in which the butterfly could live. By combining engineering analyses of organisms with studies of evolutionary relations, one can begin to understand how physical mechanisms constrain evolutionary change and thus shape the frail structure that enables the butterfly to flutter through the air.

The ultraviolet reflection of male butterflies has been studied. The color is structural rather than pigmentary, and originates from optical interference

in a microscopic lamellar system associated with ridges on the outer scales of the wing. The dimensions and angular orientation of the lamellar system conform to predictions based on physical measurement of the spectral characteristics, including "color shifts" with varying angles of incidence, of the reflected UV light. The female lacks such scales and is consequently nonreflectant. The UV dimorphism supposedly serves as the basis for sexual recognition in courtship.

Butterflies of economic concern include:

Cabbage butterfly (*Pieris rapae*). A white butterfly with black-tipped forewings and two or three black spots on the wings of each side. Introduced from Europe in the mid-nineteenth century, the species spread rapidly and it is found throughout the United States and much of Canada. The caterpillar feeds on all cruciferous plants, but is especially important as a pest on cabbage and cauliflower. Related caterpillars include the *potherb butterfly* (*Pieris oleracea*, Harris); the *southern cabbageworm* (*Pieris protodice*, Boisduval and LeConte); and the *Gulf white butterfly* (*Pieris monuste*, Linne). Caterpillars chew holes in leaves and attack buds to cause misshapen produce. Caterpillar droppings as well as the feeding damage can cause produce to be unmarketable. The caterpillars are usually exposed and relatively easy to control when young. Older caterpillars are difficult to kill and are usually found in protected places on the plant. Among control chemicals used are methomyl, chlordimeform, and thuricide, biotrol, and dipel (the latter contain Bacillus Thuringiensis spores as the active ingredient).

Blue butterfly (*Feniseca tarquinius*). The larva of this butterfly is an economical inset. The larva feeds on the woolly aphid.

Thistle butterfly. Feeds on Canada thistle, considered economically beneficial. But, it is also known to feed on cultivated crops when thistle is not available.

BUTTERFLY VALVE. As shown in Fig. 1, a butterfly valve consists of a body, a disc supported on a shaft, and a suitable packing box to allow the shaft to protrude for operation by manual and/or automatic actuators. The flow path in a butterfly valve is straight through the body with only the disc to obstruct the flow, resulting in relatively high capacity. These valves are self-cleaning, thus permitting their use for the control of heavy stocks, slurries, and sludges.

Two body styles generally are available: (1) a spool type similar to a conventional gate or globe valve; and (2) a solid ring type. The spool type requires a greater installation space and weighs more than the solid ring type. The latter type bolts between pipeline flanges, eliminates transfer of pipeline stresses to the valve body, and permits the use of lower strength and lower cost body materials.

Butterfly valves are made in many materials for a wide variety of pressure, temperature, and fluid service conditions. They can be modified for tight shutoff with a soft seat or elastomer liner. Where temperatures prohibit the use of elastomers, other low-leakage designs, such as piston ring, step seated, and angle seated designs are available. Line sizes range from 1 inch (2.5 centimeters) through 108 inches (274 centimeters). Versatility of application is a feature of butterfly valves.

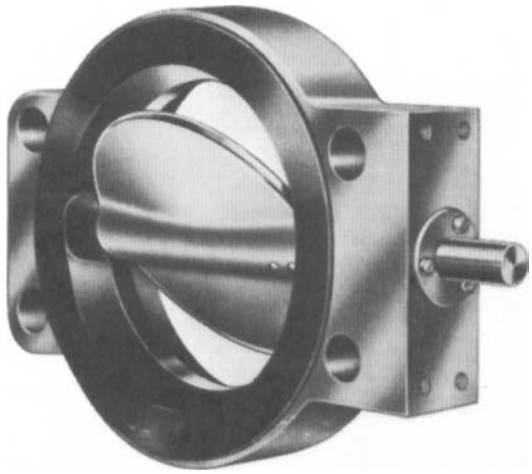

Fig. 1. Elastomer-lined butterfly valve.

BUTTONWOOD TREE. See **Sycamore and Plane Trees**.

BUTYL ALCOHOLS. Butyl alcohols encompass the four structurally isomeric 4-carbon alcohols of empirical formula $C_4H_{10}O$. One of these, 2-butanol, can exist in either the optically active *R*(−) or *S*(+) configuration or as a racemic (±) mixture [CAS: 15892-23-6].

The butanols are all colorless, clear liquids at room temperature and atmospheric pressure with the exception of *t*-butyl alcohol which is a low melting solid (mp 25.82 °C); it also has a substantially higher water miscibility than the other three alcohols. Physical constants of the four butyl alcohols are given in Table 1.

The butanols undergo the typical reactions of the simple lower chain aliphatic alcohols. For example, passing the alcohols over various dehydration catalysts at elevated temperatures yields the corresponding butenes. The ease of dehydration increases from primary to tertiary alcohol: *t*-butyl alcohol undergoes dehydration with dilute sulfuric acid at low temperatures in the liquid phase whereas the other butanols require substantially more stringent conditions.

With the exception of the *t*-butyl compound, the butyl alcohols are dehydrogenated to the corresponding carbonyl compounds when passed over copper or silver catalysts at temperatures around 300 °C. Thus, *n*- and isobutyl alcohols are dehydrogenated to *n*- and isobutyraldehyde, respectively, while 2-butanol gives methyl ethyl ketone (2-butanone). Continued or more vigorous oxidation of *n*- and isobutyl alcohol yield the corresponding carboxylic acids whereas 2-butanol is degraded to acids of shorter chain length.

The butyl alcohols undergo esterification with organic acids in the usual manner in the presence of trace amounts of mineral acid catalysts. Esterification is fastest with *t*-butyl alcohol and slowest with the primary alcohols although *t*-butyl alcohol undergoes substantial dehydration in the presence of the typical acid esterification catalysts.

1-Butanol and isobutyl alcohol are aminated with ammonia over alumina at 300–350 °C to give the corresponding mono-, di-, and tributylamines.

The principal commercial source of 1-butanol is *n*-butyraldehyde [CAS: 123-72-8], obtained from the Oxo reaction of propylene. A mixture of *n*- and isobutyraldehyde [CAS: 78-84-2] is obtained in this process. This mixture is either separated initially and the individual aldehyde isomers hydrogenated, or the mixture of isomeric aldehydes is hydrogenated directly and the *n*- and isobutyl alcohol product mix separated by distillation. Typically, the hydrogenation is carried out in the vapor phase over a heterogeneous catalyst.

The largest-volume commercial derivatives of 1-butanol are *n*-butyl acrylate [CAS: 141-32-2] and methacrylate [CAS: 97-88-1]. These are used principally in emulsion polymers for latex paints, in textile applications and in impact modifiers for rigid poly(vinyl chloride).

Butyl glycol ethers, the largest volume derivatives of *n*-butyl alcohol used in solvent applications, are obtained from the reaction of 1-butanol with ethylene oxide. The most important of these derivatives, 2-butoxyethanol, is used principally in vinyl and acrylic paints as well as in lacquers and varnishes. It is also employed in aqueous cleaners to solubilize organic surfactants. 2-Butoxyethanol [CAS: 111-76-2] has

TABLE 1. PHYSICAL PROPERTIES OF THE BUTYL ALCOHOLS (BUTANOLS)

Property CAS Registry Number	*n*-Butyl alcohol [71-36-3]	Isobutyl alcohol [78-83-1]	*sec*-Butyl alcohol [78-92-2]	*t*-Butyl alcohol [75-65-0]
Systematic name	1-butanol	2-methyl-1-propanol	2-butanol	2-methyl-2-propanol
Formula	$CH_3(CH_2)_3OH$	$(CH_3)_2CHCH_2OH$	$CH_3CH(OH)C_2H_5$	$(CH_3)_3COH$
Critical temperature, °C	289.90	274.63	262.90	233.06
Critical pressure, kPa[a]	4423	4300	4179	3973
Normal boiling point, °C	117.66	107.66	99.55	82.42
Melting point, °C	−89.3	−108.0	−114.7	25.82
Heat of fusion, kJ/mol[b]	9.372	6.322	5.971	6.703
Heat of vaporization at normal boiling point, kJ/g[b]	43.29	41.83	40.75	39.07
Liquid density, kg/m^3 at 25 °C	809.7	801.6	806.9	786.6[c]
Refractive index at 25 °C	1.3971	1.3938	1.3949	1.3852
Flash point, closed cup, °C	28.85	27.85	23.85	11.11
Dielectric constant, ε	17.5^{25}	17.93^{25}	16.56^{20}	12.47^{30}
Solubility in water at 30 °C	7.85	8.58	19.41	Miscible
Solubility of water in alcohol at 30 °C	20.06	16.36	36.19	Miscible

[a]To convert kPa to mm Hg, multiply by 7.50. [b]To convert kJ to kcal, divide by 4.184. [c]For the subcooled liquid below melting point.

achieved some growth at the expense of the lower alkoxyethanols (i.e., methoxy and ethoxyethanol) because of 2-butoxyethanol's lower toxicity.

1-Butanol is used as a direct solvent in paints and other surface coatings. It acts synergistically with butyl acetate as a latent solvent system for nitrocellulose lacquers and thinners to give a solvent system stronger than either solvent alone. Other direct solvent applications for *n*-butyl alcohol are in the formulation of pharmaceuticals, waxes, and resins. Slightly more 1-butanol is consumed in Western Europe in direct solvent applications than in the production of butyl acrylate and methacrylate in contrast to the United States where the acrylate and methacrylate esters are the predominent end products.

Butyl acetate [CAS: 123-86-4], one of the more important derivatives of *n*-butyl alcohol produced commercially, is employed as a solvent in rapid drying paints and coatings. In some instances, butyl acetate, $C_6H_{12}O_2$, has replaced ethoxyethyl acetate [CAS: 111-15-9] due to the latter's reported toxicity and teratogenicity. Butyl acetate is used in leather treatment, perfumes, and as a process or reaction solvent and is also used extensively with wood coatings, maintenance coatings, and in coatings for containers and closures.

Isobutyl alcohol has replaced *n*-butyl alcohol in some applications where the branched alcohol appears to have preferred properties and structure.

All four butanols are thought to have a generally low order of human toxicity. However, large dosages of the butanols generally serve as central nervous system depressants and mucous membrane irritants.

All four butanols are registered in the United States on the Environmental Protection Agency Toxic Substances Control Act (TSCA) Inventory, a prerequisite for the manufacture or importation for commercial sale of any chemical substance or mixture in quantities greater than 454 kg (1000 lbs.). Additionally, the manufacture and distribution of the butanols in the United States are regulated under the Superfund Amendments and Reauthorization Act (SARA), Section 313, which requires that anyone handling at least 4545 kg (10,000 lbs.) a year of a chemical substance report to both the U.S. EPA and the state any release of that substance to the environment.

The C-4 alcohols are preferably stored in baked phenolic-lined steel tanks. However, plain steel tanks can also be employed provided a fine-porosity filler is installed to remove any contaminating rust.

Storage under dry nitrogen is also recommended since it limits flammability hazards as well as minimizing water pickup.

BUZZ. 1. In supersonic diffuser aerodynamics, a nonsteady shock motion and airflow associated with the shock system ahead of the inlet, very rapid pressure pulsations are produced which can affect downstream operation in the burner, nozzle, etc.

2. Sustained oscillation of an aerodynamic control surface caused by intermittent flow separation on the surface, or by a motion of shock waves across the surface, or by a combination of flow separation and shock-wave motion on the surface.

BYPASS CAPACITOR. A capacitor placed in an electrical circuit to provide a low impedance alternative path of current flow for one of a combination of two or more signals (one of which may be D.C.). The most common usage is in bypassing various voltage-dropping resistors used in transistor circuits to adjust the voltages applied to the several parts of the circuits. These resistors are bypassed so there will be no, or very little, alternating signal voltage drop to produce undesirable feedback. The reactance of the bypass capacitor should be small compared to the impedance (resistance for dc) of the current path which it is desired to bypass. See Fig. 1.

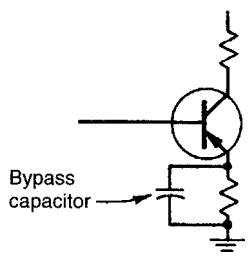

Fig. 1. Bypass capacitor in transistor amplifier.

BYSMALITH. A plug-like igneous intrusion related to a loccolith but bounded laterally by faults due to upward "punching" rather than "pushing" of the magma as it forces its way into a series of stratified rocks.

BYTE. A group of binary digits handled as a unit and usually used to represent a character. The byte may be a group or *string of pulses*. Bytes are used to constitute alphanumeric characters — for example, to represent decimal digits or letters. Past usages have included modifiers, such as octet (8-bit byte), sextet (6-bit byte), etc. Computers traditionally have provided for instructions that operate on bytes, as well as word-oriented instructions. The capacity of computer storage units is often specified in terms of bytes.

C

CABBELING. (Also spelled cabbaling.) Any physical process that is caused by the nonlinear terms in the expression of density as a function of *S* (salinity) and *T* (temperature) measured at constant pressure. The original meaning of cabbeling is described by considering the mixing of two fluids of similar density but different *T* and *S*. The volume of the mixture will generally be slightly smaller than the total volume of the two original fluids (contraction upon mixing). Therefore, the mixture will have a slightly higher density than the average density of the original fluids. This densification upon mixing is thought to cause the mixed fluid to flow downward, away from the zone of mixing, and so will allow new source fluids to come in contact. In situations where vertical mixing is occurring, the effects of nonlinearity are more subtle, leading to differential entrainment and upward migration of the mixing interface.

CABIN PRESSURIZATION. Cabin pressurization is the active pumping of air into the cabin of an aircraft to increase the air pressure within the cabin. It is required when an aircraft reaches high altitudes, because the natural atmospheric pressure is too low to allow people to absorb sufficient oxygen, leading to altitude sickness and ultimately hypoxia.

A lack of sufficient oxygen will bring on hypoxia by reducing the alveolar oxygen tension. In some individuals, symptoms may begin as low as 1500 metres (5,000 feet) above MSL, although most passengers can tolerate altitudes of 8,000 feet without ill effect.

Passengers may also develop fatigue or headache as the plane flies higher. As the operational altitude increases, reactions become sluggish and unconsciousness will eventually result. Sustained flight operations above 10,000 feet generally require supplemental oxygen (through a canula or mask) or pressurisation.

Aircraft which routinely fly above 10,000 feet are generally equipped with an oxygen system fed through masks or canulas (typically for smaller aircraft), or are pressurized by an Environmental Control System (ECS) using air provided by compressors or bleed air. These systems maintain air pressure equivalent to 8,000 ft or less, even during flight at altitudes above 40,000 ft.

As the airplane pressurizes and decompresses, some passengers will experience discomfort as trapped gases within their bodies respond to the changing cabin pressure. The most common problems occur with gas trapped in the gastrointestinal tract, the middle ear and the paranasal sinuses (i.e., the common "popping" of the ear). Note that in a pressurized aircraft, these effects are not due directly to climb and descent, but to changes in the pressure maintained inside the aircraft.

It is always an emergency if a pressurized aircraft suffers a pressurisation failure above 10,000 feet. If this occurs the pilot must immediately place the plane in an emergency descent and activate emergency oxygen for all.

Cabin Air System Operation

Pressurized air for the cabin comes from the compressor stages in the aircraft's jet engines. Moving through the compressor, the outside air gets very hot as it becomes pressurized. The portion drawn off for the passenger cabin is first cooled by heat exchangers in the engine struts and then, after flowing through ducting in the wing, is further cooled by the main air conditioning units under the floor of the cabin.

The cooled air then flows to a chamber where it is mixed with an approximately equal amount of highly filtered air from the passenger cabin. The combined outside and filtered air is ducted to the cabin and distributed through overhead outlets.

Inside the cabin, the air flows in a circular pattern and exits through floor grilles on either side of the cabin or, on some airplanes, through overhead intakes. The exiting air goes below the cabin floor into the lower lobe of the fuselage. The airflow is continuous and quickly dilutes odors while also maintaining a comfortable cabin temperature.

About half of the air exiting the cabin is immediately exhausted from the airplane through an outflow valve in the lower lobe, which also controls the cabin pressure. The other half is drawn by fans through special filters under the cabin floor, and then is mixed with the outside air coming in from the engine compressors.

These high efficiency filters are similar to those used to keep the air clean in hospitals. Such filters are very effective at trapping microscopic particles as small as bacteria and viruses. It is estimated that between 94 and 99.9 percent of the airborne microbes reaching these filters are captured.

CABLE (Electrical). An electrical cable is one or more conductors surrounded by an insulating medium and a protective sheath. Such cables are used for the transmission of electric power and for transmission of communication signals. The power cables have relatively few conductors of heavy gauge and are insulated for high voltages. Such cables are frequently filled with oil to increase the insulation strength. The outer sheath is commonly of lead, although for submarine work this is often strengthened by a second sheath of steel strands. Communications cables usually contain many pairs of small-gauge copper conductors, paper-insulated, surrounded by a lead sheath. Sometimes the entire cable is nitrogen-filled under pressure. The various pairs of conductors are arranged by twisting and placing to minimize pick-up between them (see **Crosstalk**). Common practice is to include two extra pairs for spares for each hundred active pairs. Cables used for submarine circuits have fewer pairs and are heavily insulated and armored to withstand the severe strains to which they may be subjected in laying and by ocean currents. The coaxial cable (see **Coaxial Line**) is a special type in which the pair of conductors is formed by a center wire and the outer sheath. In this case the sheath is copper and the insulation is often a gas with solid dielectric spacers at intervals to hold the inner conductor centered. This coaxial cable may in turn be enclosed with others in a lead sheath for protection. Coaxial cables have a wide usable frequency range and hence are used for transmission of television programs. They are also often used for radio-frequency transmission lines as the electromagnetic fields necessary for the transmission of signals penetrate the space exterior to the sheath of the cable to a negligible extent. See Fig. 1.

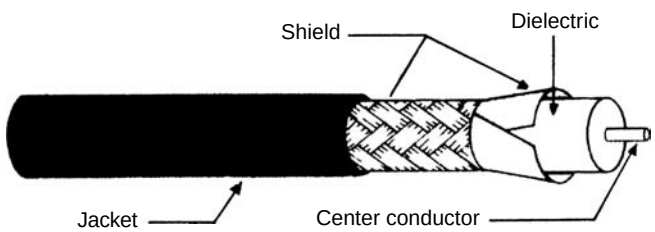

Fig. 1. Construction of a network coaxial cable. The center conductor may be bare copper, copper-clad aluminum, copper-covered steel, silvered copper, or tinned copper. The shield may be aluminum, bare copper, foil plus aluminum braid, foil plus tinned copper braid, silvered copper, or tinned copper. The dielectric may be an air dielectric polyethylene, solid Teflon®, foam Teflon®, foam polyethylene, or solid polyethylene. The jacket may be Teflon® fluorinated ethylenedipropylene, noncontaminating polyvinylchloride, polyethylene, or polyvinylchloride. (*Illustration provided by M/A-Com, Inc., Hickory, North Carolina.*)

The types of wire and cable available are extensive. Principal types as cataloged in the *Electronic Engineers Master Catalog* (Hearst Business

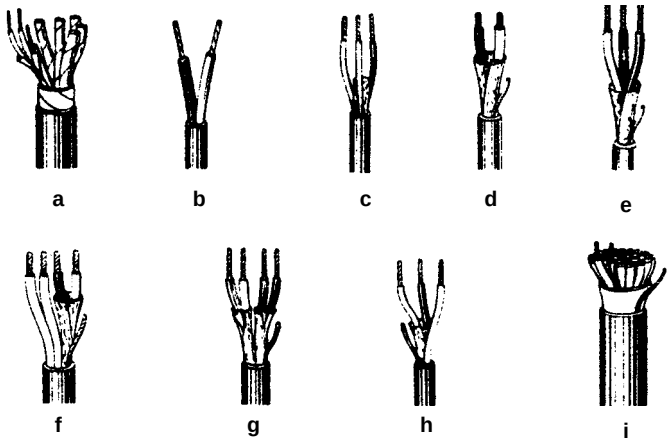

Fig. 2. Examples of the wide variety of electrical cables commercially available for hundreds of specialized applications are the multiconductor cables shown here: (**a**) Individually shielded pair cable; (**b**) unshielded two-conductor cable; (**c**) unshielded three conductor cable; (**d**) shielded two-conductor cable; (**e**) shielded three-conductor cable; (**f**) one pair shielded, one pair unshielded; (**g**) individually shielded two-pair cable; (**h**) three conductor cables, one pair shielded, one conductor unshielded; and (**i**) overall shielded multiple-pair cable. The conductors are stranded, tinned copper, with color-coded polyethylene (PE), polypropylene (polyp), or polyvinylchloride (PVC) insulation. Conductors are shielded with Mylar® polyester reinforced aluminum foil shield overall. (*Illustrations provided by Consolidated Electronic Wire & Cable, Franklin Park, Illinois.*)

Communications, Inc.) include hook-up wire, cables for computers and communication, coaxial cable, power cords, and multiconductor cables. Within any given category, there are usually dozens of configurations. The wide design variations available are exemplified by Fig. 2. For information transmission by fiber optics, see also **Optical Fiber Systems**; and **Telephony (Telecommunications)**.

CABLE LENGTH. A cable length or cable's length is a nautical unit of horizontal distance, for which at least four definitions seem to exist:

- Common definition: 1/10 nautical mile, i.e. 185.2 m for international nautical mile, was used with other precise definitions of the nautical mile as well.
- "Ordinary" definition: 100 fathoms (600 feet), i.e. 182.88 m.
- US Navy definition: 120 fathoms (720 feet), i.e. 219.456 m.
- Royal Navy definition: 1/10 Admiralty nautical mile, 608 feet, i.e. 185.3184 m.

The unit is named after the length of a ship's "cable". The cable length is now almost unused.

CABLE MODEMS. Since the inception of the Internet as a high-speed data connection between universities in the early 1970s, the search for a low-cost broadband last-mile delivery system has been pursued. The fiberoptic backbone is capable of sustaining terabits of data throughput, but the last mile connection has traditionally been limited to, at best, about 28 kb (kilobits) and more recently 56 kbits. Realizing that the needed bandwidth for these high-speed data links could be supplied by the television cable plant, in the mid 1970s the FCC mandated that all new cable television trunk lines and drop lines be installed as two-way-ready. Two-way amplifiers were installed allowing both downstream and upstream data traffic to occupy selected frequency spectra on a single coaxial cable. New head-end cable equipment was installed, and the cable operators began to deploy broadband Internet access over the cable infrastructure (Fig. 1**a**, and 1**b**). In the event that a cable plant had not been upgraded for two-way operation, the Telco modem (or cable downstream and telephone upstream) has been successfully deployed. Typical bandwidth usage models require a broadband downstream channel, since users nominally request large amounts of data from the Internet server. The return path (or upstream) bandwidth can be reduced, since users rarely transmit large amounts of data upstream. In fact, the limited upstream traffic has allowed for further bandwidth efficiency by utilization of a time-division multiple access (TDMA) scheme for two-way cable modem implementation. This method allows multiple users to transmit data on the same IF carrier frequency, but at different times. This is known as *burst-mode transmission*, and is contrasted to the subscriber modem receiver downstream data, which are supplied as a continuous bitstream. Exceptions to this limited upstream bandwidth are applications requiring two-way videoconferencing, and these have just recently (at the time of writing) been addressed in new specifications.

In 1995 efforts were made by the newly formed Multi-media Cable Network Systems (MCNS) organization and the IEEE 802.14 committee to define and establish standards for transmission of IP data over existing cable lines. Both of these bodies eventually dissolved into what is known today as the Data over Cable Service Interface Specification (DOCSIS) standard. The lower four layers of the data protocol are primarily what DOCSIS 1.0/1.1 defines and are outlined as follows:

Layer 1— PHY (physical layer): defines upstream and downstream modulation schemes, 64/256-QAM downstream and QPSK/16-QAM upstream

Layer 2— MPEG2: defines the data packet organization and FEC (forward error correction) codes

Layer 3— MAC (media access control): defines the data processing protocols between cable modem (CM) at the customer premise, and the head-end (HE) equipment, also known as the cable modem termination system (CMTS) residing at the central office

Layer 4— BPI (Baseline PrIvacy): sets the key codes for encryption to provide security on the shared cable network

The structure of the downstream payload data has a unique packet ID (PID), service ID (SID), and destination address (DA) embedded in the data packets. The PID is used to identify a "data type" packet as opposed to digital video information. The downstream SID identifies the security association of each packet and the DA identifies packets that belong to a particular user. Packets are framed in standard MPEG-2 format. This allows the data channels to occupy the already defined digital video channel spacing and decoder technology. MPEG-2 defines what is specified as "well known" packet identifiers, and for cable modem data traffic this hex value is $0 \times 1FFE$.

Thus, as the packet parser contained in the cable modem MAC looks at each PID inserted in each MEG packet received, it will proceed to the next level of decoding of the SID only if it finds a PID indicating that this is a data channel. If there are no payload data (actual data to receive), then a "null packet" will be transmitted consisting of the hexadecimal (hex) value 0xFF for all payload data bytes, enabling the downstream to remain locked to the QAM channel and decoding MPEG packets at all times. A block diagram of the cable modem is shown in Fig. 2.

For both upstream and downstream data to coexist on a single cable, a means to separate the frequency spectra is necessary. For the North American standard, the downstream data services reside with the already established downstream video channels occupying the 54–860-MHz band (using 6-MHz channel spacing). The upstream data are placed in the unused frequency bands from 5 to 42 MHz (Fig. .3). A diplex filter is used to mitigate crosstalk between the respective frequency allocations. The diplex filter consists of a HI-PASS section for the downstream channels and a LO-PASS section for the upstream channels. As mentioned earlier, upstream return channels are burst mode and symbol rates are assigned during the logon process on the basis of requested/available bandwidth. Thus, the head end can allocate bandwidth in accordance with the demands as more users logon and require more channel capacity. This results in a slow

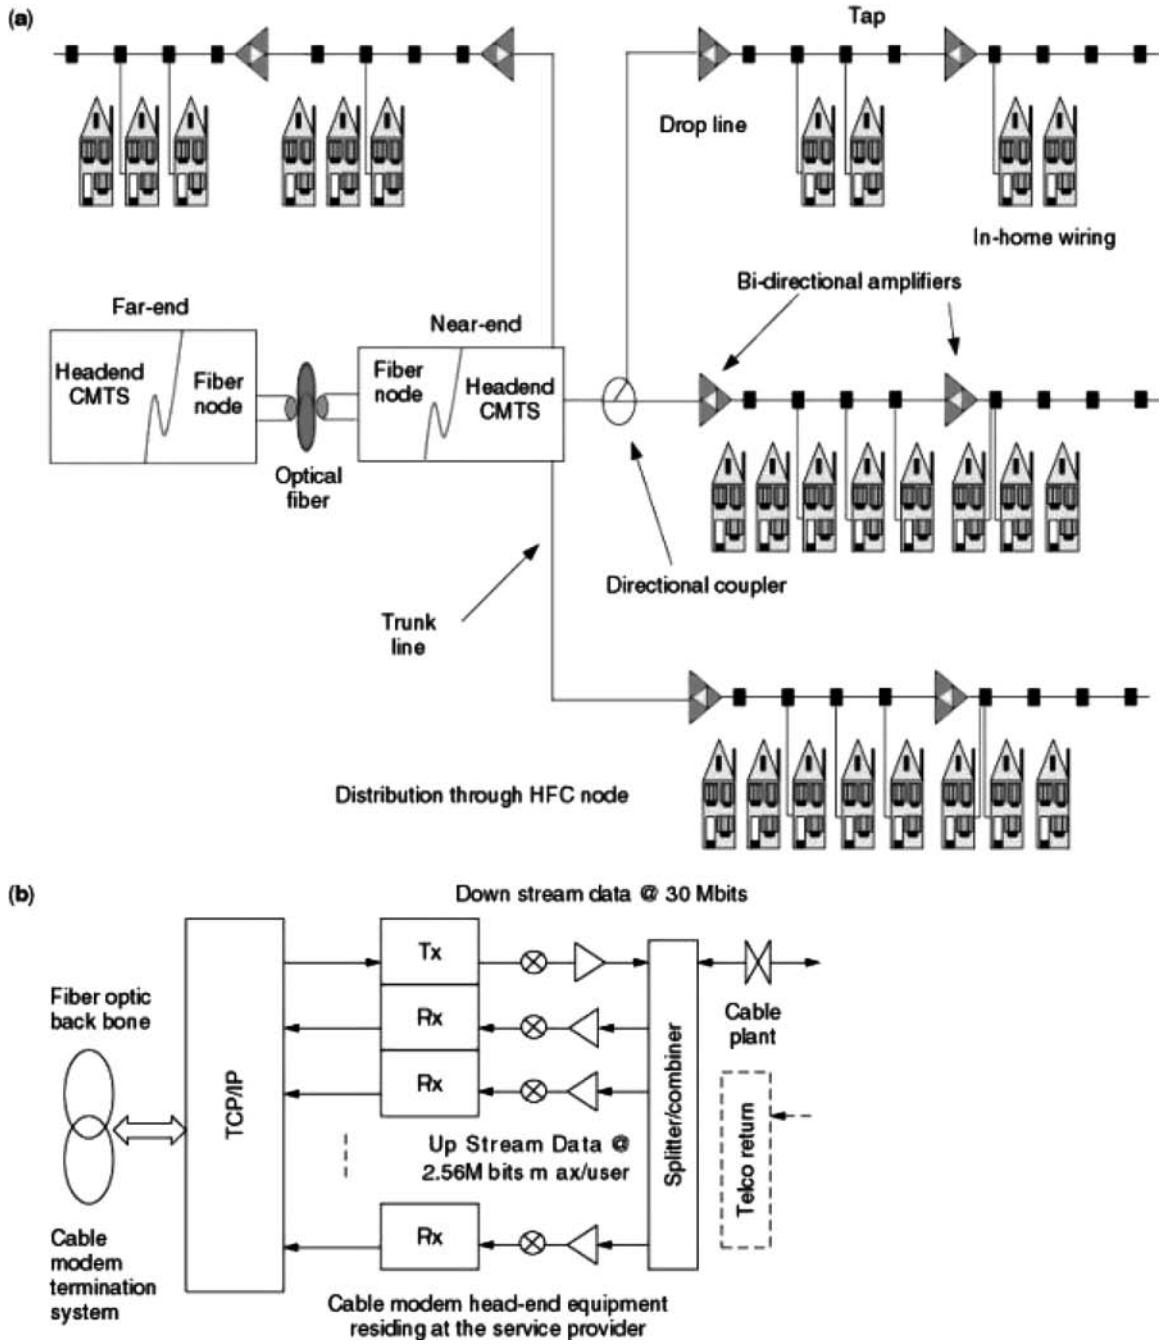

Fig. 1. Block diagrams of (**a**) HFC plant and (**b**) CMTS.

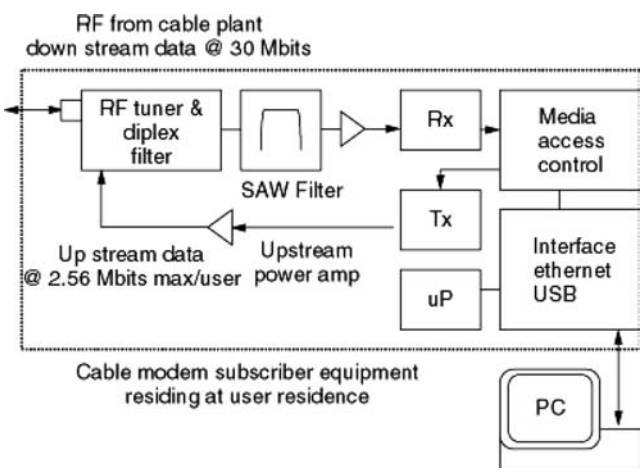

Fig. 2. Block diagram of CM.

degradation in system performance, in contrast to a telephone modem, whereby when no more switch ports are available, the user cannot establish a connection at all. Additionally, when the cable system bandwidth reaches an unacceptable level of performance, a new RF downstream or IF upstream frequency is assigned to some of the users, and the system data throughput can be restored dynamically without disruption of service or any knowledge by the users. Typical loading currently is about 200 or so users per downstream channel and optimum channel loading has been established by historical usage models for telephone lines.

Current video delivery to most homes in the United States is via cable, and as more interactive services are offered, there will be increasing emphasis on providing simultaneous high-speed data available to these users. The bandwidth is available from the existing cable plants to provide this growth. Cable modems have shown increases in speed of 1000 times over telephone modems, and nearly all housing developments in the United States have a cable infrastructure already in place. Increased levels of integration have dramatically reduced the cost of cable modems, enabling

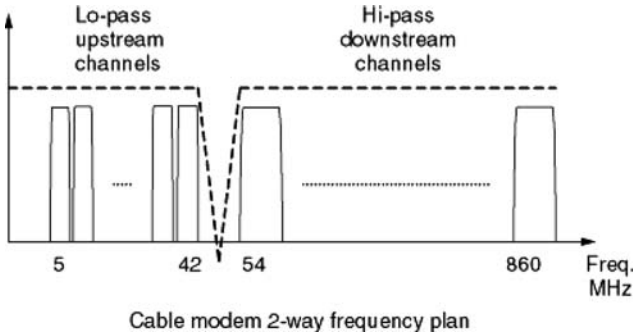

Fig. 3. Cable modem frequency plan.

explosive growth and accelerated deployment for the near future. See also **Modems**.

CABLE TELEVISION. See **Television (TV)**.

CABLEWAY. A suspended steel cable acting as a track for aerial hoisting and conveying devices is a cableway. While occasionally used for transporting persons across deep gorges, where the amount of traffic does not warrant the building of a bridge, the cableway, in its more common application, handles construction material for building of dams, or has a permanent use in connection with the handling of material such as rock or gravel which is taken from open pits. Clear spans up to a half-mile in length are possible in a cableway. The carriage that operates on the cableway may or may not have provision for carrying passengers, depending on the purpose of the cableway. Cableways are used at winter resorts to transport skiers up steep slopes.

CACAO TREE. Of the family *Sterculiaceae* (chocolate family), there are two species of principal commercial interest: *Theobroma cacao*, native to Mexico, and *T. leiocarpum*, native to Brazil. The tree is found in its wild state, growing in the lowlands from Mexico southward to northern South America. It is of medium size with shiny, evergreen leaves about a foot long. The flowers are small. They grow from buds on the trunk or large branches of the tree. The fruits are melon-like, from 6 to 12 inches (15 to 30 centimeters) long and about 4 inches (10 centimeters) in diameter. They have a ribbed, rough surface. Each fruit contains from 20 to 50 flattened seeds or beans embedded in a gelatinous pulp. The tree is extensively cultivated in humid, tropical latitudes where rich soil is available. Important cacao bean producers include Ghana, Nigeria, and Brazil. The tree cannot tolerate sustained temperatures below 60 °F (∼15 °C). The cultivated tree is somewhat smaller than the wild one and begins to bear within 4 to 5 years when grown from seed. Trees may continue to bear well up to an age of 50 years.

The mature pods are cut from the tree and split open. The seeds are then scooped out and fermented for 1 or 2 weeks. During fermentation, the color of the seeds darkens to a reddish tone and a rich aromatic essence develops. The pulp surrounding the seeds liquefies and runs off. After fermentation, the seeds are dried and shipped to processors throughout the world, but notably located in Europe and the United States. In the processing plants, the seeds are cleaned, after which they are roasted for 1 to 2 hours. After roasting, the seeds are cracked and the shell separated from the cotyledons. The shells may be ground up and used in the manufacture of cheap grades of cocoa, or they may be burned as fuel. From the cotyledons, an oily liquid is ground out by heated mills. This liquid hardens into familiar chocolate. If part of the oil is squeezed out and the residue ground to a powder, the product is called cocoa. When chocolate is mixed with sugar or flavoring is added, the product is called *bitter chocolate*. The vegetable fat removed from the pressed beans is known as *cocoa* butter and is used in the manufacture of various pharmaceuticals, soaps, and in the preparation of confections.

CACTUS *(Cactaceae)*. The cactus is known to all as a prickly inhabitant of dry American deserts. In popular parlance, the name "cactus" applies to any fleshy spine-covered plant. But not all spiny plants are cacti, nor are all cacti characterized by spines. See Fig. 1.

Fig. 1. Cactus.

With the exception of a single genus *Rhipsalis*, some of whose members are said to occur in Sri Lanka and Madagascar, all cacti are natives of America, where they are found widely scattered from latitude 59° in North America through the tropics to the southern Andean region and Argentina. They are particularly conspicuous features of the flora of dry desert regions where they are found in a wide variety of forms and sizes.

A few genera, and especially *Pereskia*, are very like ordinary mesophytic plants, having well-developed ovate leaves borne alternately on a long slender stem. But in nearly all of the Cactus Family the leaf surface is very much reduced, the leaves appearing as small fleshy bodies which last but a brief time before dropping off. In many species leaves of any recognizable kind are never formed, the green fleshy stem taking over the function of leaves completely. In these fleshy stems large amounts of water are stored, a feature which enables these plants to survive in the arid regions in which they so frequently grow. Due to the mucilaginous nature of the cell contents and to the greatly reduced surface of the plants, the contained water is held most tenaciously and lost very slowly.

In their natural environment cactus plants have an extensive system of long fibrous roots which not only extend outward from the plant to considerable distances, but also penetrate the soil deeply. In cultivated plants the root system is usually greatly reduced. The stems of cacti show a variety of forms. In addition to the normal-stemmed *Pereskia*, there are the Prickly Pears, species of *Opuntia*. In most of these the stem is a series of flattened, fleshy joints often abundantly protected with bristling bunches of barbed spines. In species of *Mammillaria* and *Cereus* the stem is a cylindrical or globular body, often conspicuously ridged, and armed with numerous spines. In *Phyllocactus* and *Epiphyllum* the stem is flattened and largely unarmed, the small weak spines being borne in notches along the edges of the stem. The familiar night-blooming "cereus" is of this type.

One of the best known and largest of all the cacti is the saguaro or giant cactus (*Cereus giganteus*). This species is a native of southern Arizona, northern Sonora, and extreme southeastern California. This massive cactus may grow to a height of 50 feet (15 meters) with many side branches. Some individuals probably attain an age of 200 years. In some parts of its range extensive "forests" of this species have developed.

The flowers of most species of cactus are large and brightly colored. They are regular, although in some species a definite tendency toward zygomorphic flowers is seen. The flowers are borne singly. The perianth is composed of a large number of separate members, which show a gradual transition from the outer small sepals (see **Flower**) through to large brightly colored petals. The stamens are likewise numerous and have long filaments. The single compound pistil contains many ovules and in fruit becomes a many-seeded berry. In many species the fruit is edible.

Species of *Opuntia* are frequently planted in rows to form an impenetrable barrier against intruders. These plants were early introduced into the Old World and later into Australia, where in many places they have become a troublesome and almost worthless weed. Cactus plants are frequently seen in cultivation, being especially sought by those who like the bizarre effect they give. Somewhat similar in appearance are many species of *Euphorbia* from tropical Africa, and of *Stapelia*, a genus of the Milkweed Family, and likewise native to Africa. The flowers of these plants are quite unlike cactus flowers, however, so that the plants are readily distinguished when they bloom.

CADDIS FLY (or Caddice Fly). *Insecta, Trichoptera*. The adult of any species of this order. The caddis flies are slender insects with four wings, sometimes clothed with hair-like scales, which give them a moth-like appearance. The mouth parts are formed for biting but are vestigial. Since the larvae are aquatic, the caddis flies are much more abundant in the vicinity of water, but they are attracted to light, often at some distance.

CADDIS WORM *(Insecta, Trichoptera).* The aquatic larva of a caddis fly. They are noteworthy for the silken webs and cases they build, some for protection and some to catch prey. Some species spin silken nets attached to rocks in the bottom of a stream in such a position that the current washes into the wide mouth and passes out through a web at the smaller end. In this way the insect, which lives in a tube nearby, snares its food. Many of the caddis worms live in cases from which only the head and legs protrude. These cases are formed of many different materials, held together by silk. Some are made of small flat pebbles, some of bits of leaves, and some of small snail shells. The worms are economically of some value as food for fishes.

CADMIUM. [CAS: 7440-43-9] Chemical element, symbol Cd, at. no. 48. at. wt. 112.41, periodic table group 12, mp 321 °C, bp 765 °C, density 8.65 g/cm^3 (20 °C). Elemental cadmium has a hexagonal crystal structure. Cadmium is a silver-white metal, malleable and ductile, but at 80 °C becomes brittle. It remains lustrous in dry air and is only slightly tarnished by air or H_2O at standard conditions. The element may be sublimed in a vacuum at a temperature of about 300 °C, and when heated in air burns to form the oxide. Cadmium dissolves slowly in hot dilute HCl or H_2SO_4 and more readily in HNO_3. The element first was identified by M. Stromeyer in 1817. Naturally occurring isotopes 106, 108, 110–114, 116. ^{113}Cd is unstable with respect to beta decay (0.3 MeV) into ^{113}In ($t_{1/2} \geq 10^{13}$ years). Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 5s^2$. Ionic radius Cd^{2+} 0.99 Å. Metallic radius 1.489 Å. First ionization potential, 8.99 eV; second, 16.84 eV; third, 38.0 eV. Oxidation potentials $Cd \rightarrow Cd^{2+} + 2e^-$, 0.402 V; $Cd + 2OH^- \rightarrow Cd(OH)_2 + 2e^-$, 0.915 V; $Cd + 4CN^- \rightarrow Cd(CN)_4 + 4e^-$, 0.90 V. Other important physical properties of cadmium are given under **Chemical Elements**.

Although ranking 57th in abundance in the earth's crust (0.15 ppm), cadmium is not encountered alone, but is always associated with zinc. The only known cadmium minerals are greenockite (sulfide) and otavite (carbonate), both minor constituents of sphalerite (zinc oxide) and smithsonite (zinc carbonate), respectively. See also **Greenockite**; **Smithsonite**; and **Sphalerite Blends**.

Production. Two major processes are used for producing cadmium: (1) pyro-hydro-metallurgical and (2) electrolytic. Zinc blende is roasted to eliminate sulfur and to produce a zinc oxide calcine. The latter is the starting material for both processes. In the pyro-hydro-metallurgical process, the zinc oxide calcine is mixed with coal, pelletized, and sintered. This procedure removes volatile elements such as lead, arsenic, and the desired cadmium. From 92–94% of the cadmium is removed in this manner, the vapors being condensed and collected in an electrostatic precipitator. The fumes are leached in H_2SO_4 to which iron sulfate is added to control the arsenic content. The slurry then is oxidized, normally with sodium chlorate, after which it is neutralized with zinc oxide and filtered. The cake goes to a lead smelter, while the filtrate is charged with high-purity zinc dust to form zinc sulfate or zinc carbonate and cadmium sponge. The latter is briquetted to remove excess H_2O and melted under caustic to remove any zinc. The molten metal then is treated with zinc ammonium chloride to remove thallium, after which it is cast into various cadmium metal shapes. The process just described is known as the *melting under caustic process*. In a *distillation process*, regular rather than high-purity zinc is used to make the sponge. Then, after washing and centrifuging to remove excess H_2O, the sponge is charged to a retort. The heating and distillation process is under a reducing atmosphere. Lead and zinc present in the vapors contaminate about the last 15% of the distillate. Thus, a redistillation is required. The cadmium vapors produced are collected and handled as previously described.

Reactions that occur in the foregoing processes are: (Leaching): $CdO + H_2SO_4 \rightarrow CdSO_4 + H_2O$; (Oxidation): $3As_2O_3 + 2NaClO_3 \rightarrow 3As_2O_5 + 2NaCl$; and $6FeSO_4 + NaClO_3 + 3H_2SO_4 \rightarrow 3Fe_2(SO_4)_3 + NaCl + 3H_2O$; (Neutralization): $Fe_2(SO_4)_3 + As_2O_5 + 3ZnO + 8H_2O \rightarrow 2FeAs(OH)_8 + 3ZnSO_4$; (Cadmium Precipitation): $CdSO_4 + Zn \rightarrow Cd + ZnSO_4$; (Melting Under Caustic): $Zn + 2NaOH + \frac{1}{2}O_2 \rightarrow Na_2ZnO_2 + H_2O$.

In the electrolytic process, the calcine first is leached with H_2SO_4. Charging the resultant solution with zinc dust removes the cadmium and other metals that are more electronegative than zinc. The sponge that results is digested in H_2SO_4 and purified of all contaminants except zinc. Nearly pure cadmium sponge is precipitated by the addition of high-purity, lead-free zinc dust. The cadmium sponge then is redigested in spent cadmium electrolyte, after which the cadmium is deposited by electrolysis onto aluminum cathodes. The metal is then stripped from the electrodes, melted, and cast into various shapes. Reactions which occur during the electrolytic process are: (Roasting): $ZnS + 1\frac{1}{2}O \rightarrow ZnO + SO_2$; (Leaching): $ZnO + H_2SO_4 \rightarrow ZnSO_4 + H_2O$; (Neutralization): $Fe_2(SO_4)_3 + 3ZnO + 3H_2O \rightarrow 2Fe(OH)_3 + 3ZnSO_4$; (Cadmium Precipitation): $CdSO_4 + Zn \rightarrow Cd + ZnSO_4$; (Electrolysis): $CdSO_4 + H_2O \rightarrow Cd + H_2SO_4 + O_2$.

Industrial specifications normally require that impurities in cadmium metal not exceed the following: zinc, 0.035%; copper, 0.015%; lead, 0.025%; tin, 0.01%; silver, 0.01%; antimony, 0.001%; arsenic, 0.003%; and tellurium, 0.003%. The metal is available in numerous forms. Electroplaters generally prefer balls 2 inches (5 centimeters) in diameter.

Uses: A major use of cadmium is for electroplating steel to improve its corrosion resistance. It is also used in low-melting-point alloys, brazing alloys, bearing alloys, nickel-cadmium batteries, and nuclear control rods, and as an alloying ingredient to copper to improve hardness. Cadmium, unfortunately, is limited in its usefulness because fumes and dusts containing cadmium are quite toxic. Melting and handling conditions that create dust or fumes must be equipped with exhaust ventilation systems. See also specific Cd compounds in this article.

Biological Properties. Over the last several years, concern over the poisonous nature of cadmium, particularly of Cd powder and chips from Cd plating, has increased. For example, cadmium-plated hardware has not been used for food processing equipment for a decade or more. A part of this concern pertains to the incineration of waste materials that may contain cadmium, for fear of introducing Cd particles into the atmosphere. Also, although the quantity of cadmium used in pigments by artists is indeed very small, many artists are adamant concerning possible legislation. One painter has said, "Losing cadmiums would be like a composer losing the use of several keys." As another artist has pointed out, "Van Gogh could

not have painted his 'Sunflowers' without cadmium." The jewelry industry also uses cadmium as an ingredient of low-melting silver solders.

In February 1990 the Occupational Safety and Health Administration (U.S.) published a report that summarizes the history of cadmium regulation, studies of health problems, and risk calculations for cancer, kidney damage, and other disorders. This report represents a formal step toward implementation of stricter limits on cadmium exposure in the workplace. Some authorities admit that considerably more research is required.

The battery industry also has been plagued with metal pollution problems. These problems began with lead storage batteries several years ago and was at least partially solved by a lead recycling program based upon manufacturers' recalling "spent" car batteries. This was followed in the 1980s by the grossly reduced quantities of mercury, which is used to coat the electrodes in alkaline batteries. Initially, mercury accounted for about 1% of a battery's weight. By 1993 this has been reduced to 0.025% of battery weight.

In the early 1990s it is estimated that nearly 300 million nickel-cadmium batteries were sold in the United States. A large percentage of these were embedded in a variety of cordless appliances, such as power tools, small vacuum cleaners, and even toothbrushes. It was recently estimated that nearly 2,000 tons of cadmium appeared in the industrial waste stream as the result of equipment "junked" during the mid-1980s. Legislation directed toward keeping cadmium out of landfills and incinerators already has been passed in Connecticut and Minnesota. Other states considering similar legislation include New Jersey, Vermont, Michigan, California, and Oregon. Battery makers are investigating suitable substitutes for Cd, including nickel–nickel hydride batteries. Metal hydrides, which are porous compounds capable of storing hydrogen, ultimately may suffice for low-power devices (toys, photoflash devices), but presently do not look promising for high-power devices, such as motorized hand tools.

Chemistry and Compounds. In virtually all of its compounds, cadmium exhibits the +2 oxidation state, although compounds of cadmium(I) containing the ion Cd_2^{2+}, have occasionally been reported. Cadmium hydroxide is more basic than zinc hydroxide, and only slightly amphiprotic, requiring very strong alkali to dissolve it, and forming $Cd(OH)_3^-$ or $Cd(OH)_4^{2-}$ depending upon the pH.

Cadmium is found in metallothioneins, which are low-molecular-weight, cysteine-rich proteins that bind metal ions. Metallothioneins and their genes have several potential kinds of physiological activity. See Metallothioneins. Furey et al. (1986) report on a thorough investigation of the crystal structure of Cd,Zn metallothionein.

Cadmium Oxide. [CAS: 1306-19-0] CdO, formed by burning the metal in air or heating the hydroxide or carbonate, is soluble in acids, ammonia, or ammonium sulfate solution, and is more readily reduced on heating with carbon, carbon monoxide or hydrogen than zinc oxide. Cadmium suboxide, Cd_2O, formed by thermal reduction of cadmium oxalate with carbon monoxide, is believed to be a mixture of CdO and finely divided cadmium. CdO_2 and Cd_4O have been reported. Sodium hydroxide solution precipitates cadmium hydroxide, $Cd(OH)_2$, from solutions of the sulfate or nitrate, but with the chloride the $Cd(OH)_2$ precipitate is mixed with CdOHCl and other hydroxychlorides. $Cd(OH)_2$ exists in two forms, an "active" and an "inactive" one, which have different solubility products. Cadmium(I) hydroxide $Cd_2(OH)_2$, prepared by hydrolysis of Cd_2Cl_2, is, like Cd_2O, believed to be a mixture of the metal and the divalent compound. The Cd_2^{2+} ion is definitely established, however, in such compounds as $Cd_2(AlCl_4)_2$.

Cadmium Halides. These compounds can be prepared by the action of the corresponding hydrohalic acids upon the carbonate; or by direct union of the elements. If bromine water is used, some hydrobromic acid must be added to prevent hydrolysis of the bromide to the oxybromide, CdOHBr.

In general, the cadmium halides show in their crystal structure the relation between polarizing effect and size of anion. The fluoride has the smallest and least polarizable anion of the four and forms a cubic structure, while the more polarizable heavy halides have hexagonal layer structures, increasingly covalent and at increasing distances apart in order down the periodic table. In solution the halides exhibit anomalous thermal and transport properties, due primarily to the presence of complex ions, such as CDI_4^{2-} and $CdBr_4^{2-}$, especially in concentrated solutions or those containing excess halide ions.

Cadmium Sulfide. [CAS: 1306-23-6] CdS is the most extensively used of cadmium compounds and generally is prepared by precipitation from cadmium salts. The wide range of colors, varying from lemon yellow through the oranges and deep red, coupled with the stability and intensity of these colors, qualify CdS as a most desirable pigment for paints, plastics, and other products. The range of colors of CdS precipitates results from differing conditions in their formulation, including the temperature and acidity of the salt solutions from which they are precipitated. The particular salt, such as nitrate, chloride, sulfate, etc., also affects the resulting color. The rate of addition of hydrogen sulfide to the liquor affects particle size and color of the precipitates. Cadmium sulfide is insoluble in H_2O, is dimorphous, and sublimes at 1,350 °C. Several crystalline forms exist. When precipitated from normal H_2SO_4 and HNO_3 solutions, the crystals are cubic. From other media, stable alpha hexagonal and unstable beta cubic forms may be formed, these ranging in specific gravity from 3.9 to 4.5, respectively. Pigment colors are not due to crystal form, but rather derive from the particle size and dispersion of the precipitates. Of total cadmium production, pigments account for 20–25% of the total.

Other cadmium compounds used as pigments in ceramics, glass, and paints include cadmium nitrate, selenide, sulfoselenide, and tungstate. Cadmiopone ($BaSO_4$ plus CdS) ranges from yellow to crimson and is used for coloring plastics and rubber goods. Cadmium stearate, when combined with barium stearate, is widely used as a stabilizer in thermosetting plastics and accounts for well over 20% of the total cadmium produced.

Cadmium Carbonate. [CAS: 513-78-0] $CdCO_3$, $pK_{sp} = 11.3$, is formed by the hydroxide upon absorption of CO_2, or upon precipitation of a cadmium salt with ammonium carbonate. With alkali carbonates, the oxycarbonates are produced.

Cadmium nitrate tetrahydrate, solubility 215 g/100 ml H_2O at 0 °C, is obtained by action of HNO_3 upon the carbonate. It is ionized completely only in solutions weaker than about tenth molar. However, it does not form hydroxy compounds as readily as the zinc salt, requiring the action of NaOH, which in moderate concentration gives $Cd(NO_3)_2 \cdot 3Cd(OH)_2$ and $Cd(NO_3)_2 \cdot Cd(OH)_2$; excess sodium hydroxide precipitates the hydroxide.

Cadmium forms a wide variety of other salts, many by reaction of the metal, oxide, or carbonate with the acids, although some can be obtained only by fusion of the oxides or hydroxides. They include the antimonates (pyro- and meta-), the arsenates (ortho-, meta-, and pyro-, including acid salts as well as normal), the arsenites, the borates ($Cd(BO_2)_2$, $Cd_2B_6O_{11}$, $Cd_3(BO_3)_3$ and $Cd_3B_2O_6$ have been identified), the bromate, the bicarbonate, the chlorate, the chlorite, chromates and dichromates, the cyanide, the ferrate, the iodate, the molybdate, $CdMoO_4$, the nitrate, the perchlorate, various periodates, the permanganate, various phosphates (*ortho*, *meta*, and *para*, including acid salts as well as normal), the selenates and selenites, various silicates, the stannate, the sulfate (which reacts with limited amounts of NaOH or NH_3 solution to give various hydroxy sulfates), the thiosulfate, the titanate, the tungstate, and the uranate.

Cadmium arsenide, nitride, selenide, and telluride are known, the first and third obtainable from the elements, while the nitride is obtained by heating the amide (obtained by reaction of cadmium thiocyanate and potassium amide in liquid NH_3), and the telluride is obtainable by reduction of the tellurate with hydrogen. Cadmium arsenide is used as a semiconductor.

One of the features of the chemistry of cadmium is that it forms a relatively large number of complexes. A number of solid double halides of compositions $MCdX_3$, M_2CdX_4, M_3CdX_5 and M_4CdX_6 where M is an alkali metal and X a halogen are known, the last two probably existing only in the solid state. Conductance studies of solutions indicate the presence of such ions as CdX^+, CdX_3^- and CdX_4^{2-}. The donor ability of oxygen is less toward cadmium than toward zinc, fewer oxygen complexes and organic oxygen-linked complexes being known. Sulfur is a better donor than oxygen; additives of the type $(R_2S)_2 \cdot CdX_2$ are formed from di-alkyl sulfides and cadmium halides. The ready reactions with NH_3, as with amines, give large numbers of complexes; those with ammonia include tetrammines and hexammines, containing $[Cd(NH_3)_4]^{2+}$ and $[Cd(NH_3)_6]^{2+}$, respectively. Ethylenediamine forms 6-coordinate compounds containing $[Cd(en)_3]^{2+}$. Prominent among the carbon donor complexes are the cyanides, principally compounds of $Cd(CN)_4^{2-}$, although $Cd(CN)_3^-$ is also known. Other carbon donor compounds are the organometallic compounds CdR_2, where R may be methyl, ethyl, propyl, butyl, isobutyl, isoamyl, amylthio, phenyl, octylthio, decylthio, and higher organic radicals.

CADMIUM RED LINE. A line in the spectrum of cadmium at 6438.4696 angstroms which, because it was the most narrow line known to Michelson, was used by him in measuring the standard meter and was formerly accepted as the primary standard of wavelengths.

CAESALPINA TREE. Of the family *Caesalpiniaceae*, this large, wide-spreading, and showy tree is found in tropical America, Sri Lanka, India, and Malaya. Some trees have been introduced into other tropical climates, but the tree is not considered plentiful. Flowers of all genera have colorful orange and red blossoms with five thin, spreading petals and long stamens. The wood is a rich red and takes a high polish. The wood also can be dyed to yield various shades of crimson and purple and thus, if available, is suited for fine items of furniture and musical instruments. Originally the tree was called the poinciana, after a governor of the French West Indies, M. dePoinci. The name was changed some years ago in honor of the Italian botanist, Andrew Cesalpino.

CAFFEINE. See **Alkaloids**.

CAIRNGORM STONE. The name given to the smoky brown variety of quartz, particularly when transparent, from Cairngorm, Scotland, a well-known locality. See also **Quartz**.

CAISSON DISEASE. Those conditions including collapse, neurological changes, and pain, associated with relatively rapid reduction of ambient pressure from levels appreciably higher than 1 atmosphere to 1 atmosphere; and due to the release of inert gases in the body. Also called *compressed air illness, bends.*

CAJAL, SANTIAGO RAMÓN Y (1852–1934). Santiago Ramón y Cajal was born on May 1, 1852, in Petilla de Aragon, a Navarre enclave in Aragon, Spain. As a boy he was apprenticed first to a barber and then to a cobbler. He himself wished to be an artist — his gift for draftsmanship is evident in his published works. His father, however, who was Professor of Applied Anatomy in the University of Saragossa, persuaded him to study medicine, which he did, chiefly under the direction of his father.

In 1873 he took his Licentiate in Medicine at Saragossa and served, after a competitive examination, as an army doctor. He took part in an expedition to Cuba in 1874-75, where he contracted malaria and tuberculosis. On his return he became an assistant in the School of Anatomy in the Faculty of Medicine at Saragossa (1875) and then, at his own request, Director of the Saragossa Museum (1879). In 1877, he obtained the degree of Doctor of Medicine at Madrid and in 1883, he was appointed Professor of Descriptive and General Anatomy at Valencia. In 1887, he was appointed Professor of Histology and Pathological Anatomy at Barcelona and in 1892, he was appointed to the same chair at Madrid. He was Director of the National Institute of Hygiene 1899. In 1902, he founded the *Laboratorio de Investigaciones Biológicas*, which later became the Cajal Institute.

The Cajal Institute is the largest neuroscience research centre in Spain. It was inaugurated in 1932 and named in honor of our famous Nobel Prize winner in Medicine and Physiology. When the CSIC was created in 1939, the Cajal Institute was incorporated into this national organization. The present facilities were inaugurated on October 3, 1989. http://www.cajal.csic.es/

Among his many distinctions and memberships of societies, he was made an honorary Doctor of Medicine of the Universities of Cambridge (1894) and Würzburg (1896), and Doctor of Philosophy of the Clark University (Worcester, MA, U.S.A. 1899).

Cajal is considered the most prestigious Spanish scientist and his discoveries are the cornerstone of the neurological sciences. Widely thought of as the founder of neuroscience, Cajal made remarkable explorations into the organization and function of the nervous system. His brilliant studies were so important for the scientific community that in histology there is talk of two periods: before and after Cajal. His name is currently one of the most mentioned in the collection of the more than 12,000 existing scientific reviews.

Cajal was much more than a histological wise man. He was, overall, a man of sciences and, together with Bernard the greatest man in the medical field. Both of them, together with Galileo, Newton, Darwin, Pasteur and Einstein, possibly are the greatest seven gifted scientists of the whole Modern Era.

He published over 100 scientific works and articles in French, Spanish and German. His most famous works are the *Rules and Advices on Scientific Investigation, Histology*, *Degeneration and Regeneration of the Nervous System, Manual of Normal Histology and Micrographic Technique, Elements of Histology, etc., Manual of General Pathological Anatomy, New Ideas on the Fine Anatomy of the Nerve Centres*, Textbook on *The Nervous System of Man and the Vertebrates*, and *The Retina of Vertebrates*.

To describe the work of Cajal is rather a difficult task, because, unlike other great scientists, he is not known for one discovery only. His most famous studies were on the structure of the cortex of the brain. He discovered that the nervous system is made up of billions of separate nerve cells (neurons) and that nerve cells are polarized. He described the terminal branching of neurons, devised a way to stain nerve tissues, and made many other discoveries in the structure of the nervous system. For this work, he was awarded the Nobel Prize in 1906, which he shared with Camillo Golgi. See also **Golgi, Camillo (1843–1926)**.

Besides his medical work, Cajal developed his knowledge in a great number of other fields due to an incomparable intellect, work capacity and natural curiosity. Cajal was a photographer, a draftsman and a man of literature, arts to which he devoted himself with great care, determination, effort and good making.

CALANDRIA. A common device used for the heating of vacuum-evaporating apparatus, known as vacuum pans. It comprises a system of vertical steam-jacketed metal tubes open at both ends and joined by heavy metal plates so that a honeycomb structure is formed. Both the tubes and the space beneath the calandria are filled with liquid, which is heated by contact with the tubes.

CALAVERITE. A gold telluride, $AuTe_2$, associated with quartz in low-temperature veins. A valuable gold ore from Kalgorrlie, Western Australia and the Cripple Creek region of Colorado. The ore occurs in bladed to lath-like monoclinic crystals with striations parallel to the long axis of the crystals. The ore has a metallic luster of brass-yellow to silver-white color, a hardness of 2.5 to 3, a specific gravity of 9.24 to 9.31, and a yellowish to greenish-gray streak.

CALCAREA. A class of the phylum *Porifera* containing sponges whose spicules are calcareous. They are marine animals exclusively.

The sponges of this class include the simplest of the entire phylum. Some are of the ascon type, with canals passing completely through the body wall, and others are sycon sponges with two sets of canals, the incurrent

leading into the body wall from the exterior and the radial leading from the body wall to the interior of the sponge. Common sponges are available to illustrate both forms. These structural differences and the examples mentioned characterize the two orders into which the class is divided:

Order Homocoela. Ascon sponges.
Order Heterocoela. Sycon sponges.

CALCIFICATION (Bone). See **Bone**.

CALCINATION. The subjection of a substance to a high temperature below its fusion point, often to make the substance friable. Calcination frequently is carried out in long, rotating, cylindrical vessels, known as kilns. Material so treated may (1) lose moisture, e.g., the heating of silicic acid or ferric hydroxide resulting in the formation of silicon oxide or ferric oxide, respectively, (2) lose a volatile constituent, e.g., the heating of limestone (calcium carbonate) resulting in the formation of carbon dioxide gas and calcium oxide residue — destructive distillation of many organic substances is of this type — (3) be oxidized or reduced, e.g., the heating of pyrite (iron disulfide) in air resulting in the formation of sulfur dioxide gas and ferric oxide residue. When the calcination involves oxidation, as in the preceding case, the operation is termed roasting. When heating involves reduction of metals from their ores with separation from the gangue of the liquid metal and slags, the process is termed smelting.

CALCITE. The mineral calcite, carbonate of calcium corresponding to the formula $CaCO_3$, is one of the most widely distributed minerals. Its crystals are hexagonal-rhombohedral although actual calcite rhombohedrons are rare as natural crystals. However, they show a remarkable variety of habit including acute to obtuse rhombohedrons, tabular forms, prisms, or various scalenohedrons. It may be fibrous, granular, lamellar or compact. The cleavage in three directions parallel to rhombohedron is highly perfect; fracture, conchoidal but difficult to obtain; hardness, 3; specific gravity, 2.7; luster, vitreous in crystallized varieties; color, white or colorless through shades of gray, red, yellow, green, blue, violet, brown, or even black when charged with impurities; streak, white; transparent to opaque; it may occasionally show phosphorescence or fluorescence.

Calcite is perhaps best known because of its power to produce strong double refraction of light such that objects viewed through a clear piece of calcite appear doubled in all of their parts. A beautifully transparent variety used for optical purposes comes from Iceland, for that reason is called Iceland spar.

Acute scalenohedral crystals are sometimes referred to as dogtooth spar. Calcite represents the stable form of calcium carbonate; aragonite will go over to calcite at 470 °C (878 °F). Calcite is a common constituent of sedimentary rocks, as a vein mineral, and as deposits from hot springs and in caves as stalactites and stalagmites.

Localities that produce fine specimens in the United States include the Tri-State area of Missouri, Oklahoma, and Kansas, as well as Wisconsin, Tennessee, and Michigan with inclusions of native copper; several areas in Mexico, notably Charcas and San Luis Potosi; Iceland; Cumberland and Durham regions in England; and at various regions in S.W. Africa, notably Tsumeb. The exceptionally fine sand-calcite crystals from South Dakota and Fontainebleau in France are well known.

CALCIUM. [CAS: 7440-70-2] Chemical element, symbol Ca, at. no. 20, at. wt. 40.08, periodic table group 2 (alkaline earths), mp 837–841 °C, bp 1,484 °C, density 1.54 g/cm^3 (single crystal). Elemental calcium has a face-centered cubic crystal structure when at room temperature, transforming to a body-centered cubic structure at 448 °C.

Calcium is a silver-white metal, somewhat malleable and ductile; stable in dry air, but in moist air or with water reacts to form calcium hydroxide and hydrogen gas; when heated burns in air to form calcium oxide emitting a brilliant light. Discovered by Davy in 1808.

There are six stable isotopes, ^{40}Ca, ^{42}Ca, ^{43}Ca, ^{44}Ca, ^{46}Ca, and ^{48}Ca, with a predomination of ^{40}Ca. In terms of abundance, calcium ranks fifth among the elements occurring in the earth's crust, with an average of 3.64% calcium in igneous rocks. In terms of content in seawater, the element ranks seventh, with an estimated 1,900,000 tons of calcium per cubic mile (400,000 metric tons per cubic kilometer) of seawater. Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2$. Ionic radius Ca^{2+} 1.06 Å. Metallic radius 1.874 Å. First ionization potential 6.11 eV; second, 11.82 eV; third, 50.96 eV. Oxidation potentials $Ca \rightarrow Ca^{2+} + 2e^-$, 2.87 V; $Ca + Ca(OH)_2 + 2e^-$, 3.02 V.

Other important physical properties of calcium are given under **Chemical Elements**.

Calcium occurs generally in rocks, especially limestone (average 42.5% CaO) and igneous rocks; as the important minerals limestone (calcium carbonate, $CaCO_3$), gypsum (calcium sulfate dihydrate, $CaSO_4 \cdot 2H_2O$), phosphorite, phosphate rock (calcium phosphate, $Ca_3(PO_4)_2$), apatite (calcium phosphate-fluoride, $Ca_3(PO_4)_2$ plus CaF_2), fluorite, fluorspar (calcium fluoride, CaF_2); in bones and bone ash as calcium phosphate, and in egg shells and oyster shells as calcium carbonate. See also **Apatite**; **Calcite**; **Fluorite**; and **Gypsum**.

In the United States and Canada, calcium metal is produced by the thermal reduction of lime with aluminum. Before World War II, most elemental calcium was made by electrolysis of fused calcium chloride. In the thermal reduction process, lime and aluminum powder are briquetted and charged into high-temperature alloy retorts, which are maintained at a vacuum of 100 μm or less. Upon heating the charge to 1,200 °C, the reaction takes place slowly, releasing Ca vapor. The latter is removed continuously by condensation, thus permitting the reaction to proceed to completion. High-purity lime is required as a starting ingredient if resulting calcium metal of high purity is desired. Aluminum contamination of the resulting calcium is removed by an additional vacuum-distillation step. Other impurities also are reduced by this distillation step.

Uses of Elemental Calcium: The very active chemical nature of calcium accounts for its major uses. Calcium is used in tonnage quantities to improve the physical properties of steel and iron. Tonnage quantities are also used in the production of automotive and industrial batteries. Other major uses include refining of lead, aluminum, thorium, uranium, samarium, and other reactive metals.

Calcium treatment of steel results in improved yields, cleanliness, and mechanical properties. Because it is a very strong deoxidizer and sulfide former, calcium will improve the deoxidation and desulfurization of steel. In addition, it alters the morphology and size of inclusions, reduces internal and surface defects, and reduces macrosegregation. Hydrogen-induced cracking of line pipe steels by high-sulfur fuels is reduced with calcium treatment. Several grades of calcium-treated steel are used in automotive, industrial, and aircraft applications. Oil line pipe, heavy plate, and deep drawing sheet were first treated in Japan. Additional uses have been developed in the United States and Europe.

The high vapor pressure and reactivity of calcium limited its use in steel and iron making prior to the development of injection systems and mold nodularization processes. There are two types of injection systems. One consists of the use of a holding furnace, a sealed vessel, a carrier gas, and a lance through which calcium or calcium compounds are blown into the molten metal. This system is effective for massive desulfurization of large quantities of steel. It is a ladle process. The second type of injection process is wire feeding. A steel-jacketed calcium-core wire is fed through a delivery system that drives the composite wire below the surface of the liquid metal bath. The steel jacket protects the solid metallic calcium from reacting at the surface and allows it to penetrate deep into the bath. Because the reaction occurs below the surface, high and reproducible calcium recoveries are possible. This process is used in both ladle additions and in tundish additions for continuous casting. It provides shape control, deoxidation, final desulfurization and reduction of macrosegregation.

Ladle and mold processes using calcium ferroalloys are important in the production of nodular iron castings. The principal calcium alloy used is magnesium ferrosilicon. Calcium reduces the reactivity of the alloy; with the molten iron it enhances nucleation and improves morphology. The calcium content of the alloy is proportional to the magnesium content, typically in the range of 15–50% of magnesium content. In ladle or sandwich treatment techniques, pieces of the ferroalloy are placed in a pocket cut in the refractory lining of the ladle and the molten iron is then poured into the ladle. The treated, nodularized iron is then cast from the ladle into molds.

In the mold addition process, a granular form of the alloy is placed in a small reaction chamber in the mold. The nodularization treatment occurs in the mold when the iron is cast, rather than in the ladle. The reaction is contained in the mold, and high recoveries result. The production of nodular iron castings is over three million tons per year.

A calcium lead alloy is used in maintenance-free automotive and industrial batteries. The use of calcium reduces gassing and improves the life of the battery. From 0.1 to 0.5% calcium is alloyed with the lead prior to the fabrication of the battery plates either by casting or through the

production of coiled sheet. With calcium present, these lead-acid batteries can be sealed and do not require the service of conventional batteries. The batteries have a higher energy-to-weight ratio. Of the battery market in the United States, over 50 million batteries per year, 40% are maintenance-free types.

Calcium is used in refining battery-grade lead for removing bismuth. Calcium is also used as an electrode material in high-energy thermal batteries.

The production of samarium cobalt magnets requires the use of calcium. The reaction is

$$3\ Sm_2O_3 + 10\ Co_3O_4 + 49\ Ca\ (vapor) \xrightarrow[\Delta]{850-1150\,^\circ C} 6\ SmCo_5 + 49\ CaO$$

$$0.75 \text{ weight units of Ca} \longrightarrow 1 \text{ weight unit of } SmCo_5$$

Samarium cobalt magnets have three to six times greater magnetic energy than alnico magnets.

Calcium serves as a reductant for such reactive metals as zirconium, thorium, vanadium, and uranium. In zirconium reduction, zirconium fluoride is reacted with calcium metal. The high heat of the reaction melts the zirconium. The zirconium ingot resulting is remelted under vacuum for purification. Thorium and uranium oxides are reduced with an excess of calcium in reactors or trays under an atmosphere of argon. The resulting metals are leached with acetic acid to remove the lime.

Calcium is also used in aluminum alloys and as an addition in a magnesium alloy used for etching. An alloy of 80% Ca-20% Mg is used to deoxidize magnesium castings. The metal also is used in the production of calcium pantothenate, a B-complex vitamin.

Chemistry and Compounds: Calcium exhibits a valence state of +2 and is slightly less active than barium and strontium in the same series. Calcium reacts readily with all halogens, oxygen, sulfur, nitrogen, phosphorus, arsenic, antimony, and hydrogen to form the halides, oxide, sulfide, nitride, phosphide, arsenide, antimonide, and hydride. It reacts vigorously with water to form the hydroxide, displacing hydrogen. Calcium oxide (quicklime) adds water readily and with the evolution of much heat (slaked lime) to form the hydroxide. Calcium hydroxide forms a peroxide on treatment with hydrogen peroxide in the cold. Calcium exhibits little tendency to form complexes; the ammines formed with ammonia are unstable, although a solid of composition $Ca(NH3)^6$ can be isolated from solutions of the metal in liquid ammonia.

Calcium acetate. [CAS: 62-52-4] $Ca(C_2H_3O_2)_2 \cdot H_2O$, white solid, solubility: at 0 °C, 27.2 g; at 40 °C, 24.9 g, at 80 °C, 25.1 g of anhydrous salt per 100 g saturated solution, formed by reaction of calcium carbonate or hydroxide and acetic acid.

Calcium aluminates. Four in number, have been prepared by high-temperature methods and identified, tricalcium alumenate $3CaO \cdot Al_2O_3$, at 1,535 °C, decomposes with partial fusion; pentacalcium alumenate $5CaO \cdot Al_2O_3$, mp 1,455 °C, monocalcium alumenate $CaO \cdot Al_2O_3$, mp 1,590 °C and dodecacalcium hepta alumenate $12CaO \cdot Al_2O_3$, mp around 1,400 °C.

Calcium aluminosilicates. Two in number, have been prepared by high-temperature methods and identified: $2CaO \cdot Al_2O_3 \cdot SiO_2$, gehlinite; $CaO \cdot Al_2O_3 \cdot 2SiO_2$, anorthite.

Calcium arsenate. [CAS: 7778-44-1] $Ca_3(AsO_4)_2$, white precipitate, formed by reaction of soluble calcium salt solution and sodium arsenate solution. $pK_{sp} = 18.17$.

Calcium arsenite. [CAS: 524740-16-6] $Ca_3(AsO_3)_2$, white precipitate, formed by reaction of soluble calcium salt solution and sodium arsenite solution.

Calcium borates. Found in nature as the minerals colemanite, $Ca_2B_6O_{11} \cdot 5H_2O$, borocalcite, $CaB_4O_7 \cdot 4H_2O$, and pandermite $Ca_2B_6O_{11} \cdot 3H_2O$. See also **Colemanite**.

Calcium bromide. [CAS: 7789-41-5] $CaBr_2 \cdot 6H_2O$, white solid, solubility 1,360 g/100 ml H_2O at 25 °C, formed by reaction of calcium carbonate or hydroxide and hydrobromic acid.

Calcium carbide. [CAS: 75-20-7] CaC_2, grayish-black solid, reacts with water yielding acetylene gas and calcium hydroxide, formed at electric furnace temperature from calcium oxide and carbon.

Calcium carbonate. [CAS: 471-34-1] $CaCO_3$, found in nature as calcite, Iceland spar, marble, limestone, coral, chalk, shells of mollusks, aragonite. $pK_{sp} = 8.32$. It is (1) readily dissolved by acids forming the corresponding calcium salts, (2) converted to calcium oxide upon heating. Aragonite is an unstable form at room temperature, although no change is observable until heated, when, at 470 °C, it is quickly converted into calcite; calcium hydrogen carbonate, calcium bicarbonate, $Ca(HCO_3)$, known only in solution, formed by reaction of calcium carbonate and carbonic acid. See also **Aragonite**; and **Calcite**.

Calcium chloride. [CAS: 10043-52-4] $CaCl_2 \cdot 6H_2O$, white solid, solubility 536 g/100 g H_2O at 20 °C, absorbs water from moist air, formed by reaction (1) of calcium carbonate or hydroxide and HCl, (2) of calcium hydroxide and ammonium chloride.

Calcium chromate. [CAS: 13765-19-0] $CaCrO_4$, yellow solid, formed by the reaction of chrome ores and calcium oxide heated to a high temperature in a current of air. $pK_{sp} = 3.15$.

Calcium citrate. [CAS: 813-95-5] $Ca_3(C_6H_5O_7)_2 \cdot 4H_2O$, white solid, solubility: at 18 °C 0.085 g/100 g H_2O, formed by reaction of calcium carbonate or hydroxide and citric acid solution.

Calcium cyanamide. [CAS: 156-62-7] $CaCN_2$, white solid, formed (1) by heating cyanamide or urea with calcium oxide, sublimes at 1,050 °C, (2) by heating calcium carbide at 1,100–1,200 °C in a current of nitrogen. Decomposes in water with evolution of NH_3.

Calcium fluoride. [CAS: 4789-75-5] CaF_2, white precipitate, formed by reaction of soluble calcium salt solution and sodium fluoride solution. $pK_{sp} = 10.40$. See also **Fluorite**.

Calcium formate. [CAS: 544-17-2] $Ca(CHO_2)_2$, white solid, solubility at 0 °C 13.90 g, at 40 °C 14.56 g, at 80 °C 15.22 g of anhydrous salt per 100 g saturated solution, formed by reaction of calcium carbonate or hydroxide and formic acid. Calcium formate, when heated with a calcium salt of a carboxylic acid higher in the series, yields an aldehyde.

Calcium furoate. $Ca(C_4H_3O \cdot COO)_2$, formed by reaction of calcium carbonate or hydroxide and furoic acid.

Calcium hydride. [CAS: 7789-78-8] CaH_2, white solid, reacts with water yielding hydrogen gas and calcium hydroxide; when electrolyzed in fused potassium lithium chloride, hydrogen is liberated at the anode.

Calcium hypochlorite. [CAS: 7778-59-3] $CaOCl_2$ or $Ca(ClO)_2 \cdot 4H_2O$, white solid, contains 60%–65% "available chlorine" and sufficient calcium hydroxide to stabilize, formed by reaction of calcium hydroxide and chlorine. Very soluble in water.

Calcium hypophosphite. [CAS: 7789-79-9] $Ca(H_2PO_2)_2$, white solid, solubility 15.4 g/100 g H_2O at 25 °C, formed (1) by boiling calcium hydroxide suspension in water and yellow phosphorus, (2) by reaction of calcium carbonate or hydroxide and hypophosphorous acid.

Calcium iodide. [CAS: 10002-68-8] CaI_2, yellowish-white solid, solubility 66 g/100 g H_2O at 10 °C, formed by reaction of calcium carbonate or hydroxide and hydriodic acid. The hexahydrate, $CaI_2 \cdot 6H_2O$, is soluble to the extent of 1.680 g/100 g H_2O at 30 °C.

Calcium lactate. [CAS: 814-80-2] $Ca(C_3H_5O_3)_2 \cdot 5H_2O$, white solid, solubility at 0 °C 3.1 g, at 30 °C 7.9 g of anhydrous salt per 100 g H_2O, formed by reaction of calcium carbonate or hydroxide and lactic acid.

Calcium malate. [CAS: 17482-42-7] $CaC_4H_4O_5 \cdot 2H_2O$, white solid, solubility at 0 °C 0.670 g, at 37.5 °C 1.011 g of anhydrous salt per 100 g saturated solution. Formed (1) by reaction of calcium carbonate or hydroxide and malic acid, (2) by precipitation of soluble calcium salt solution and sodium malate solution. See also **Malic acid**.

Calcium nitrate. [CAS: 10124-37-5] $Ca(NO_3)_2 \cdot 4H_2O$, white solid, solubility 660 g/100 g H_2O at 30 °C, formed by reaction of calcium carbonate or hydroxide and HNO_3.

Calcium oxalate. [CAS: 563-72-4] CaC_2O_4, white precipitate, insoluble in weak acids, but soluble in strong acids, formed by reaction of soluble calcium salt solution and ammonium oxalate solution. Solubility at 18 °C 0.0056 g anhydrous salt per liter of saturated solution.

Calcium oxide. [CAS: 1305-78-8] CaO (quicklime), white solid, mp 2,570 °C, reacts with H_2O to form calcium hydroxide with the evolution of much heat; reacts with H_2O vapor and CO_2 of the atmosphere to form calcium hydroxide and carbonate mixture (slaked lime); formed by heating limestone at high temperature (800 °C) and removal of CO_2. This process is conducted industrially in a lime kiln.

Tricalcium phosphate. [CAS: 7758-87-4] $Ca_3(PO_4)_3$, white solid, insoluble in water; reactive with silicon oxide and carbon at electric furnace temperature yielding phosphorus vapor; reactive with H_2SO_4 to form, according to the proportions used, phosphoric acid, or dicalcium hydrogen phosphate, $CaHPO_4$, white solid, insoluble; or calcium dihydrogen phosphate, $Ca(H_2PO_4)_2 \cdot H_2O$, white solid, soluble. $pK_{sp} = 28.70$. See also **Apatite**.

Calcium silicates. [CAS: 1344-95-2] Four have been prepared by high-temperature methods and identified: $3CaO \cdot SiO_2$, prepared by heating the constituents to a temperature below the mp (mp is 1,700 °C but substance unstable); $2CaO \cdot SiO_2$, mp 2,080 °C, but upon slow cooling changes to forms of different volume; $3CaO \cdot 2SiO_2$, mp 1,475 °C; and $CaO \cdot SiO_2$, wollastinite, mp approximately 1,400 °C. See also **Clinozoisite**; **Datolite**; **Diopside**; **Feldspar**; **Lawsonite**; **Tremolite**; and **Wollastoiite**.

Calcium sulfate. [CAS: 7778-18-9] Gypsum, $CaSO_4 \cdot 2H_2O$, plaster of Paris, $CaSO_4 \cdot \frac{1}{2}H_2O$, anhydrite $CaSO_4$, white solid, slightly soluble (about 0.2 g per 100 ml of H_2O), formed by reaction of soluble calcium salt solution with a sulfate solution. pK_{sp} of $CaSO_4 = 4.6_{25}$. See also **Anhydrite**; and **Gypsum**.

Calcium sulfide. [CAS: 20548-54-3] CaS, grayish-white solid, reactive with H_2O, formed by reaction of calcium sulfate and carbon at high temperatures. Calcium hydrogen sulfide, $Ca(HS)_2$, formed in solution by saturating calcium hydroxide suspension with $H_2S \cdot pK_{sp}$ of $CaS = 7.24$.

Calcium sulfite. $CaSO_3 \cdot 2H_2O$, white precipitate, $pK_{sp} = 7.9$, formed by reaction of soluble calcium salt solution and sodium sulfite solution, or by boiling calcium hydrogen sulfite solution; calcium hydrogen sulfite, $Ca(HSO_3)_2$, formed in solution by saturating calcium hydroxide or carbonate suspension with sulfurous acid.

Calcium tartrate. [CAS: 3164-34-9], dehydrate [CAS: 5692-21-7], anhydrous $CaC_4H_4O_6 \cdot H_2O$, white solid, solubility: at 0 °C 0.0875, at 80 °C 0.180 g anhydrous salt in 100 ml saturated solution, formed by reaction of calcium carbonate or hydroxide and tartaric acid, or by precipitation of Ca^{2+} with a tartrate solution. Calcium tartrate is a by product of the wine industry.

CALCIUM (In Biological Systems). The biological role and, consequently, the importance of calcium in foods for humans and feedstuffs for livestock is well established. Although about 99% of the calcium in the bodies of animals is found in bones and teeth, the element is an essential constituent of all living cells.

Various calcium salts and organic compounds fall into this category of dietary supplements and are frequently used in feeds and foods. Some of the more important additives include calcium carbonate, calcium glycerophosphate, calcium phosphate (di- and monobasic), calcium pyrophosphate, calcium sulfate, and calcium pantothenate.

Limestone is frequently used to augment animal feedstuffs. When used, it must be low in flourine. Calcite limestone is preferred. Calcium is also supplied in the form of crushed oyster shells, marl, gypsum (calcium sulfate), bone meal, and basic slag. In compounding feedstuffs, the specific selection of calcium source is dependent upon the species to be fed. The requirements differ, for example, between cattle, swine, and poultry. The quantity required also varies with the life stage of the animal. For example, laying hens require a much higher percentage of calcium in their diet than starting poultry.

In the mammalian body, calcium is required to insure the integrity and permeability of cell membranes, to regulate nerve and muscle excitability, to help maintain normal muscular contraction, and to assure cardiac rhythmicity. Calcium plays an essential role in several of the enzymatic steps involved in blood coagulation and also activates certain other enzyme-catalyzed reactions not involved in any of the foregoing processes. Calcium is the most important element of bone salt. Together with phosphate and carbonate, calcium confers on bone most of its mechanical and structural properties.

Calcium Metabolism

The aggregate of the various processes by which calcium enters and leaves the body and its various subsystems can be summarized by the term *calcium metabolism*. The principal pathways of calcium metabolism are intake, digestion and absorption, transport within the body to various sites, deposition in and removal from bone, teeth, and other calcified structures, and excretion in urine and stool.

Pathways. The principal pathways involve three subsystems of the body: (1) the oral cavity where ingestion occurs and the gastrointestinal tract where digestion and absorption take place and from which the feces is excreted; (2) the body fluids, including blood, which transport calcium, and the soft tissues and body organs to which calcium is transported and where many of its physiological functions are carried out (some of the organs, like the kidney, the liver, and sweat glands, are also responsible for calcium excretion); and (3) the skeleton, including the teeth, where calcium is deposited in the form of bone salt and from where it is removed (resorbed) after destruction of the bone salt.

Calcium Intake. This varies in different populations and is related to the food supply and to the cultural and dietary patterns of a given population. The intake of a substantial fraction of the world population falls between 400 and 1,100 mg/day, but a range encompassing 95% of all people would undoubtedly be even wider. Most populations derive half or more of their calcium intake from milk and dairy products. Calcium intakes of domestic and laboratory animals are higher than are those of humans. For example, rats typically ingest 250 mg Ca/kg body weight, and cattle 100 mg/kg, whereas humans ingest only 10 mg/kg. Ingestion falls with age in all species. The average percentage concentration of minerals in the lean body mass of vertebrates ranges from 1.1 to 2.2%.

Calcium Absorption. In most animals, including the human body, this occurs mainly in the upper portion of the small intestine. The amount and, therefore, the fraction of calcium absorbed from the gut are a function of intake, age, nutritional status, and health. Generally, the fraction absorbed decreases with age and intake and as the nutritional status improves. The absolute amount absorbed increases with intake and may or may not decrease with age. The mechanisms by which calcium is absorbed are not well understood. Active transport of the ion against an electrochemical gradient seems to be involved, but not all of the calcium appears to be absorbed by ways of this process, because calcium absorption continues under conditions when active transport is severely depressed, as in vitamin D deficiency. Calcium absorption can be enhanced by the administration of large doses of vitamin D and is depressed in vitamin D deficiency. There is uncertainty regarding the effect on calcium absorption of the parathyroid hormone, the major endocrine control of the blood calcium level. Patients with hyperparathyroidism have been shown to have higher than normal absorption and patients with hypoparathyroidism to have lower than normal absorption. Similar effects have been observed in acute animal experiments, but in most of these instances a possible indirect effect has not been excluded.

Effects of Microgravity. Experience to date with humans who have lived under microgravity conditions in spacecraft has indicated possible "demineralization" of bone structure. Research has been difficult because the time spans of exposure have been so short. More must be known, however, as plans for programs requiring living under microgravity conditions for months and years are getting underway. Some analytic marker, which can return a record of changes that have occurred during space travel, is needed. A marker isotope, calcium-48, is now being seriously considered. The isotope is not abundant in nature and must be produced in the laboratory. Researchers contemplate that, by using a laser to excite calcium-48 at its resonance frequency, it will be possible to extract the isotope from samples.

Interrelationship with Phosphorus and Vitamin D. The interdependence of calcium, phosphorus, and vitamin D is exemplary of how synergistic effects can occur from combinations of feed and food components, either with a positive or negative result in the animal body. The relative concentrations (proportions) of each component in such a combination can be quite critical. Much research has gone into these particular interrelationships; much further research is required. The relationship between phosphorus and calcium nutrition has been known since the early 1840s, when Chossat in France first discovered that pigeons develop a poor bone structure when fed diets low in calcium. A few years later, the fundamental relationship of calcium and phosphorus in animal diets was developed by French and German researchers. It was not until 1922, however, with the discovery of vitamin D, that a triangular relationship was observed. See also **Bone**; **Phosphorus**; and **Vitamin D**.

Calcium in Blood Plasma. The concentration of calcium in the blood plasma of most mammals and many vertebrates is quite constant at about 2.5 mM (10 milligrams per 100 milliliters plasma). In the plasma, calcium exists in three forms: (1) as the free ion. (2) bound to proteins, and (3) complexed with organic (e.g., citrate) or inorganic (e.g., phosphate) acids. The free ion accounts for about 47.5% of the plasma calcium; 46% is bound to proteins; and 6.5% is in complexed form. Of the latter, phosphate and citrate account for half.

The mechanism involved in the regulation of the plasma calcium level is not fully understood. The parathyroid glands regulate both level and constancy; when these glands are removed, the plasma level drops and tends to stabilize at about 1.5 mM, but variations in calcium intake may induce fairly wide fluctuations in the plasma level. In the intact organism, wide variations in intake produce essentially no variations in the plasma calcium value, which is stabilized at about 2.5 mM. The equilibrium between bone and plasma is believed to determine the level of the plasma calcium in parathyroidectomized animals, but this reasonable hypothesis requires further experimental support. See also **Blood**; **Endocrine System**; and **Parathyroid Gland**.

The problem of whether parathyroid regulation is due to a single hormone with hypercalcemic properties or to two hormones, one hypocalcemic, termed calcitonin, the other hypercalcemic, termed parathyroid hormone, continues under investigation.

When the calcium ion concentration is lowered in the fluids bathing nerve axons (fluids which are in very rapid equilibrium with the blood plasma) the electrical resistance of the axon membrane is lowered, there is increased movement of sodium ions to the inside, and the ability of the nerve to return to its normal state following a discharge is slowed. Thus, on the one hand, there is hyperexcitability. But, the ability for synaptic transmission is inhibited because the rate of acetylcholine liberation is a function of the calcium ion concentration. The neuromuscular junction is affected in a similar fashion; hence, the end plate potential is lowered before the muscle membrane potential and the muscle membrane is in a hyperexcitable state. These events are reversed when the calcium ion concentration is raised above the normal in the blood plasma and in the fluids bathing muscle and nerve. It is for these reasons that hypocalcemia is associated with hyperexcitability and ultimately tetany and hypercalcemia with sluggishness and bradycardia. See also **Central and Peripheral Nervous Systems and the Brain**.

Muscular Contraction and Relaxation. The role of calcium in this function is not fully understood. Some researchers have proposed that calcium is the link between the electrical and mechanical events in contraction. It has been shown *in vitro* that when calcium ions are applied locally, muscle fibers can be triggered to contract. It has further been postulated that relaxation of muscle fibers is brought about by an intracellular mechanism for reducing the concentration of calcium ions available to the muscle filaments. Others postulate that contraction occurs because calcium inactivates a relaxing substance, which is released from the sarcoplasmic reticulum in the presence of ATP (adenosine triphosphate).

Bone. This is the most important reservoir of calcium in the animal body. Accounting for the largest portion of the body's calcium, bone calcium also constitutes about 25% (weight) of fat-free, dried bones. Calcium occurs in bone mostly in the form of a complex, apatitic salt, so named for its structural resemblance to a family of calcium phosphates of which hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$ is the best-known mineralogical example. Since calcium occurs also as the carbonate, there is discussion as to whether bone salt contains the carbonate as a separate phase, whether some of the surface phosphate in apatite has been substituted for by carbonate, or whether bone mineral is a carbonato-apatite, such as dahlite. It is important to recognize that the crystal lattice of the bone mineral, when first laid down, does not and probably cannot have all possible calcium positions occupied. Whether stability is derived from hydrogen and/or organic bonds to which the mineral may be attached is not fully determined. It has been proposed that bone salt is a lamellar mixture of octocalcium phosphate and hydroxyapatite. This hypothesis has to account for the amount of pyrophosphate formed when bone salt is heated and also for its evolution with age, i.e., the increase with age in the calcification of bone and the corresponding drop in its induced pyrophosphate content, observations for which the apatitic structure can account. The proponents of the octocalcium phosphate hypothesis explain this by showing that octocalcium phosphate breaks down to apatite and anhydrous dicalcium phosphate, which upon further heating give rise to pyrophosphate. Finally, it is postulated that octocalcium phosphate may be present in young and presumably newly formed bone, whereas in older bone an apatitic phosphate admittedly dominates the equilibrium.

Calcium enters and remains in bone as a result of calcification processes that involve two steps: (1) deposition of bone salt of a minimum calcium content and specific gravity, which occurs by way of nucleation, probably an epitactic process on the collagen fibers, with the ground substance (mostly mucopolysaccharides) between the fibers exerting either a positive or an inhibitory effect on the nucleation process; and (2) subsequent further mineralization of the bone mineral, leading to an increase in its calcium content and its specific gravity.

Calcium removal, in contrast, involves destruction of the calcified structure *in toto*. There is no evidence that only particular structures are resorbed, e.g., those with a given degree of mineralization.

The amount of calcium deposited in bone at any moment may be determined from experiments with radioactive calcium. In growing individuals, it exceeds the amount removed by bone destruction. In adults, it is about the same as the amount removed. Such individuals are considered to be in "zero" calcium balance. In older persons, the amount deposited is less than the amount removed. See **Bone**.

Calcium's Role in Postmenopausal Women. The effectiveness of calcium supplementation in retarding the rate of bone loss in older, postmenopausal women, continued to be debated in the 1990s. Some studies demonstrated that calcium could reduce the rate of bone loss; other studies were not fully convincing, particularly with regard to slowing bone loss from the spine and hip. Dowson-Hughes and a group of researchers (Tufts University) conducted a double-blind, placebo-controlled, random trial to determine the effect of calcium on bone loss from the spine, femoral neck, and radius in over 300 healthy postmenopausal women. Conclusions: Healthy postmenopausal women whose usual dietary calcium intake is low should increase their calcium intake to 800 mg per day (essentially consistent with most RDAs). In the study calcium citrate maleate was found to be a better source of calcium than calcium carbonate for dietary augmentation.

A 1990 study by Sheikh and Fordtran (Baylor University Medical Center) indicated that there are important differences in the bioavailability of calcium from different calcium-containing compounds. The ability to dissolve a preparation in dilute acid is a major factor that contributes to bioavailability. Currently, the FDA (Food and Drug Administration, U.S.) does not require commercially available products to meet specific dissolution standards.

R.L. Prince and a group of investigators (Sir Charles Gairdner Hospital, Nedlands, Western Australia and King Edward Memorial Hospital, Subiaco, Western Australia) researched the effects of exercise, calcium

supplementation, and hormone replacement therapy over a two-year period involving 120 postmenopausal women. General conclusions of the study: "In postmenopausal women with low bone density, bone loss can be slowed or prevented by exercise plus calcium supplementation, or prevented by exercise plus calcium supplementation or estrogen-progesterone replacement. Although the exercise-estrogen regimen was more effective than exercise and calcium supplementation in increasing bone mass, it also caused more side effects.

Preclampsia. During but mainly at the end of pregnancy, a syndrome referred to as *preclampsia* may develop during labor or in the immediate puerperium. The condition is relatively common and poses a danger to mother and baby. With current knowledge, the condition is unpredictable in its onset and progression. See also **Embryo**; and **Pregnancy**. Presently, the only known treatment is to terminate the pregnancy.

Although there is no specific diagnostic test, certain abnormalities, including hypertension and proteinuria, may be detected. Zemel et al., as the result of conducting a study of over 50 women during each trimester of pregnancy, have found that an increase in the sensitivity of platelet calcium to arginine vasopressin may be an early predictor of subsequent preclampsia.

Excretion of Calcium. The principal routes of excretion are stool and urine. Calcium in the stool may be considered as made up of unabsorbed food calcium and non-reabsorbed digestive juice calcium. The latter is termed the fecal endogenous calcium. The proportion of fecal endogenous calcium to urinary calcium varies in different species. It is approximately 1:1 in humans and 10:1 in the rat and in cattle. The calcium in the urine may have a dual origin — calcium that was filtered at the glomerulus and failed to get reabsorbed along the length of the nephron, and calcium that may have originated from trans-tubular movement in certain regions of the nephron. The amount of calcium that may be lost in sweat can be large, but there is no convincing evidence that sweat is a habitual route of significant loss. See also **Kidney and Urinary Tract**.

Natural Availability of Calcium. The soils of humid regions are commonly low in calcium; thus, ground limestone usually is applied to add the element, reduce the toxicity of aluminum and manganese, and correct soil acidity. The soils of dry areas are frequently rich in calcium. There is little evidence to indicate a strong relationship between human nutrition and calcium excesses or deficiencies in the soil. Even with farm livestock, most calcium deficiencies are not related to levels of available calcium in the soil. The reason for this anomaly is evident when one examines some of the controls over the movement of calcium in the food chain.

At the step in the food chain when calcium moves from the soil to the plant, controls based upon the genetic nature of the plant are very important. Because of these controls, certain plant species always accumulate fairly high concentrations of calcium; while other plants accumulate rather low concentrations. Among the forage crops, red clover grown, for example, on the low-calcium soils of the northeastern United States, contains more calcium than grasses grown on the high-calcium soils of the western United States. Among the food crops, snap beans and peas normally contain about three to five times as much calcium as corn (maize) and tomatoes. Thus, the level of calcium in the diets of people or of animals depends more on what kinds of plants are included in the diet than it does on the supply of available calcium in the soil where these plants are grown.

Adding limestone to soils to correct soil acidity and to supplement available calcium will, of course, indirectly affect human and calcium nutrition, but this is a difficult quantity to measure.

See also **Diet**. Calcium channel blockers are described under **Hypertension**.

CALCULATOR (Abacus). This scheme represents one of the first formalized approaches to counting and calculating beyond the use of fingers and toes. Essentially, the abacus is a manually manipulated digital device. Records indicate that some form of the abacus was used as early as 3,000 B.C. by the Babylonians. Formats have ranged from ruled tables to moving coins around on checkered tablecloths (from which the term British Exchequer was derived) to the currently more familiar frame-and-bead construction. Experienced operators of commercial versions of the abacus, particularly in the Orient, can add, subtract, multiply, and divide with speeds comparable to those obtainable with modern, nonelectronic adding machines. Special versions of the abacus are used in some elementary schools for teaching the fundamentals of counting and arithmetic.

The principle of the abacus is shown in Fig. 1. Visualize a box or frame containing movable squares. In (a) the squares, all indicated by a gray tone, are in their "rest" or "zero" position. The squares along the top may be moved down into the "reckoning space" A, whereas the squares in the bottom portion of the box may be moved upward into "reckoning space" B. There is a "datum" line or bar that separates spaces A and B. The abacus is read by noting the number of squares that have been moved into the reckoning space, i.e., that make contact with the datum line. The squares in the upper portion, from right to left, represent, 5, 50, 500, 5,000. . . etc. Note that there is only one square in each column. The squares in the lower portion, from right to left, represent 1's, 10's, 100's, 1,000's. . . etc. The extreme right-hand column permits counting from 1 to 4, depending upon how many of the squares the operator moves upward to contact the datum line.

In Fig. 1(b) through (d), the squares that have been moved into contact with the datum line, i.e., the squares to be read, are shown in black. The indication of "1" is shown in (b); of "423" in (c). In (d), the squares in the upper portion of the box are brought into play. As indicated by (e), there is no limit to the number of columns that may be used in a frame, thus permitting calculations into 8 or 10 figures, or more. Because of the limitations of squares in the columns, however, the abacus operator frequently is called upon to make minor mental calculations, i.e., to introduce a subroutine. For example, in (c), the addition of "525" to the "423" indicated is quite simple, requiring no interim calculation. There is a "5" available to be moved down; there are two remaining "20's" which can be moved up; and there is a "500" available to be moved down. Thus, the abacus will read the correct sum, i.e., "948." However, in the case of adding "107" to the "423," the operator cannot handle the "7" because only one "5" and only one "1" is available, accounting for "6" whereas "7" is required. In this case, the operator will add "10" and take away "3." There is a further problem in adding the "100" because all four of the available "100's" are in use. This can be handled by adding "500" and taking away "400." With these manipulations completed, the abacus reads the proper sum, i.e., "530."

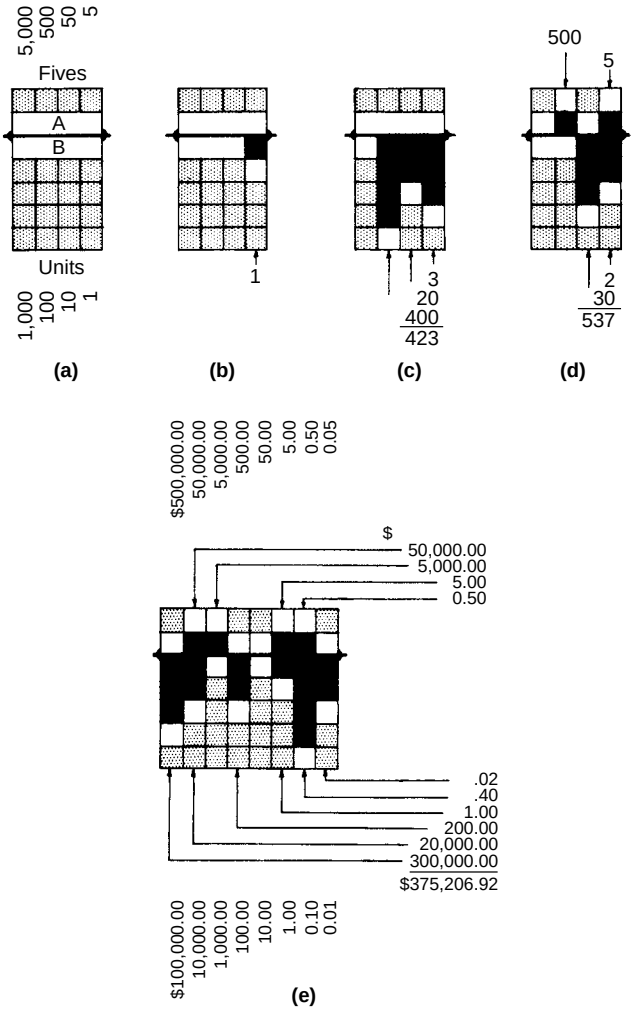

Fig. 1. Fundamentals of the abacus.

CALCULATORS. A calculator is a machine that performs the standard arithmetical operations of addition, subtraction, multiplication, and division along with a selection of pre-programmed functional operations.

The earliest form of a calculator is the *abacus*. It is a frame bearing parallel wires on which beads are moved. In a modern abacus each wire represents one place value. In many parts of Asia this device is still used. See also **Calculator (Abacus)**. Another early form of the calculator was invented by John Napier (1550–1617), a Scottish mathematician. This calculator performed multiplication and division using sliding rods and is a forerunner of the slide rule; a device used well into the 1970's by scientists, engineers, and mathematicians for making quick arithmetical calculations. Mechanical devices, using geared wheels, first appeared in the 17th century. Blaise Pascal (1623–1662) and Gottfried William Leibniz (1646–1716) were some of the early pioneers of this technology. In the 18th and 19th centuries, inventors produced smaller machines that were less laborious to use.

Others active in the field included Charles Babbage (1792–1871), who in the 1830s designed and built mechanical computing machines on principles that would later be used in modern day computers. Babbage worked on the "analytical engine," which was to have been an automatically sequenced, general-purpose calculating machine. Babbage's thoughts on the analytical engine were entirely in mechanical terms, with no suggestion, even in his later years, that electricity might be used as an aid. The analytical engine was to be decimal, although Babbage considered other scales of notation. Numbers were to be stored on wheels, with ten distinguishable positions, and transferred by a system of racks to a central *mill*, or processor, where all arithmetic would be performed. Babbage had in mind a storage capacity for a thousand numbers of 50 decimal digits. He studied exhaustively a wide variety of schemes for performing the four operations of arithmetic and he invented the concept of *anticipatory carry*, which is much faster than carrying successively from one stage to another. He also knew about *hoarding carry*, by which a whole series of additions could be performed with one carrying operation at the end. The sequencing of the analytical engine was to have been fully automatic, but not on the basis of what would be called today the stored-program principle. Punched cards of the type used in a Jacquard loom were to be adopted both for sequencing and for the input of numbers. Babbage proposed to have two sets of sequencing cards, one for controlling the mill and one for controlling the store. These would be separately stepped and would not necessarily move together.

Important allied developments in the calculating and data processing field included the development of punched-card (Hollerith code) data processing by Herman Hollerith in the 1880s, among the first applications of which were used by the U.S. Army Surgeon General for handling Army medical statistics. In 1890, the system was used in tabulating the findings of the U.S. Census for that year. See also **Hollerith**. In 1935, Alan Turing became interested in mathematical logic and, in 1937, published a paper on "On Computable Numbers with an Application to the Entscheidungsproblem," in which he introduced the concept of a Turing machine. Turing's concepts are considered and reconsidered and he is generally accredited as a major contributor to computing science as we know it today. See also **Turing Machine**.

Before 1960, most calculating machines were mechanical. They contained identical columns of digits from 0 through 9. The columns represented the place value of a number. A number was entered by pressing the corresponding digit in the correct column. The pressing of a digit moved a series of levers that recorded the number in a display, called an accumulator. As a second number was entered the levers advanced the numbers in the accumulator accordingly, either one column at a time or all at once, depending upon the design of the machine. Subtraction was done in a similar manner. Multiplication had to be done by repeated addition, and division was done by repeated subtraction. The first calculators using electricity appeared during the 1950's. Although they only replicated the simple arithmetical operations of a mechanical unit, their design was drastically new in that small non-moving electrical circuits were replacing bulky moving parts. Consequently, the technological development of the calculator was directly tied to that of the electrical circuit. One of the biggest impacts on the development of the calculator came with the invention of the integrated circuit. This allowed the calculator to perform many different calculations using the same circuit. Since less circuitry was needed, the size of the calculator decreased as well as its power consumption. This made possible the development of the pocketsize, battery-powered calculator. More importantly, as more of these circuits were used, the function capabilities of the calculator greatly increased. The logarithmic, power, trigonometric, and statistical functions were included. Three other electrical developments that were of major importance to the calculator were the ability to store information electronically, the circuitry that exhibited very low power consumption (CMOS circuitry), and the development of the liquid crystal display (LCD). The first two made it possible to save and retrieve *programs* in battery-powered calculators. Programs are sequences of operational instructions that the calculator automatically performs at the request of the operator. The third development made it possible to display alphabetic characters and pictures in addition to the standard numeric characters. The LCD also used little energy and prolonged battery life. In fact, having a calculator with programming capabilities and LCD readout is like having a miniature computer.

The general operating pattern of a calculator resembles that of a computer. The four main functions are input, storage, processing, and output. *Input* takes the information entered through the keyboard and encodes it into a digital command. The *storage* is where information is placed for current or future use. It consists of four units. Variable commands are stored in the program memory unit. Small preprogrammed routines are stored in the microprogram memory unit. The constant memory unit stores numbers that are frequently used. Copies of these numbers are placed in the number memory unit where they await usage. The constant memory and microprogram memory are read only memories (ROM). These memories cannot be altered. *Processing* in a calculator has two parts, one called the controller unit, and the other called the arithmetic and logic unit (ALU). The controller takes information sent to it either from the memory or from the encoded keyboard input and generates a series of signals. These are flows of electrical current that make the calculator programs respond in certain ways. The ALU can add and subtract digits that have been encoded as signals and it can compare two digits for size. The other operations are stored in the microprogram memory and are

simply microprogrammed sequences of addition or subtraction of digits. The *output* function takes a number stored in the number memory and translates it into a signal that controls the display.

Although any programmable calculator can be specialized to do a task by the insertion of a program, some calculators are already microprogrammed to do a particular application. Financial calculators can perform compound interest calculations, loan and mortgage amortization, present and future value yields, depreciation, effective annual rate of return, and other related items. Scientific calculators can perform all the basic engineering and statistical calculations. Some calculators perform arithmetic in, and conversion between, different number systems. Others perform non-mathematical functions such as spell checking, remembering phone numbers, addresses, appointments — and can even accept handwritten as well as alphabetic keypad input. There are Braille calculators for the blind. For the outdoor person there are calculators that determine altitude, air temperature, barometric pressure, and global position (GPS). Some calculators accept plug-in ROM cards that can change a general-purpose calculator to one that does specialized computations in a wide range of fields. There are graphing calculators that have the graphic capabilities to sketch two or three dimensional curves and surfaces. Then there are the programmable units that permit the construction of programs using BASIC language or a set of specialized commands. Finally, the powers of the personal computer and the Internet have made available thousands of virtual calculators. These are graphic renderings of calculators that the viewer can interact with as a person would a real calculator. At just one on-line sight alone, 12,000 different calculators are available; each designed to perform a different task. There are agricultural calculators, air travel calculators, arts and crafts calculators, personal finance calculators, business calculators, insurance calculators, medical health calculators, translation calculators, hundreds of different mathematical, statistical, engineering and science calculators. The categories go on and on and are too numerous to list here. See *http://www-sci.lib.uci.edu/HSG/RefCalculators.html*.

The calculator has had a strong impact on many areas. The ability to determine complicated and intricate calculations is now made available to all. Increasingly, calculators are being used in mathematics instruction because they help students learn concepts through both graphic and algebraic representations of problems and reduce tedious computations. Many standardized tests now require the use of a calculator. Some calculators are designed to communicate with other calculators and computers. This enables teachers to place programs and data on a central computer or calculator. Students can then access and retrieve these programs for independent study or group projects. In addition, some calculators can be connected to projection screens so that an entire class can view the display of a calculator. All of this has had a significant impact on the methodology of teaching.

If calculator technology progresses like that of the computer, one can expect further advancement in the area of artificial intelligence and a radically new design based on DNA programming. See also **Artificial Intelligence**.

CALCULI. A deposit from the precipitation of mineral salts in various parts of the body. Mineral salts in urine, for example, may precipitate and form calculi, commonly called stones. Calculi (singular: calculus) may be found in any part of the urinary tract — from the tubules to the orifice of the urethra. Abnormal concretions of bone or teeth are also sometimes called stones or calculi. Causes of calculus formation include decrease in intake of water over a long period, alterations of the pH of body fluids, and excessive ingestion of certain minerals.

CALCULUS. The word comes from the Latin, *calculus*, a stone or pebble used in reckoning. Sir Isaac Newton (1642–1727), the English scientist and mathematician, and Gottfried Wilhelm Leibniz (1646–1716, also called von Leibniz or spelled Leibnitz), the German philosopher and mathematician, are considered to be the founders of calculus. The unqualified word is usually taken to mean differential and integral calculus. It deals with the rate of change of a function and with the inverse process. For some of the methods and applications of calculus, consult the following topics: **Area; Curvature; Curve; Derivative (Mathematics); Differential (Mathematics); Differentiation (Mathematics); Indeterminate Form; Integral; Integration; Length of a Curve; Limit; Mean Value Theorems; Multiple Integral; Series; Singular Point of a Function; Slope; Surface; Tangent (Geometry)**; and **Volume (Geometry)**.

There are several other kinds of calculus. Sometimes called the twin sister of differential calculus is the calculus of finite differences (see **Difference**). Its principles were understood by both Newton and Leibniz. The former wrote about it in 1711 and the first book on this calculus was by Brook Taylor in 1715. It is concerned with interpolation, numerical differentiation and integration, summation of series, the solution of difference equations, and linear equations with an infinite number of unknowns.

The calculus of variations is a study of maximum and minimum properties of definite integrals. The first work on this subject was also done by Newton and, at about the same time, by the Bernoulli brothers. The founders of it as a branch of mathematics are Lagrange (1736–1813) and Euler (1707–1783). A simple case in the calculus of variations is

$$I = \int_a^b f(x, y, y')\, dx$$

where y (x) is to be determined so that the integral is either a maximum or a minimum. In either case, y is said to be an extremal and the integral has a stationary value. Thus it is of a more general character than the maximum or minimum problems of differential calculus, for they require the location of a point with specified properties while in the calculus of variations, a curve or surface is sought. The subject has applications in economics, business, and other practical affairs for there one usually wishes to proceed in such a way as to secure maximum profit, minimum cost and effort, etc. See also **Abel Equation**; and **Brachistochrone**.

The calculus of residues is founded on the Cauchy integral and theorem. It is applied to the evaluation of integrals in the complex variable. Suppose $f(z)$ is analytic within a region C, except for a finite number of poles, then the value of the contour integral is given by

$$\int_C f(z)dz = 2\pi i \sum$$

where $\sum$ is the sum of the residues of the functions at the poles inside C.

CALDERA. Derived from a Spanish word meaning caldron, the term caldera has been given to great crater-like depressions which are either the result of subsidence of lava within the body of a volcano or of an explosive eruption of terrific violence. Examples of these craters of explosion or subsidence are Crater Lake, Oregon, Mt. Tamboro in Indonesia, and the original *La Caldera* in the Canary Islands. Crater Lake, which occupies the caldera, is 2000 feet (610 meters) deep and about 25 sq. mi. (65 sq. km) in area, surrounded by cliffs whose maximum height is 2000 feet (610 meters) above the lake.

CALENDAR. The problem of timekeeping has always been a vexing one. There are three "natural" units, the solar day, the lunar month, and

the tropical year. The normal or true solar day had to be abandoned with the improvement of mechanical timekeeping devices, and the mean solar day has been adopted as the standard short unit for keeping records. The task of the calendar builder is to combine this unit with the two longer units and, since the three are mutually incommensurable, a rigorous solution of the problem is impossible, and compromises must be made.

The fact that the economic world is largely dependent upon agriculture introduces one important restriction on the freedom of the calendar builder. The seasons should remain at approximately the same place in the completed calendar from year to year. The date upon which the sun apparently passes through the vernal equinox is of fundamental importance to the agriculturalist and, for many centuries, was considered as the time of starting a new year. One of the earliest calendars on record started the year on this date and then proceeded through ten lunar months. This calendar covered only 295.3 mean solar days, whereas the period from one passage of the sun through the vernal equinox to the next is 365.2422 days. The period between the end of one year to the beginning of the next was determined by the priesthood and by politicians, and there was conflict and confusion.

The first step toward the modern calendar was taken by Julius Caesar, with the advice of the astronomer Sosigenes. The so-called Julian calendar discards the lunar month and adopts 365.25 days as the length of the year. This year is divided into twelve periods (months) of 30 or 31 days. The normal year was 365 days in length but, to make up the extra $\frac{1}{4}$ day, an extra day was intercalated (i.e., put into the normal calendar) every four years.

Running parallel with the Julian calendar, we find the far more ancient calendar of Jewish and Mohammedan people , which holds rigorously to the lunar month. Division of the number of days in the tropical year by the days in the lunar month will indicate that there are 12.36 lunar months in a tropical year. To retain the synchronism between the calendar and the seasons, this calendar is variable in the number of months it contains, and the process of intercalating months becomes very complicated. However, the Eastern calendar exerts a powerful effect upon the calendar of the Western world, because of the fact that the date of Easter is fixed by a date on the Eastern calendar.

In A.D. 325, the Christian Church took its first step in calendar building and at the Council of Nice made two decrees: a decree that the sun should pass through the vernal equinox on the 21st of March on the Julian calendar, and a second decree relative to the date for the celebration of Easter. The latter of the two decrees was within the province of the Church and can be followed; the former, however, applies to factors beyond the control of people.

It should be noted that the length of the tropical year is 0.0078 day less than the 365.25 days of the Julian calendar. This means that, after the lapse of 1000 years, the sun will pass through the vernal equinox 7.8 days earlier than the 21st of March, assuming that it was at the vernal equinox on this date in the first place. By 1582, the date of the vernal equinox was the 11th of March instead of the 21st, and Pope Gregory decided to return the sun to its proper date and to modify the calendar in such a way that the error would not reappear. The Gregorian calendar is identical with the Julian except in the fact that only such century years are leap years as are divisible by 400. This is equivalent to dropping 3 days every 400 years, leaving an average length for the year of 365.2425 days, which differs from the tropical year by only 0.0003 day. This calendar was immediately adopted by all Catholic countries, but the Greek Church and most Protestant countries refused to recognize it. The confusion following this change persisted well down into the present century (Rumania used the Julian calendar until 1919), and is still felt by historians in reading records of the early years of this country when both calendars were in use.

Within the past several decades, a movement has been underway to modify the calendar in the attempt to have dates and days of the week agree in successive years. Any such scheme involves the necessity of introducing one day each year without date or day of the week, and two such days on leap years, if the year and the seasons are to retain the present synchronism. This intercalation of a day will break the 6-day sequence between Sabbaths, an idea that is abhorrent to many religious sects. The scheme that has the most general support is one in which the year is divided into four equal quarters of 3 months each. In each quarter, the first month has 31 days and the second and third, 30 each. This gives exactly 13 weeks in each quarter, and 52 weeks in each year. The days are to be intercalated without date or day of the week between December 30 and January 1 each year and between June 30 and July 1 every leap year (e.g., the normal calendar would read Saturday, Dec. 30; New Year's Day; Sunday, Jan. 1). See also **Time**.

CALEOMETER. An electrical instrument used to measure the heat loss from a calibrated wire and useful in making a number of determinations, such as that of the variation of the concentration of one of the components of the gas surrounding the wire.

See also **Gas Analyzers (Combustion-Type)**; and **Gas Analyzers (Thermal-Conductivity Type)**.

CALIBRATION. With reference to industrial and scientific instruments, the Instrument Society of America defines *calibrate* as follows:

1. To ascertain by the use of a standard, the locations at which scale or chart graduations of a device should be placed to correspond to a series of values of the quantity which the device is to measure, receive, or transmit.
2. To adjust the output of a device, to bring it to a desired value, within a specified tolerance, for a particular value of the input.
3. To ascertain the error in the output of a device by measuring or comparing against a standard.

CALICHE (Nitrate). The gravel, rock, soil, or alluvium cemented with soluble salts of sodium in the nitrate deposits of the Atacama Desert of northern Chile and Peru. The material contains from 14 to 25% sodium nitrate, 2 to 3% potassium nitrate, and up to 1% sodium iodate, plus some sodium chloride, sulfate, and borate. At one time, this was an important natural fertilizer.

CALICHE (Soil). A commonly used term in the southwestern United States, particularly Arizona, to describe an opaque, reddish-brown to buff or white calcareous material of secondary accumulation, usually found in layers on, near, or within the surface of stony soils of arid and semiarid regions. The material also occurs as a subsoil deposit in subhumid climates. Caliche soil is composed mainly of crusts or succession of crusts of soluble calcium salts, plus gravel, sand, silt, and clay. The cementing material is essentially calcium carbonate, but magnesium carbonate, silica, or gypsum also may be present. Caliche also has been used as a term to describe the calcium carbonate cement per se. In some localities, the material is called *hardpan*, calcareous *duricrust, calcrete*, and *kankar* (in India).

CALIFORNIA CURRENT. See **Ocean Currents**.

CALIFORNIUM. [CAS: 7440-71-3] Chemical element, symbol Cf, at. no. 98. at. wt. 251 (mass number of the most stable isotope), radioactive metal of the *Actinide* series, also one of the *Transuranium* elements. All isotopes of californium are radioactive; all must be produced synthetically. See also **Radioactivity**. The isotope ^{245}Cf was first produced by S.G. Thompson, K. Street, Jr., A. Ghiorso, and G.T. Seaborg at the University of California at Berkeley in 1950 by bombarding microgram quantities of ^{242}Cm with helium ions. The reaction: $^{242}\mathrm{Cm}\ (\alpha, \mathrm{n}) \rightarrow {}^{245}\mathrm{Cf}$. The isotope has a half-life of 44 min. A number of other isotopes of Cf have been made, one of which, ^{254}Cf, half-life 55 days, is of interest because it decays predominantly by spontaneous fission. The longest-lived isotope is ^{251}Cf ($t_{1/2}$ = about 700 yrs), the next is ^{249}Cf ($t_{1/2}$ = 470 yrs). Except for ^{250}Cf ($t_{1/2}$ = 10 yrs), and ^{252}Cf ($t_{1/2}$ = 2.2 yrs), all other isotopes have half-lives less than one year. Several other isotopes (246, 248, 249, 250, 252) also decay by spontaneous fission, but with fission half-lives much longer than the half-lives for alpha-decay. Californium is considered to occur in its compounds only in the tripositive state.

Studied through the use of tracer quantities, the chemical properties of californium indicate that its chemical properties are analogous to those of the tripositive actinides and lanthanides, showing the fluoride and the oxalate to be insoluble in acid solution, and the halides, perchlorate, nitrate, sulfate and sulfide to be soluble.

Probable electronic configuration:

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^{10} 5f^{10} 6s^2 6p^6 7s^2$$

Ionic radius: Cf^{3+} 0.98 Å.

In 1960, Cunningham and Wallmann isolated 0.3 microgram of californium (as californium-249) oxychloride. The best isotope for the study

of californium is ^{249}Cf, which can be isolated in pure form through its beta particle-emitting parent, ^{249}Bk.

Californium-252 is an intense neutron source. One gram emits 2.4×10^{12} neutrons per second. This isotope shows promise for applications in neutron activation analysis, neutron radiography, and as a portable source for field use in mineral prospecting and oil well logging.

CALLISTO. See **Jupiter**.

CALL NUMBER. In computer operations, a set of characters identifying a subroutine and containing (a) information concerning parameters to be inserted in the subroutine, (b) information to be used in generating the subroutine, or (c) information related to the operands.

CALLUS. In humans, an area of thickened skin, or new growth of bony tissue at the site of a fracture that has been reunited.

In plants, it is a protective tissue that occurs in many plants after injury. When the root or stem of a woody plant is wounded, exposing the tissues within, the cambium cells around the wound begin to divide rapidly, forming a protective mass of soft parenchymatous tissue. These living cells are called callus, or wound tissue, and in time will entirely close the wound if the latter is not too extensive. After the tissue is formed, cell differentiation goes on and a new phellogen layer may be formed, as well as the other tissues composing the cortex of the stem. The cambium becomes once more a continuous layer. When wounds are made in pruning, that is, when a branch is cut off, callus tissues gradually form a ring which spreads over and finally completely closes the wound.

CALORESCENCE. A term designating the production of visible light by means of energy derived from invisible radiation of frequencies below the visible range. Tyndall found it possible to raise a piece of blackened platinum foil to a red heat by focusing upon it infrared radiation from an arc or from the sun, the visible wavelengths having been filtered out. It is to be noted that the transformation is indirect, the light being produced by heat and not by any direct stepping up of the infrared frequency. A somewhat analogous phenomenon is the production of visible sparks or the glowing of a fine platinum wire in a resonant circuit energized by long-wave Hertzian radiation.

CALORIE. See **Heat**; **Units and Standards**.

CALORIMETRY. Calorimetry is one of the oldest reported scientific measurement techniques. Calorimetry is derived from the Latin calor meaning heat, and the Greek metry meaning to measure. All calorimetric techniques are based on the measurement of heat that may be generated (exothermic process) or consumed (endothermic process) by a sample or system. The approaches to measuring such heat transfers are numerous. Since calorimetry's advent in the late 18th century, a large assortment of techniques has been developed. Initially calorimetric techniques were based on simple temperature measurement methods. More recently, advances in electronics and control have added a new dimension to calorimetry, enabling users to collect data and maintain samples under conditions that were previously unattainable.

Any process that results in heat being generated and/or exchanged with the environment is a candidate for a calorimetric study. As a result, it is not surprising to discover that calorimetry has a very broad range of applicability, with examples ranging from characterizing the heating value of fuel materials to drug design in the pharmaceutical industry, to quality control of process streams in the chemical industry, and the study of metabolic rates in biological systems.

Traditionally, calorimeters have been classified according to the degree of heat transfer occurring between the reacting system and its surroundings. At one extreme, the calorimeter is isolated as fully as possible from its surroundings so that heat transfer is minimized. Work added or energy converted by a chemical process causes a change in temperature of the calorimeter and its contents. For an exothermic reaction, the ideal situation is approximated by heating the jacket that surrounds the calorimeter in order to nullify the temperature differential between the calorimeter cell and its surroundings during a test. This type of calorimeter is known as an adiabiatic calorimeter.

The second extreme case uses a good, systematic path for heat to flow between the calorimeter system and its surroundings. In this type of calorimeter, there is no net change in temperature between the calorimeter cell and its surroundings. In this conduction type or isothermal calorimeter, the transfer of heat from the calorimeter to the surroundings is typically measured by integrating the voltage output of a thermoelectric transducer situated in the heat flow path between the calorimeter and a heat sink. Another variation of this type of calorimeter operates on the heat compensation principle. Either Joule heating or Peltier cooling compensation of the reaction enthalpy achieves isothermal conditions.

An important variation of the adiabatic principle is isoperibol calorimetry. Well-defined heat leaks, minimized by efficient calorimeter construction and experiment design, are compensated for by calculation and/or extrapolation. The isoperibol design holds the temperature of the immediate environment surrounding the calorimeter constant. The word isoperibol literally means "constant temperature environment."

Calorimetry is used to determine the thermodynamic properties of materials as well as to measure the thermal effects associated with physical and chemical processes. These properties are valuable, for example, in choosing practical manufacturing techniques in the chemical process industries, optimizing yields of reaction products, making energy balances, and as diagnostic or analysis tools. Calorimetry is also used to determine the important properties of complex or poorly defined materials. One example of this is in determining the heating value of fuels such as coal and coke, petroleum products and gaseous fuels. In recent years, the heating value of incinerated waste materials and other refuse-derived fuels have become important. The calorimetry of hazardous and explosive materials has direct relevance to the transport and safe handling of chemicals.

Interest in the use of calorimetry as a routine diagnostic or analysis tool has gained significant momentum only in the last 50 years. This interest has lead to the development of popular procedures such as differential thermal analysis (DTA) and differential scanning calorimetry (DSC). A wide variety of solution calorimetric techniques exist today. These techniques include thermometric titration, injection and flow enthalpimetry. The major growth of commercial instrumentation for calorimetry has occurred to address applications in routine analysis and the rapid characterization of materials.

The following discussion will use an oxygen combustion calorimeter to help illustrate some of the basic concepts of calorimetry. One of the fundamental characteristics of any fuel is the amount of energy released as it is burned. This value is referred to as the heat of combustion or the calorific value of the fuel. This value is usually expressed in British thermal units per pound (Btu/lb), calories per gram (cal/g), or megajoules per kilogram (MJ/kg). The heat of combustion of fuels is routinely determined in order to establish the price of the fuel as well as to serve as a basis for calculating the overall efficiency of a power-generating facility or engine.

To determine the heat of combustion of a fuel, a representative sample (typically one gram) is burned in a high-pressure oxygen atmosphere within a metal "bomb" or pressure vessel. The energy released by this combustion is adsorbed by the calorimeter and results in a temperature rise. The heat of combustion of the sample is the product of the temperature rise and the predetermined energy equivalent or calibration factor for the instrument. Burning a sample with a known heat of combustion and recording the temperature rise of the calorimeter determines the energy equivalent of the calorimeter. This factor is usually expressed as the amount of heat necessary to raise the calorimeter one degree Celsius. Benzoic acid is used almost exclusively as a reference material for fuel calorimetry because it is nonhydroscopic and is readily available in a very pure form.

Any oxygen bomb calorimeter consists of four essential parts: (1) a bomb or vessel in which the sample is burned; (2) a bucket or container which holds the bomb as well as a precisely measured quantity of water to absorb the heat released from the bomb and a stirring device to aid in achieving rapid thermal equilibrium; (3) a jacket for protecting the bucket from transient thermal stresses; and (4) a thermometer for measuring temperature changes within the bucket. The cross section of a simple calorimeter is shown in Fig. 1.

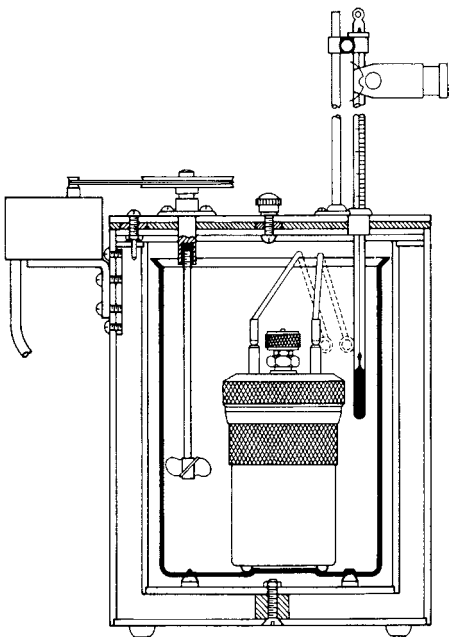

Fig. 1. Cross-section of plain jacket oxygen bomb calorimeter. (*Parr Instrument Co.*)

The bomb consists of a strong, thick-walled, metal vessel that can be opened for inserting the sample, for cleaning, and for recovering the products of combustion. Valves are provided for filling the bomb with oxygen and releasing the residual gases after the test is complete. Electrodes to carry the ignition current to a fuse wire that ignites the sample are also provided. Pressures up to 100 bar are developed during the combustion. As a result, most bombs are constructed to safely withstand pressures of at least double this value.

The calorimeter bucket contains the bomb plus a sufficient quantity of water to completely immerse the bomb in order to absorb the heat released from the combustion. A stirrer is used in the bucket to facilitate bringing the bucket and its contents to thermal equilibrium.

The jacket that contains the bucket with its bomb provides a thermal shield to control the heat transfer between the calorimeter bucket and its surroundings. In an isoperibol calorimeter, it is not necessary to prevent this transfer, as long as a means of precisely determining the amount of heat transferred during the determination can be established.

The calorimetric thermometer measures temperature changes within the calorimeter bucket. It must be able to provide excellent resolution and repeatability. High single-point accuracy is not required since it is the change in temperature that is important in fuel calorimetry. Mercurial thermometers, platinum resistance thermometers, quartz oscillators, and thermistor systems have all been successfully used as calorimetric thermometers.

The American Society for Testing and Materials (ASTM) has developed a series of standard test methods for both solid and liquid fuels in oxygen bomb calorimeters. Advanced combustion calorimeters are capable of performing 8 to 10 tests per hour with a precision of 0.1%.

Calorimeters of Historical and Special Interest

Around 1760 Black realized that heat applied to melting ice facilitates the transition from the solid to the liquid state at a constant temperature. For the first time, the distinction between the concepts of temperature and heat was made. The mass of ice that melted, multiplied by the heat of fusion, gives the quantity of heat. Others, including Bunsen, Lavoisier, and Laplace, devised calorimeters based upon this principle involving a phase transition. The heat capacity of solids and liquids, as well as combustion heats and the production of heat by animals were measured with these calorimeters.

A steam calorimeter was perfected by J. Joly (1886) and used for the accurate determination of specific heats of solids, liquids, and gases. In principle this apparatus consists of a balance, with the specimen hung from one pan and surrounded by an enclosure that can be flooded with steam. The mass of moisture condensing on the specimen, multiplied by the heat of vaporization of water, gives the quantity of heat imparted to the specimen.

The Nernst calorimeter is a calorimeter for the measurement of specific heat capacities at low temperatures. The sample to be measured is suspended in a glass or metal envelope that can be evacuated. The sample is heated by means of a platinum wire located in a bore inside the sample. The wire also serves as a resistance thermometer. The specific heat capacity is determined by recording the temperature rise in the sample for a given delivery of energy.

Differential scanning calorimetry (DSC) is a technique determining the variation in the heat flow given out or taken in by a sample when it undergoes temperature scanning in a controlled atmosphere. Any transformation taking place in a material during the temperature scan is accompanied by an exchange of heat. DSC enables the temperature of this transformation to be determined and the heat from it to be quantified. The DSC is used to measure specific heat capacity and heats of transition as well as to detect the temperature of phase changes and melting points.

Gas Calorimeters

There are three basic classifications: (1) total calorific value types, (2) net calorific value types, and (3) inferential types. Net calorific value is less than the total calorific value by an amount equal to the latent heat of vaporization of the water formed during combustion. A net calorific value instrument uses a means that give results more nearly related to the net value. Thus, these types are affected by gas composition and must be calibrated for the gas to be tested. Inferential-type instruments depend upon such characteristics as flame appearance, maximum flame temperature, specific gravity, or gas analysis as indicative of the calorific value.

CALORIZING. Production of a protective coating of iron-aluminum alloy on iron or steel. The articles are ordinarily coated by heating to a high temperature in a closed container packed with powdered aluminum. Other processes include impregnation at high temperature with an aluminum chloride vapor and spraying with molten aluminum from a spray gun and then heating to a high temperature. When the aluminum coating is held at

high temperatures, an iron-aluminum alloy forms which is resistant to oxidation and corrosion by hot combustion gases, especially those containing sulfur compounds which are particularly corrosive to bare iron or steel.

Steel sheets are aluminized by a hot-dip process similar to galvanizing. The principal applications for such a product are furnaces and ovens, automobile mufflers, and other equipment requiring heat and corrosion resistance. When a sheet which has been coated with aluminum by a hot-dip process is exposed to a temperature over 1,000 °F (538 °C), the aluminum forms an iron-aluminum alloy which is heat- and corrosion-resistant.

CALVIN, MELVIN (1911–1997). An American chemist who won the Nobel Prize for chemistry in 1961. Much of his work involved the study of photosynthesis, biophysics, and application of physics and chemistry of molecules to some of the basic problems of biology. His doctorate was from the University of Minnesota. He did postgraduate work in England and at Northwestern University and the University of Notre Dame.

CALYX. A cup-shaped or funnel-like structure, such as the body of a sea lily and the chambers branching from the principal cavity of the vertebrate kidney. Use of the term in botany is described under **Flower**.

CAM. A cam is a rotating or sliding member that imparts a desired motion or series of motions to another member. Cams are used whenever a desired motion is of such character that it cannot be obtained by using cranks or linkages. There are two important forms of cams: radial cams where the follower moves in a plane perpendicular to the axis of the shaft, and cylindrical cams where the follower moves in a plane parallel to the axis of the shaft. Each of these types may be classified further as positive motion cams in which the reciprocating motion of the follower is definitely controlled by the cam, and nonpositive-motion cams in which the follower is returned to its starting point by spring or gravity action.

Figure 1 shows a radial cam with a flat follower or cam tappet. The cam is integral with the camshaft. The cam profile is composed of two circular arcs connected by tangent lines. Cylindrical, helicoidal, and plane surfaces are used for cam faces whenever possible, since they are more easily and accurately manufactured than irregular curves.

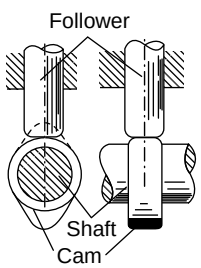

Fig. 1. Radial cam.

The radial disk cam, at the right of Fig. 2, is similar to the cam of Fig. 1. Roller followers are preferred to flat followers because the line contact between the roller and the cam is of a rolling nature, since the sliding is transferred to the pin that carries the roller. The face cam, at the left of Fig. 2, is a positive-motion cam, but is much more difficult to manufacture than a disk cam because the cam groove must be of accurate uniform width. This face cam has a cast iron disk on which the inner and outer hardened steel plates are screwed and doweled.

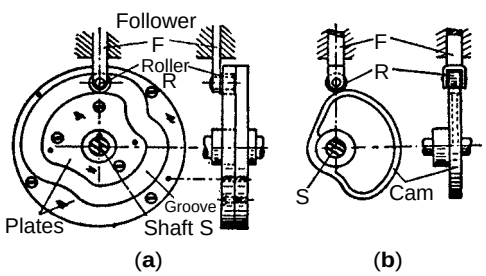

Fig. 2. (**a**) Positive-motion cam. (**b**) Radial disk cam.

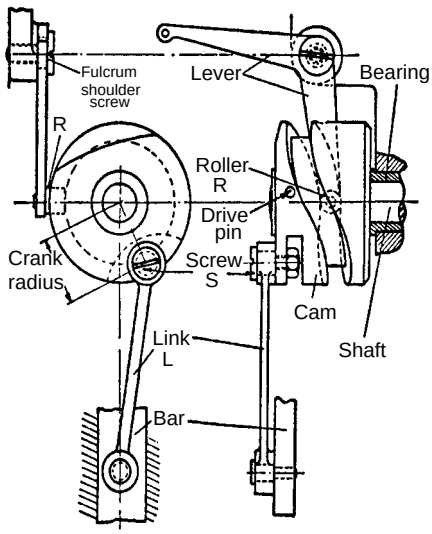

Fig. 3. Solid cylindrical cam.

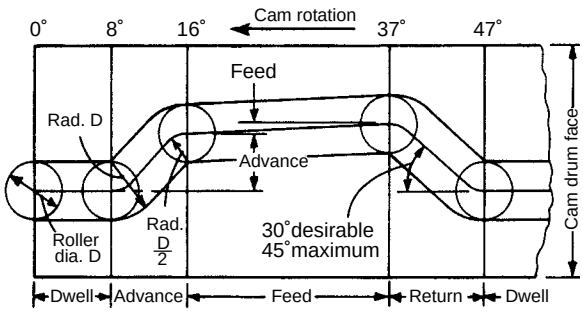

Fig. 4. Development of portion of cylindrical cam.

Figure 3 shows a solid cylindrical cam with a bell-crank or lever follower for the thread-controlling function on moderate-speed sewing machines. A development or layout of a portion of a cylindrical cam is shown in Fig. 4. This development shows uniform or straight-line motion of the roller, modified by an arc equal to the roller radius at the beginning and end of each phase of motion, to permit gradual acceleration and to provide roller clearance. The drum cam may have positive motion, and will therefore require a cam strap on either side of the roller, or it may be constructed with a single strap, in instances where the inertia of the slide is great enough to enable the roller to remain at rest unless acted on by the cam strap.

CAMBER. The curved line from the leading edge to the trailing edge of the airfoil is known as the camber. The curvature of the upper and lower surfaces, as well as a median line between them, is often referred to as camber or camber line.

The wheels of an aircraft landing gear are said to have camber when they make an angle with the vertical plane.

The term camber is also applied to the upward curvature given to bridge trusses with theoretically horizontal lower chords, bridge girders with theoretically horizontal bottom flanges, and beam bridges to compensate for the actual deflection. Although these deflections are small in a properly designed structure, they may be objectionable from the standpoint of appearance. Due to an optical illusion, these structures appear to have a pronounced downward deflection. This term is also used to denote the initial curvature that occurs in steel beams as the result of rolling.

In short-span trusses, camber is obtained by lengthening the top chords $\frac{1}{8}$ to $\frac{3}{16}$ inches (3.1 to 4.8 millimeters) for each 10 feet (3 meters) of length. No change is made in the lower chords and verticals, but the length of the diagonals must correspond to the new outline. Long-span trusses are cambered by increasing the geometrical length of the compression members and decreasing the geometrical length of tension members. The change in length is based on the calculated longitudinal deformation of the members under dead load and partial or full live load.

It is not customary to camber short-span girders. Long-span girders are cambered by fabricating them with an upward curvature corresponding to a predetermined amount of deflection. This is accomplished by using two or more plates for the web, spliced in such a way as to produce this curvature approximately. The straight flange angles and cover plates are then bent to the desired curvature during the fitting-up operation.

Camber may be obtained in a beam bridge by placing the beams so that the initial curvature due to rolling is upward. The initial curvature may be increased by heating the flange on the concave side with a torch.

CAMBIUM (Plant). In Gymnosperms and dicotyledonous Angiosperms, a large part of the tissue of the stem is derived from a special layer of cells known as the cambium. The cambium originates from certain cells of the procambial strand. In the procambial strand of the stem (that part of the growing tip in which cell differentiation first takes place), cell differentiation commences at the tangential edges of the strand and progresses towards the center, forming primary xylem cells toward the center of the stem and primary phloem cells toward the surface. Some of the cells in the middle portion of the procambial strand do not differentiate into xylem or phloem, but become meristematic cells, dividing actively. These are the cambium cells. Often they begin to divide before the other cells of the procambial strand have ceased elongating.

At first the cambium is a vaguely defined layer of cells occupying the middle portion of the procambial strand. In roots the cambium appears on the inside of the primary phloem strands, which alternate with the primary xylem strands.

Gradually additional cells are formed laterally, either from those cambium cells already formed or by differentiation of parenchyma cells of the medullary ray, until a complete cylinder of cambium exists. Once formed, the cambium of woody plants persists throughout the life of the plant; in herbaceous plants its existence is rather brief, all cells of the stem becoming mature early in its development.

There are two types of cells present in the cambium of any plant. The cells of one type are isodiametric, that is, all dimensions are more or less equal; these cells give rise to the cells of the vascular rays. The other cambium cells are long cells with tapering ends; the cells that result from the division of these become either tracheids, vessels, fibers, or sieve tubes. The elongate cambium cells vary in dimensions in different plants. In various Gymnosperms they may be 3000–4000 micrometers or more in length; in dicotyledons they are much shorter, varying from 100–800 micrometers. In width cambium cells vary in different plants from 20–40 micrometers, and in thickness, or radial dimension, 5–15 micrometers. Cambium cells have a dense cytoplasm in which vacuoles are either lacking or very minute. Each cell of the cambium has a single nucleus, which is usually elongated. The walls, especially the tangential ones, are very thin. Division of the cambium cells occurs in a longitudinal tangential plane, that is, the cell divides lengthwise to form two slender elongate cells, one of which lies outside the other, toward the outside of the stem or root.

It is certain that the division is always mitotic (mitosis). One of the cells resulting from this division soon begins to change its form. If this differentiating cell is on the inside of the cambium cylinder it may elongate even more, its ends sliding by and between those of other cells about it. Presently thickening of the wall occurs through deposits of cellulose, which are laid down on the primary wall. The cytoplasm of the cell gradually disappears. When mature, this cell, now a tracheid, is a long slender tapering cell with a thick wall and no protoplasm. In the wall are numerous simple or bordered pits, which are continuous with pits of adjoining cells.

In Gymnosperms, all elongate cells derived from the cambium become tracheids, except in those forms which have wood parenchyma cells. In these, transverse divisions occur to form a linear row of short cells. In angiosperms, other types of cells are formed. One of these, the fiber, differs little from the tracheid except that it has a thicker wall, in which there are few small pits.

The other type is quite distinct. The cambium derivative that is going to form one of these does not elongate noticeably, but does increase greatly in diameter. As it increases, a large central vacuole forms, and the nucleus moves to a position near the middle of the end wall. At that stage, the vessel appears as a series of very large vacuolate cells separated from one another by distinct end walls. When full size is reached, secondary wall thickening occurs. Then the end wall breaks down, leaving a series of cells forming a long open tube; in many plants perforations are formed in the end wall, so that direct continuity from cell to cell exists. The tremendous increase in diameter of the vessel cells causes the cells around it to be flattened and crowded into angular shapes and irregular arrangements. Once the walls have formed and the cell matured, no further change takes place. Its structure is fixed permanently.

The cells formed externally to the cambium become phloem cells. The manner of differentiation is not so well known in these cells as in the xylem cells. Apparently divisions of these phloem mother cells, cut off from the cambium cells, are much more frequent than are divisions of the xylem mother cells. Phloem parenchyma results from the transverse division of one of these cells to form a longitudinal series. In Angiosperms, each phloem mother cell divides unequally, cutting off a very small cell from the corner of the mother cell. The larger cell forms part of a sieve tube, the smaller becomes a companion cell. Often the companion cell divides again to form two or more companion cells associated with a single sieve tube. The cytoplasm of the companion cells remains dense, develops few vacuoles, and always has a well-developed nucleus. In the sieve tube, on the contrary, a cytoplasm becomes peripheral, and there is a large central vacuole. The nucleus has disappeared in the mature sieve tube. The end walls of the sieve tube cells are characterized by the presence of porous places called sieve plates. The pores of these sieve plates result from the enlargement or fusion of the protoplasmic strands, known as plasmodesma strands, which connect the protoplasts of adjoining cells. The enlargement of these strands causes an enlargement of the pores through which they pass, so that conspicuous connections are formed between adjacent cells. The development of sieve tubes in Gymnosperms is very similar to that in Angiosperms, but no companion cells are formed, and the pores in the sieve plates are much smaller. The development of phloem fibers is like that of xylem fibers.

It is obvious that with continued formation of xylem cells inside the cambium and consequent increase in stem diameter, the cambium is constantly being pushed outward and stretched. Gliding growth of cambium cells and those cut off from them causes increase in circumference of the cambium cylinder and so prevents any breaking of the same. For a time the phloem cells maintain their shape against the pressure of the enlarging stem within. In time, however, the older phloem cells become crushed and distorted beyond recognition.

The isodiametric cambium cells divide to form either xylem or wood ray cells inside, or phloem ray cells outside the cambium. These cells differentiate directly into ray cells.

All tissues derived from the divisions of the cambium cells are known as secondary tissues, in contrast to the primary tissues, which are formed by differentiation of the cells of the procambial strands.

Another cambium, the cork cambium (formerly called phellogen), arises in the pericycle of roots and in the outer cortex of stems. It produces the periderm. See also **Bark**.

CAMBRIAN PERIOD. The earliest subdivision of the Paleozoic Era. Type locality, North Wales. The formations of this system were first studied and named by Adam Sedgwick in 1835. The Cambrian period began some 500 to 570 million years ago, and lasted for 100 million years. Cambrian formations are well exposed in North America in the Appalachians and Rocky Mountains (Fig. 1). Important lower Cambrian beds containing the oldest known faunas occur in British Columbia. Other countries in which the Cambrian is well exposed are Sweden, Britain, Spain, Scandinavia, France, Germany, eastern China, northeastern Siberia, India (Himalayas and Salt Range), Morocco, Australia, Argentina and Antarctica. Cambrian sediments represent the earliest evidence of deposition in well-defined geosynclines, the principal types being sandstones, shales and limestones. Tillites indicate continental glaciation. The maximum thickness of 40,000 feet (12,190 meters) of Cambrian strata occurs in North America. The oldest known invertebrate fossils occur in this period, the principal types being trilobites, chitinous brachiopods, and primitive graptolites, all of which had a marine habitat.

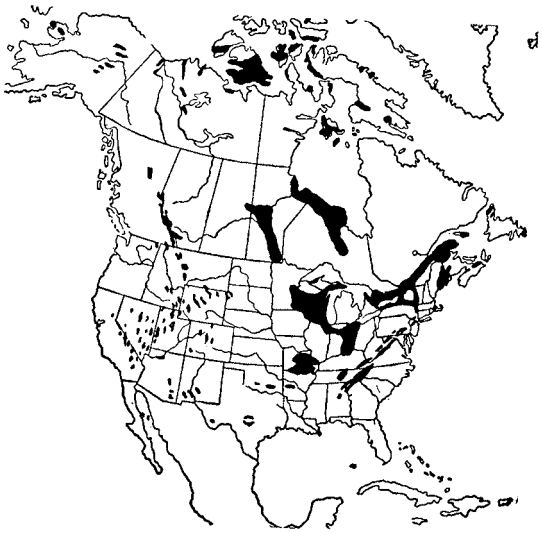

Fig. 1. Known areas of outcrops (surface distribution) of Cambrian, Ordovician, and Silurian strata in North America.

CAMEL CRICKET *(Insecta, Orthoptera).* Wingless insects related to the katydids. They live in dark moist places and are dull colored. These facts together with the strongly humped back give them their name. They are also called cave crickets.

CAMELOPARDALUS. A northern constellation situated between Ursa Major and Cassiopeia.

CAMELS AND LLAMAS *(Mammalia, Artiodacryla).* The group of *Camelines* is one of the smaller in the order of *Artiodacryla* (even-toed hoofed animals). Included are: Camels (*Camelus*) of two species, the Bactrian (*C. bactrianus*) and the Arabian (*C. dromedarius*); the Llamas (*Lama*), including the Guanaco and the Alpaca; and the Vicuña (*Vicugna*). The extremities have only a vague resemblance to hoofs. These animals are of a most early origin and, with exception of the Chevrotains, bear little resemblance to any other living mammals. Several authorities formerly believed that the *Camelines* originated in North America. The subject now is considerably less clear. Fossilized remains indicate that there were cameline-type beasts in North America, with good indication that the so-called True Camels of the Old World and the llamas of South America stemmed from these earlier creatures.

Camels. These animals have long legs and necks and a conspicuously humped back. See Fig. 1. They are adapted for life in arid regions, including sand deserts, by the broad feet and slit-like nostrils. Internally, the development of cells for the retention of water in one part of the stomach is especially important for life in such regions.

The Arabian camel is found both in Africa and Asia and is characterized by one large hump. There are considerable numbers of the one-humped camels roaming, unbranded and unclaimed, in the African, Arabian, and Middle East deserts, but it is not believed that these are truly wild specimens. Camels are known to detest domestication, the loss of freedom, and requirements to work; consequently, wandering away and keeping away from people is not unexpected. The Arabian camel was introduced into the Southwestern states by the United States government in 1856, but, after many years of apparent success, the experiment was discontinued. The animals that were freed died out after persisting for some years. The Arabian camel, often referred to as the Dromedary camel — although Dromedary applies to only a particular type — stands 7 feet (2.1 meters) high and thus is slightly taller than the Bactrian and is the faster of the two species of true camels. The Arabian camel may carry as much as 400 pounds (181 kilograms), but none go faster than 18 miles (29 kilometers) per hour and cannot endure for many hours at this speed.

When food is plentiful, fat is accumulated and later used for survival when food is scarce. The size and characteristics of the hump(s) are an index of the animal's health, stamina, and food-supply situation. The one-hump Arabians have a full, long, tall, and rigid hump when well fed and healthy. On the other hand, in the healthy and well-fed two-humped Bactrians, the humps will be bulbous and heavy, appearing to be about

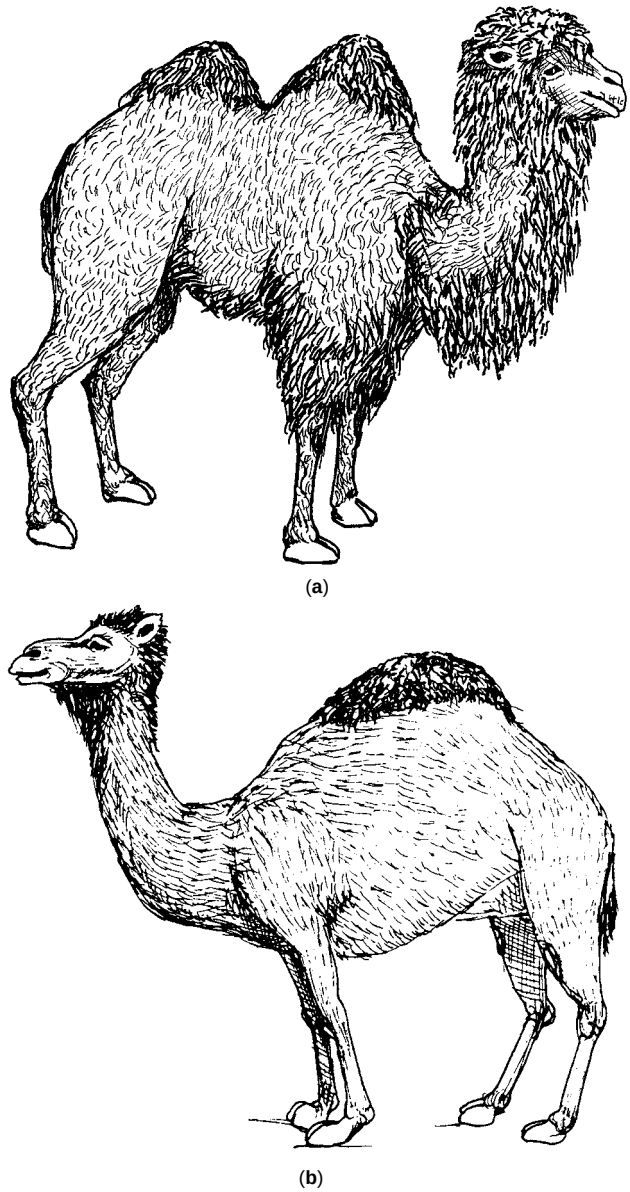

Fig. 1. Camels: (**a**) Bactrian; (**b**) Arabian. (*A.M. Winchester.*)

to collapse because of their size and weight. As is often misunderstood, camels do *not* store water in their humps, but it has been reported that camels may be able to "manufacture" water through chemical oxidation. Special stomachs account for their water storage. Camels may live for reasonable periods without water. Reports indicate that a camel may safely lose water to an extent of 25% of its body weight. This weight can be quickly restored with a few minutes of drinking. The animals do require significant amounts of water at regular intervals. Other protective means provided for enduring arid environments include a double row of heavy eyelashes for protection against blowing sand particles. Their ear openings are protected by heavy hair and they have a very keen sense of sight and smell. During winter months, the animals grow heavy hair, while in summer most of this hair is lost.

The gestation period is 11 months. One young is produced at birth. The animals require from 10 to 12 years to reach full maturity, and their life span ranges from 30 to 40 years. During the rutting reason, camels can exhibit fits of rage and may be inordinately obstinate.

The early naturalist, Alfred Brehm, described camels as dull, stubborn, stupid, apathetic, and cowardly animals. Brehm was annoyed by their odor, the earsplitting roaring of the dromedary, and even the mere sight "of its unbelievably stupid-looking head." By contrast, the great explorer, Sven Hedin, who traveled on camelback across the arid deserts of Central Asia, praised the majestic deportment of a particular male camel: "He carried his head with solemn gravity and his quiet eye searched the horizon with an

expression intimating that he felt he was the unlimited and sovereign master of all the deserts of Asia". Perhaps the contradiction between Brehm and Hedin may be explained in part by the fact that Brehm predominantly spoke about the dromedary, the one-humped camel of Africa and Southwest Asia, while Hedin's experience was with the two-humped camel of Central Asia. In German, a dull-witted person is a "kamel."

Llamas or Camelids (Lama). These are of medium size, reaching an overall length from 125–225 centimeters (49–89 inches); the tail length is 17–25 centimeters (6.7–10 inches); the body height is 70–130 centimeters (27.5–51 inches); and the weight can reach 75 kilograms (165 pounds). The males are taller than the females. The profile of the head is straight. The large eyes have long lashes on the upper lid, the ears are long and pointed, and the lips are not too large. The long, thin neck has a slightly arched base, and is usually erect. The body has no humps, and the back is level. The round tail is rather thick, with an almost naked-underside, and it is usually carried bent down and away from the body. The dense, woolly, and smooth coat has a few thin bristles, which do not protect against the rain. The cutaneous foot pads are smaller than in camels, and there is a deeper cleft between the toes. The shape of the teeth is like the camels', but in the vicuña the lower incisors have smaller crowns, with open roots and continuous growth. There are two species: Guanaco (*Lama guanicoë*); and Vicuña (*Lama vicugna*).

Llamas are found in the high altitudes of western South America and on lower ground in the southern part of the continent. See Fig. 2. The animals provide wool, hides, meat, and milk and are used as beasts of burden.

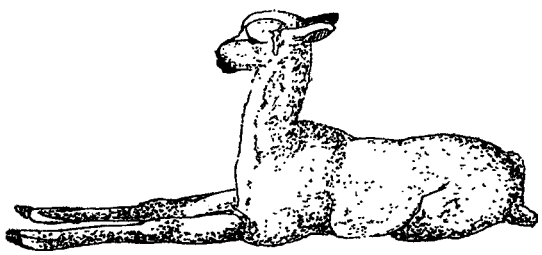

Fig. 2. Young *quancos* (and other species of llama) stretch both legs forward while they are reclining, bending them under their body, as do most other ungulates. (*Erich Thenius*.)

The guanaco is the original llama and still occurs in the wild. The animal travels in large herds and prefers open country ranging from the Altiplano (15,000 feet) (4,570 meters) to the Patagonian prairies. The animal is 4 feet high (1.2 meters) at the shoulders. The legs are long and slender. The hair is long, soft, and fawn colored with some white. The animal's cry is something like the neigh of a horse. The guanaco is hunted by the Patagonian Indians and is also a favorite dietary item of the pumas. The animal is a source of food and hides for the Indians. Dried dung is used for fuel. The guanacos display a peculiar habit of going to the same place to die, a pattern that was observed years ago by Charles Darwin and W.H. Hudson.

Two domesticated animals have risen from the guanaco, known as llamas and alpacas. See Fig. 3. The animals originally were domesticated in Peru by the Spanish. They are used for riding and as beasts of burden. In early years, the male llamas were used for carrying ore and bullion for as much as 12 miles (19 kilometers) per day. They can carry a load up to about 120 pounds (54 kilograms). If overloaded, the animal automatically lies down. Female llamas provide milk and meat, which resembles mutton. Llamas are of many colors and patterns. The alpaca is of more striking appearance and is found mainly at high altitudes in Bolivia and Peru. The wool is valuable. It grows about 8 inches (20 centimeters) annually and is clipped each year. The wool may be yellow-brown or gray-black and is somewhat elastic, fine, glossy, and straight.

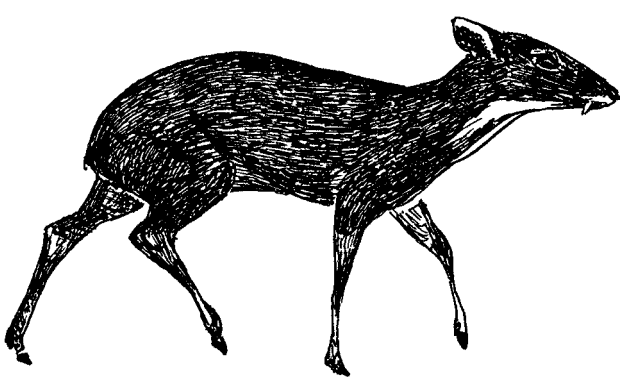

Fig. 3. Alpaca (*Lama guanicoë*). This animal is found mainly at high altitudes in Bolivia and Peru.

The vicuña differs considerably from the guanacos. It was the royal animal of the Incas. Because the pelt is silky and soft, the animal was desirable to hunters. It is now under government protection. The vicuña is found in the mountains of Ecuador, Peru, and Bolivia.

CAMERA. See **Photography and Imagery**.

CAMPBELL-STOKES RECORDER. A sunshine recorder of the type in which the timescale is supplied by the motion of the sun. It consists essentially of a spherical lens that burns an image of the sun upon a specially prepared card. The instrument must be oriented carefully so that the timescale on the card agrees with the sun time. The depth and breadth of the trace may be interpreted in terms of the approximate intensity of the sun.

CAMPHOR *(Cinnamonum camphora; Lauraceae).* A crystalline compound occurring in various parts of the wood and leaves of the camphor tree, a large evergreen tree with light green leaves growing in many warm regions of southeastern Asia, notably Taiwan. Camphor, $C_{10}H_{16}O_7$, is a white solid, mp 179 °C, bp 209 °C, of a characteristic pleasant odor, insoluble in H_2O, soluble in alcohol or ether. Camphor may be produced synthetically by converting pinene into bornyl chloride with HCl, thence to isobornyl acetate, thence to isoborneol, and finally oxidizing borneol to camphor. Camphor has found use in medicines, insecticides and moth preventives. Earlier uses included the manufacture of plastics and lacquers.

As reported by American Forests, a champion camphor tree growing in Darby Florida was selected in 1992. Dimensions of the tree: circumference (at $4\frac{1}{2}$ feet; 1.4 meters above ground level) = 422 inches (1070 centimeters); height = 67 feet (20.4 meters); spread = 103 feet (31.4 meters).

CAMPTONITE. A dark, basaltic dike rock of the essential mineralogical composition of a diorite, requiring, however, microscopical examination for proper identification. It was named from the type locality, Campton, New Hampshire.

CANADA BALSAM. A slightly yellow, transparent, fluid resin procured from a North American species of silver fir tree. Used for mounting thin sections of rocks, and of tissues of plants and animals for microscopic examination between glass slides, and for cementing glass in optical instruments. The refractive index of Canada balsam after it has been heated varies between 1.534 and 1.540, according to A. Johannsen. See also **Resins (Natural)**.

CANADIAN. Geologically, a North American provincial series: Lower Ordovician (above Croixian of Cambrian; below Champlainian). The term

also is an obsolete name once applied to a system of rocks between the Ozarkian below and the Ordovician above.

CANAL (Physiology). A tubular structure or passage, with specific applications in many groups of animals, among which are the following: (1) the passages in the wall of a sponge, (2) slender diverticula of the enteric cavity in coelenterates and ctenophores, (3) the stone canal, ring canal, and other parts of the water vascular system in echinoderms, and (4) the inguinal canal through which the testis descends from the abdomen into the scrotum in mammals.

CANANGA. The flowers of the cananga and ylang-ylang trees (*Canangium odoratu* Baill) are the source of an oil which is recovered by distillation. At one time these two trees were considered identical species, but in recent years minor differences have been noted. The recovered oil contains a multitude of organic substances, including sesqui-terpenes, linalool, geranil, eugenol, and methyl salicylate, among others. Cananga oil or ylang-ylang oil are used extensively in perfumery, as well as for flavorings in beverages, ice creams, candies, and baked goods. The oils impart a slightly woody, floral odor with a somewhat burning taste.

CANARD. Pertaining to an aerodynamic vehicle in which horizontal surfaces used for trim and control are forward of the main lifting surface; the horizontal trim and control surfaces in such an arrangement.

CANARY *(Aves, Passeriformes).* A finch, *Serinus canarius*, native to the Canary Islands, which has been extensively used as a cage bird. The wild species is brownish with yellow markings but in captivity pure yellow strains have been developed.

The goldfinch of North America and to a lesser extent the yellow warbler are called wild canaries from their similar yellow color.

The wild canaries that are found in the Canary, Azores, and Madeira Islands have an olive coloration above and yellow below. These birds have been bred in captivity for many centuries. In nature, the canary builds a cup-like nest about 10 feet (3 meters) above the ground level in trees or shrubs. There are usually five eggs of a blue-green color with reddish-brown markings. In the wild, the canary prefers arboreal fruit and seeds.

CANARY CURRENT. See **Ocean Currents**.

CANCER AND ONCOLOGY. References to cancerous tumors in humans date back many centuries to ancient Egypt and Greece (2000–1500 B.C.). In those times, attempts to cure or alleviate cancers involved excision or the application of corrosive pastes to affected areas. Throughout the intervening years in the medical history of cancer, various forms of cancer therapy have resulted from an iterative process of intuition and estimation. Contemporary cancer therapy, thus, essentially represents the empirical knowledge amassed by the professionals over a long time span, including millions of hours in laboratory and hospital settings.

One scientist has observed, "To comprehend the process of carcinogenesis is to understand, at the molecular level, the nature and workings of the cells that constitute life itself."

The probable cause of cancer at the cellular level was first suggested by the German pathologist, Rudolf Virchow (1880). This intuitively derived concept preceded by nearly a century the beginnings of molecular biology and the establishment of the gene sciences and genetic engineering. It was not until the 1970s that Frederick Sanger and coworkers unraveled the structures and functions of RNA and DNA. Nevertheless, Virchow's proposal did add a new dimension to empirical cancer investigations.

In the mid-1980s, molecular biologists and geneticists directed their research toward discovering "faults" that cause various diseases, including the numerous manifestations of cancer. As described in the article on **Genetics and Gene Science**, a number of diseases have been shown to have a gene connection. The 1990s produced a number of interesting scenarios that, at least in the laboratory, divulged a better understanding of cancer causation at the molecular level. Out of these findings may develop new cancer therapies that will be functional at the molecular level.

General Background

A tumor is a neoplasm or a new or abnormal tissue growth that is uncontrolled and progressive. A *benign neoplasm* does not spread but remains at its original site, spreading locally by simple expansion of its growth. A *malignant cancer or neoplasm* is differentiated from a benign growth in that it shows a greater degree of *anaplasia* and has the properties of invasion and *metastasis*. Cancers of neoplasms can arise in any of the body tissues; in *epithelial* tissue (skin, mucous and serous membranes), the growth is a *carcinoma*; in other types of tissues the neoplasm is a *sarcoma*. An *oncogene* is a gene that has the capacity to induce or form tumors.

Metastasis involves relocation of neoplastic (malignant) tissue cells by transport in the blood or lymph stream to other body organs or nearby lymph nodes. Metastasis from a carcinoma usually occurs by way of the lymphatic system whereas sarcoma spreads most often hematogenously. The metastatic cells reattach themselves to a new site, reproduce, and thus establish a "colony" which eventually may exceed the parent growth in size and destructiveness. The new growth may occur in a specific organ, such as the stomach or rectum, or widely throughout the body as in blood cancer (leukemia); the most frequent sites of metastases are, however, the lymph nodes close to the original tumor, the lungs, long bones, spine and ribs, liver, skin, and brain.

After many years of collecting and analyzing statistics on cancer and the treatment of millions of cases worldwide, considerable evidence is available on the qualitative causes of cancer. This information has been quite effective in designing programs for cancer prevention. Among the known qualitative causes of cancer are: (1) hereditary predisposition; (2) chronic irritation of body areas; (3) repeated exposure to carcinogenic substances; and (4) the presence of pre-existing conditions, such as white patches on the tongue and vulva (leukoplakia), clear-colored warts on older people (keratosis), large burn scars, and rectal polyps, among others.

In cancer prevention, considerable success has been achieved by anti-smoking campaigns and in ridding the environment of carcinogenic substances. Thus far, less success has been achieved in convincing people to avoid undue exposures to the damaging radiation of the sun, a common cause of skin cancer.

Literally, over the past few decades, billions of dollars have been invested worldwide on cancer prevention and cancer treatment — to the point where considerable public dissatisfaction has been expressed in terms of the results achieved by these efforts. This dissatisfaction comes at a time, however, when the scientific community, by way of applying new knowledge at the molecular level of the disease, is just coming to fruition. No longer must cancer therapy remain an empirical science. The current public delusion regarding cancer research stems principally from the lack of progress made in the diagnosis and treatment of breast cancer. This is described later in this article.

Contemporary Cancer Therapy

Amelioration and the extension of life of many cancer patients can be provided by surgery, radiotherapy, and chemotherapy.

Chemotherapy. When compared with the highly successful application of chemotherapy to microbial infection, cancer chemotherapy is somewhat less impressive. However, we do have a greater understanding of the chemistry of microorganisms than we do of the fundamentals of carcinogenesis. Anticancer chemicals have been discovered by chance, by relating parallels of structure and properties with other drugs, or by following and trying to anticipate biochemical pathways believed to exist in cancerous cells. Much experimentation in animals then precedes treatment of selected human patients in approved clinical circumstances.

The first advance in cancer chemotherapy came in 1941 when the female sex hormone, estrogen, was found useful in the treatment of prostate cancer. Nitrogen mustard's effectiveness as an anticancer drug was a product of chemical warfare research. In 1948 the first of the antimetabolites, the anti-vitamin aminopterin, was reported of use in the treatment of leukemia. In the following year, the effectiveness of a related compound, methotrexate, was reported — particularly against a rare uterine cancer known as choriocarcinoma. Before the discovery of methotrexate, five of every six women affected with this or a related cancer died within a year of diagnosis, even when the diagnosis was early and the condition treated by surgery.

For most anticancer chemicals, the levels of dosage and dangerous or lethal toxicity, is established in animals before administration to humans and is finally measured against body weight or surface. Introduction into the body is customarily by intravenous injection and variations on this approach have been introduced to enhance or ease administration. Infusion methods by which a drug is dripped slowly into a patient's blood stream and travels throughout the entire circulatory system have been modified to

focus drug effects on cancerous areas (for example, cancers of the head and neck). In another system, developed for treating liver cancer, a plastic tube carries a continuous supply of drug directly to the cancer at a uniform rate regulated by an infusion pump. The tiny pump and a seven-day supply of the drug constitute a small package which can be strapped to the chest of the out-patient for round-the-clock treatment.

Because many anticancer drugs are necrotic to normal tissue some of them are perfused in closed circuit through the blood stream of the cancerous region, while a tourniquet prevents the drug from reaching and damaging sensitive tissues beyond that. The drug may also be injected through an artery to the cancerous area and withdrawn through a vein, then recirculated through the artery and vein by means of a pump oxygenator. This technique, known as regional perfusion, is specially adapted to treating cancers of the arms and legs.

The present consensus is that anticancer drugs interfere with cell division at the core of the cell, within the nucleus, in the DNA and RNA components of the cell's genetic machinery, described further in the following paragraph. While some anticancer drugs have been found to have some efficacy at any time, others appear to have value only during specific phases of the cell development cycle. Thus, we can classify these drugs as *phase nonspecific* or *phase specific*; although much has yet to be learned about the development of malignant neoplastic cells, a cycle of five phases or periods has been designated within which drug efficacy may be matched.

M phase (mitosis): This is the beginning of the cell cycle and lasts for only 30 to 60 minutes. No DNA synthesis is assumed during this period. Drugs found effective during this stage include vincristine and vinblastine.

G_1 phase: This is the first designated gap of a few to many hours in the cell cycle. The assumption is made that DNA synthesis does not occur. Actinomycin D, mitomycin, 6-mercaptopurine, and 6-thioguanine have been found effective during this phase.

G_0 phase: This is a "resting" extension of G_1 during which the cells are assumed not to be actively dividing. The possibility exists that a cell in this G_0 period may be stimulated to reenter the G_1 phase. No chemotherapeutic agents are believed to be effective during this period.

S phase (DNA synthesis): Regarded as the period of activity during which a doubling of the DNA cell content can be assumed; this phase spans 6 to 12 hours. Once DNA synthesis is initiated, the cell is believed about to divide. Effective drugs during the period include 6-mercaptopurine, 6-thioguanine, methotrexate, 5-fluorouracil, doxorubicin, daunorubicin, mitomycin, cyclophosphamide, and cytosine arabinoside.

G_2 phase: Estimated as spanning about two hours, this is designated as the second gap between DNA synthesis and cell division. Bleomycin and cyclophosphamide are effective during this period.

The use of up to six different drugs at one time is the basis for combination chemotherapy. Through much experience and experimentation, the therapeutic advantages of each drug can be maximized while disadvantageous side-effects can be minimized. Overall, the administration of multiple drug therapy may also lessen the development of that drug's resistance, which is seen when a single drug is given over a period so prolonged that stable gene amplification is seen.

On the other hand, some interference has been observed between, e.g., methotrexate and 5-fluorodeoxyuridine or 5-fluorouracil. When the drug administered is a hormone, toxicity is sometimes manifested by changes in secondary sex characteristics, such as voice and facial hair. Other drugs may temporarily produce nausea, loss of appetite, loss of hair, hypertension, or diabetes. These side effects are usually reversed when drug treatment is discontinued.

Some of the most widely used anticancer drugs are listed in Table 1; the structures of some of these are given in Fig. 1. Each class of drugs functions in a somewhat different way.

Alkylating Agents. This group of quick-acting, highly reactive compounds includes nitrogen mustard and its close relatives. Often referred to as "cell poisons," the agents are electron rich in solution and hence combine rapidly with many of the cell constituents. The alkylating agents are believed to exert their anticancer effects by direct interference with the cellular DNA synthesis.

Apart from nitrogen mustard, the best known alkylating agents are cyclophosphamide, chlorambucil, and triethylene thiophosphoramide. They act primarily on tissues that are being quickly replaced, such as bone marrow and cells lining the intestine. They are used mainly in the treatment of Hodgkin's disease, lymphosarcoma, the chronic leukemias, and in some cancers of the lung, ovary and throat.

Antimetabolites. These drugs structurally resemble the metabolites a cell needs for growth and mimic normal nutrients so closely that they are taken up by the cell through mistaken identity. Once inside the cell they interfere competitively with the production of nucleic acids and thereby prevent cell growth.

Among the antimetabolites are antagonists of purines and pyridimines, essential components of the cell's nucleic acids. One of the most widely used antimetabolites is methotrexate, which inhibits the enzyme folic acid reductase and thus antagonizes the needed vitamin B, which in turn interferes with both purine and pyrimidine synthesis. Further examples are 6-mercaptopurine and 5-fluoroacil which are, respectively, antipurines and antipyrimidines. The antimetabolites are useful in the treatment of leukemia and in several types of solid tumors. See also **Antimetabolites**.

Plant Alkaloids. Several compounds derived from the common periwinkle plant appear to interfere with a phase of cell division. The best known are vinblastine sulfate and vincristine sulfate. Both are effective in treating certain lymphomas and the latter is applicable to acute lymphocytic

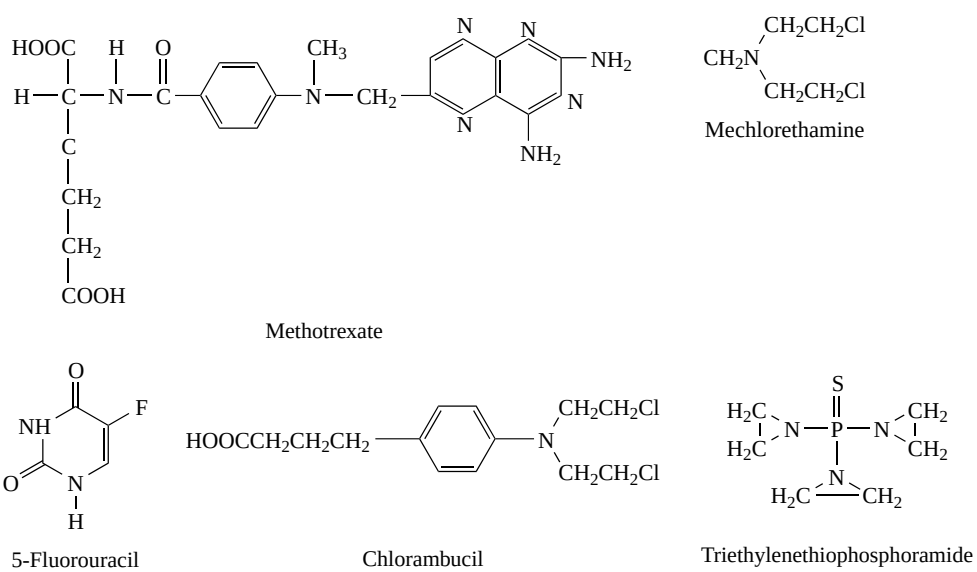

Fig. 1. Chemical structures of representative drugs used in cancer chemotherapy.

TABLE 1. DRUGS USED IN CHEMOTHERAPY OF CANCER GROUP AND GENERIC NAME

ALKYLATING AGENTS	ANTIBIOTICS
Mechlorethamine hydrochloride	Actinomycin D
Cyclophosphamide	Doxorubicin
Chlorambucil	Daunorubicin
Melphalan	Bleomycin
Busulfan	Mithramycin
Triethylenethiophosphoramide	Mitomycin C
ANTIMETABOLITES	OTHER AGENTS
Methotrexate	Hydroxyurea
6-Mercaptopurine	Carmustine
6-Thioguanine	Lomustine
5-Fluorouracil	Procarbazine
Cytosine arabinoside	Decarbazine
PLANT ALKALOIDS	Cisplatin
Vincristine	l-Asparaginase
Vinblastine	Streptozotocin

Notes: (1) See also article on *Hormones*.

(2) *Taxol*. The effectiveness of a drug, *taxol*, which is extracted from the bark of the yew tree, was demonstrated (1989) by researchers at Johns Hopkins as an effective anticancer drug, particularly in connection with ovarian cancer. The drug was approved within a few months by the U.S. Food and Drug Administration for treatment not only of ovarian cancers, but also of breast, head, and neck cancers. An initial problem arose from the fact that the projected demands for the drug could exceed, within a comparatively short time span, the availability of the relevant yew species, even at a cost per treatment of nearly $1,000. It was estimated that the average patient would require about ten treatments, three initial doses to determine if the taxol was effective for a specific patient, and if effective, an additional seven cycles would be required to arrest the cancer. In 1992, plant pathologists (Montana College of Mineral Science and Technology) explored for fungi on local yew trees and found that the fungi on certain yew species contained extractable taxol. The question, as of mid-1993, remains: Does taxol originate in the tree or the fungus? In any event, after thorough laboratory tests and by producing several genera of the fungus, researchers found that taxol can be produced by the fungus. Unfortunately, the tree produces taxol in recoverable amounts in terms of milligrams, whereas the fungus yields the substance in nanogram amounts. Studies are now underway to develop a large-scale fermentation process for producing taxol and thus lower the price substantially.

leukemia. Search is now concentrating on plants from rain forests of South America to which Indian tribes attribute medicinal properties.

Antibiotics. Notable in this group is Actinomycin D, which is believed to attach itself to a base of the DNA molecule, thereby blocking cell growth. As the result of recent studies, a compound called Fredericamycin A may be added to the anticancer antibiotic armory. The molecule of Fredericamycin A contains a cyclopentanoisoquinolone fused to a cyclopentanonaphthoquinone nucleus in a spiro fashion. The compound is produced by a strain of *Streptomyces griseus*. One interesting aspect of the drug is that free radical formation may be a key to the anticancer activity of the compound; a hypothesis in the etiology of cancer is that free radicals may be responsible for the development of neoplasms; now, however, it is postulated that production of superoxide radical may be the mechanism of Fredericamycin A's anticancer activity.

Other Agents. Cancer of the adrenal glands can be treated with *o*, *p′*-DDD, a close relative of the insecticide DDT. The drug appears to have a selective destructive effect upon adrenal cells. Methylglyoxal-*bis*-(guanylhydrazone), often called methyl-GAG, is active against acute myelocytic leukemia, the type most often occurring in adults.

Hormones. Also described in the entry on **Hormones**. The exact biochemical pathways by which hormones influence cell growth is unclear, but nucleic acids are undoubtedly implicated. In cancer chemotherapy hormones tend to accelerate or suppress the growth of specific cells, tissues, and target organs. The female hormone estrogen, for example helps to suppress the growth of disseminated cancer of the prostate. Conversely, male hormones or androgens cause temporary regression of disease in 20% of breast cancer patients and are especially useful in premenopausal women. Among the other hormone types, corticosteroids seem to suppress the growth of lymphocytes and for this reason are frequently prescribed in acute lymphocytic leukemia. Interferon, once hopefully regarded as of high potential use in many forms of malignant neoplasms, now has been found wanting. Cost of treatment is no longer a factor; the drug simply has very limited potential.

Common Sites of Cancer

Gastrointestinal Cancer. In both sexes, gastrointestinal cancer has the highest frequency of occurrence and that involving the colon and rectum is the most prevalent. Cancer of the colon, particularly when it occurs on the right side, is more prevalent in women; cancer of the rectum is more common in men. Carcinoma of the stomach is also a frequently occurring disease, although its incidence is declining in North America, Western Europe and Australia. Slight diminution in the number of cases has been noted in South America and Japan. High rates are now confined to China, Russia, and Central America. Diet, smoking, and cooking appear to be the main etiological agents. Increasing, however, are cancers of the liver, lungs, and pancreas — usually attributable to the use of tobacco.

Diagnostic measures include x-ray examination of chest and barium opaque examination of the gastrointestinal tract. Usually a liver scan is indicated and determination of serum alkaline phosphatase levels. Levels of carciono-embryonic antigen, although nonspecific, have some value.

To aid in treatment and prognosis, a classification system has been established based upon conditions presenting at time of diagnosis:

Stage A: The neoplasm is confined to mucosa with no lymph node involvement. The 5-year survival potential ranges from 60 to 80%.

Stage B: The tumor penetrates to the serous coat without lymph node involvement. The 5-year survival potential ranges from 25 to 65%.

State C: Lymph nodes are involved. The 5-year survival potential ranges from 5 to 40%.

Treatment of gastrointestinal cancers essentially is confined to surgery, radiation therapy, or a combination of both. Chemotherapy has so far been of marginal value. In carcinomas of the middle and lower rectum, colostomy may be required. Radiation therapy is a palliative for local problems, such as obstruction and bleeding among other symptoms. Chemotherapy, when it is used, is almost completely confined to 5-fluorouracil.

Evidence of a genetic connection with cancer of the colon was revealed by two independent groups of researchers in late 1993. These scientists claim to have identified the gene that relates to hereditary nonpolyposis colon cancer, which possibly accounts for up to 15% of all colon cancers. Approximately one person in 200 carries the gene. Rather than having the normal gene that encodes a protein necessary for the repair of damaged DNA, the defective gene lacks this ability. Consequently, cancerous cells develop. Because this type of colon cancer is not rare, genetic screening may be a practical method for identifying persons at risk. Because this particular cancer can be cured only if found very early, such screening could provide an effective way to save lives.

As aptly pointed out by Marx (reference listed), these findings grew out of earlier studies of a particular gene-repair pathway in yeast, known as "mismatch repair" because it removes nucleotides that have paired up with the wrong partners in the DNA double helix and replaces them with the correct ones. Richard Kolodner (Harvard Dana Farber Cancer Center) observes, "We thought that these genes would be good candidates for being involved in human disease, since any mutation that destroys the effectiveness of the repair genes could lead to the accumulation of mutations that could cause diseases, including cancer."

The repair of defective genes may prove to be an effective strategy for treating certain other types of cancers.

Breast Cancer. This is the most common malignancy in women of the western world and has accounted for the greatest number of deaths in women in the 40 to 45 year group. In the United States, 5% of women will contract breast cancer and, when treated with current therapy, about one third will survive for 20 years after diagnosis; about 50% of the women with cancers where there are no axillary lymph node metastases at the time of diagnosis will have a longer period of survival. The term "cured," defined as no further risk of recurrence, still remains appropriate.

In general, the course of an *untreated* breast cancer will commence with a small malignant tumor or tumors in one or both breasts. These neoplasms will enlarge and more may be formed. The cancer will spread axillary and/or clavicular lymph nodes and edema of the arm may occur. *Peau d' orange* (skin dimpling resembling an orange) may also be observed. Ultimately — in a few months — the cancer will further metastasize, frequently involving the pelvic region; metastasis will continue, leading ultimately to death.

A familial history of breast cancer presents a predisposition for acquisition of the disease and the increased risk factor varies with the

number and degree of affected relatives, reaching a ninefold value for pre-menopausal women who have one or more first-degree relatives (mother and sisters) with pre-menopausal bilateral breast cancer. Although the genetic factors involved are poorly understood, evidence of hormonal participation in the etiology of the disease suggests that it may be mediated through a genetically transmitted endocrine factor. In a controlled study, thirty young women genetically at risk and thirty not at risk, fully matched for age and physical characteristics, presented only differences in urinary values of estrone and estradiol. The women at risk had lower values of both substances. This endocrine abnormality may be a discriminant for identifying women at risk in the population at large.

Diagnosis and Prognosis. As an aid to differentiation, treatment, and prognosis, a classification scheme has been devised in which breast cancers at the time of diagnosis are weighted in terms of various factors.

Stage I: Tumor size ranges from impalpable to less than two centimeters. *Node size* ranges from impalpable to palpable but clinically benign. *Metastasis* is negative.

Stage II: Tumor size ranges from impalpable to over two centimeters, but less than five centimeters. *Node size* ranges from impalpable to palpable (clinically benign) or palpable (clinically malignant). *Metastasis* is negative.

Stage III: Tumor is present (any size). *Node* is present (any size) and arm edema may be present. *Metastasis* is negative. This stage can be broken down into four substages, but in any of these, both a tumor and a node will be present.

Stage IV: Tumor is present (any size). *Node* is present (any size). *Metastasis* is positive.

These stages are used as guidelines and assist in communication between diagnosticians, treating physicians, and surgeons. Identification of the stages also facilitates statistical analysis and prognosis for a given patient. The stage of disease at time of diagnosis and prognosis are closely related. Patients diagnosed at Stage I have a 5-year survival potential in 85% of cases. Survival potential can only be estimated out to five years, but this does *not* indicate that the patient will survive only five years. Persons who have survived a treated cancer over a 5-year span most likely will survive (this condition) for many more years. Patients diagnosed at Stage II have a 5-year survival potential in 66% of cases; in Stage III, 41%; and in Stage IV, 10%.

Mammography. Radiation mammography was introduced during the 1960s and became the principal diagnostic tool for breast cancer. Rules pertaining to the use of mammography for women of various age classes during the last few years have become the subject of considerable controversy among professional oncologists. Guidelines established in 1994 are not given here because it is highly likely that they will be changed again. As is usually the case, the best guidance can be obtained from one's personal physician or specialist. In addition to radiation mammography, thermography in past years has been used.

Radical Mastectomy. As with the use of mammography, the need for the radical mastectomy has been the subject of vigorous debate for a number of years among professionals in the field. In recent years, somewhat of a consensus along the following lines has been reached:

1. For Stage I and selected cases of Stage II breast cancer, total mastectomy with axillary dissection is suggested. The Halstead radical mastectomy is not advocated.
2. In advanced Stage II and in Stage III and IV diseases, radical surgery is not indicated simply because current techniques are effective in only a small proportion of patients. In individuals with a large primary lesion, external radiation therapy supplemented with ridium needle implantation is suggested.
3. A two-step procedure should be followed in nearly all cases: (a) study permanent sections of a diagnostic biopsy specimen, and (b) select the best therapeutic approach.
4. Therapeutic alternatives should be fully discussed with the patient.

Palliation. Where metastatic breast cancer does not respond to surgery, irradiation and/or adjuvent chemotherapy, palliation (supportive relief of symptoms) alone remains. Three approaches have been used: *chemotherapy, endocrine ablation*, including adrenalectomy and hypophysectomy, and *hormone therapy*. The most effective approach depends upon many factors, such as the patient's age and menstrual status, the site of metastases, the presence of other life-threatening consequences (hypercalcemia, vertebral collapse) and whether or not there is estrogen-binding receptor protein available.

Male Breast Cancer. This accounts for only 1% or less of all breast cancers. The disease usually occurs in men between the ages of 55 and 60. The first symptom is a lump in the breast followed by ulceration of the skin over the breast and enlarged axillary lymph nodes. These latter indicate an advanced state of the disease. If discovered at an early time, surgery may eradicate the growth. Otherwise treatment follows that advocated for women.

In the most recent budget year, U.S. federal funding for breast cancer research (considerably less than the funds assigned to AIDS research) was appropriated along the following lines:

Treatment	27.3%
Basic Research	25.0
Detection	18.2
Prevention	15.1
Epidemiology	12.9
Rehabilitation	1.5

Lung Cancer. About 100,000 deaths per year are attributed to lung cancer in the United States. It presents a major medical problem and has been statistically linked to tobacco smoking — not only directly, but also in non-smokers who are imperiled by their exposure to other people's tobacco smoke. There is clear evidence that non-smokers who live with smokers face a 35% greater risk of getting lung cancer than those who do not. Young children are more likely to have respiratory problems if they are raised by smoking rather than non-smoking parents.

Among the major cancers, lung cancer continues to present a poor prognosis, thus giving emphasis to preventing exposure of the lungs to carcinogens. While the incidence of lung cancer has increased dramatically, the therapy for this disease, as contrasted with some other forms of cancer, has not kept pace.

The primary types of lung cancers are bronchogenic carcinoma, bronchiolar or alveolar carcinoma, and pleural mesothelioma. See also **Respiratory System**. Bronchogenic carcinomas account for 90% of all lung cancers. These are (1) *squamous* (scaly or plate-like), 50%; (2) *oat cell* (undifferentiated small cell), 20%; (3) *adenocarcinoma*, which is a malignant tumor composed of glandular tissue, 15%; and (4) *undifferentiated large cell tumors*, 15%. Because each of these different forms of bronchogenic carcinomas follows a different histopathologic pathway and requires different treatment, correct diagnosis is extremely important. Statistically, only 5% of lung cancer patients are "cured" on the basis of 5-year survival potential. Until recently, surgery and irradiation were the principal procedures used, but it is now recognized that surgery has been notably ineffective in connection with the oat cell form of the disease. In contrast, this is the only major type of lung cancer responsive to single-agent chemotherapy. In about 50% of cases there has been a positive response to alkylating agents. However, such response has only been short term, with no impact upon the ultimate terminal course of the disease. Greater success has been obtained with multiple drug therapy, which has produced good results in a number of patients with the non-oat cell type of cancers. One combination found to have some success is cyclophosphamide, methotrexate, and vincristine. Other drugs used in various combinations include the nitrosoureas, procarbazine, bleomycin, and doxorubicin. Combination chemotherapy should be under the supervision of specialty medical oncologists and preferably be part of clinical trials.

In order to select the best therapy and to estimate prognosis, a staging system is used for identifying the severity of lung cancer at time of diagnosis. As with breast cancer, the system is based upon three factors — tumor size, involvement of lymph nodes, and extent of metastases:

Stage I. Presence of a *tumor* less than 3 centimeters in diameter. *Nodes* are absent. *Metastasis* is negative.

Stage II. Tumor is larger than 3 centimeters in diameter. *Nodes* are present. *Metastasis* is negative.

Stage III. Tumor is larger than in Stage II. Lymph *node* involvement is extensive. *Metastasis* is positive. Distant sites involved may include the vertebrae, pelvis, liver, and brain.

In untreated lung cancers, system involvement may include bone lesions, airway obstruction, brain metastases, and neuropathy. Radiation therapy can relieve most of these symptoms for a while. In oat cell carcinomas,

where life expectancy is one to two years, the incidence of brain metastases may be reduced by use of whole brain radiation.

In general, radiotherapy is the treatment of choice and is the logical option where patients have unresectable tumors. A decision for surgical resection (thoracotomy) is critical and often difficult to make. Borderline situations exist where the full extent of the disease is unknown until the operation is underway. Success in lung cancer therapy is low because in about half the cases diagnosis comes too late — at a time when the cancer is widespread — and in about 30% of cases resection is not possible at thoracotomy. Even when the disease is correctly diagnosed at an early stage and the tumor is highly localized, the 5-year survival rate may only be as high as 30%.

Gynecological Cancers. The principal cancers of the female genital organs involve the uterus, cervix, and ovaries.

Management of localized uterine carcinomas has established a high success rate. Since the 1930s, there has been a threefold reduction in deaths from cancer of the uterus. Again, a staging system is used to classify cancer of the endometrium as well as for other gynecological cancers. These stages range in severity from Stage 0, which describes a cancer *in situ*, to Stage IV, a situation where the carcinoma extends beyond the pelvis or involves mucosa of the bladder or rectum. Combination chemotherapy is the treatment of choice and the drugs used include the progestational hormones.

Major improvements in the treatment of cervical cancer occurred during the period 1940–1960 and the survival rate has remained relatively steady in more recent years. Improvements are attributed to better sexual hygiene, widespread use of the Pap (Papanicolaou's) test, early detection, and more effective surgical and radiation procedures. The Pap test involves microscopic examination of cells collected from the vagina that are normally shed there from the uterus. If examination of the cell smear reveals any abnormalities, a cervical biopsy specimen is taken for further examination. This widely accepted procedure reevaluated and, while a respected value is still placed on the test, the need for annual screening is in question.

Multidrug therapy has been found to be effective in the treatment of cervical cancer. Ovarian cancer also responds to multiple chemotherapy, although surgery frequently is indicated.

Prostate Cancer. According to the American Cancer Society, prostate cancer is the most commonly occurring cancer in males today and the second-leading cause of cancer-related deaths in men, ahead of colon cancer and second only to lung cancer. It is estimated that in the United States one male in ten develops this disease during his lifetime. A new diagnostic blood test, prostate-specific antigen PSA, has markedly increased the physicians's ability to detect prostate cancer early. The identical blood test also allows the monitoring of cancer decline after treatment. In past years, radical prostatectomy has been a standard procedure for this cancer. In a relatively new procedure, radioactive iodine seeds are permanently implanted directly in the middle of the cancer. The ultimate success of this approach remains to be determined.

Skin Cancers. Whereas benign tumors of the skin may attain a certain size and cease growth, a malignant neoplasm will continue growing indefinitely, although its rate of growth may vary through the years. Uncontrolled skin cancer growth may eventually become so large that it can destroy nearby blood vessels supplying other parts of the body and also it may metastasize to more vital organs which, in turn, may be so damaged that the patient dies.

Skin cancers can be treated successfully if this is commenced early. A preliminary biopsy will distinguish cancer from other skin diseases. A sore or growth persisting for more than two to three weeks, or a sore or lump which shows signs of rapid growth or spread should always be regarded with suspicion.

Excessive exposure to sunlight appears to be a major factor in the production of most skin carcinomas, the highest frequency of which is seen in fair skinned persons who spend much time out of doors in a dry sunny climate.

There are two types of skin carcinoma. *Basal cell carcinoma* accounts for over half of the cases and is composed of cells resembling those of the innermost cells of the stratum mucosum, the deepest layer of the epidermis. A typical basal cell carcinoma presents as a hard, pinkish or waxy growth which may spread slowly, or show signs of healing with formation of a tight cluster of similar nodules around it. Its appearance is usually altered by accidental injury, bleeding and scaling. Basal cell carcinomas may become pigmented so that they appear more like a dark malignant mole; the growths occur more frequently on the face than on other areas of the body.

Squamous cell carcinomas arise from the outermost layer of the stratum mucosum and in their early stages closely resemble basal cell neoplasms, but are more keratinized. Skin cancers of this type are found most often in persons who have been long exposed to sun and wind, the growths being usually found on the face, the ears and back of the hands and appearing as either the *ulcerating* form or as *papillary* growths (cauliflower-like in shape and structure). Although varying greatly in growth rate, squamous cell carcinomas generally grow faster than basal cell carcinomas and have a greater tendency to metastasize.

In intra-epidermal and superficial carcinomas of the skin, the cancerous nature of the growths may remain confined to the skin for years without metastasis or damage of nearby tissue. These diseases respond well to treatment.

Metastases of cancer of internal organs may appear on the skin on the torso, abdomen, or around the genitals. These *metastatic skin carcinomas* may range from ivory to red in color and sometimes grow quite rapidly.

Surgical excision, radiation therapy or chemotherapy are used in the treatment of skin cancer. In surgical excision, skin grafting may be required if a large defect is left. Podophyllin resin, fluorouracil and methotrexate are among the anticancer drugs that appear to selectively destroy some kinds of carcinomas while leaving the surrounding skin intact. In treating malignant melanomas by surgery, extensive removal of the growth, the skin surround it and the lymph nodes draining the area usually are indicated.

Skin cancers arising from layers below the epidermis are called *sarcomas* and, unlike carcinomas, occur more frequently in young persons. The different types of sarcoma are named according to the types of cells principally involved. *Fibrosarcoma* is so named because it involves fibrous connective tissue; *fibroneurosarcoma* is made up mainly of nerve cells. Sarcomas may also arise from muscle, blood and lymph tissue, fat, and other tissues. Because most of these lesions are resistant to irradiation, treatment is largely surgical. See also **Dermatitis and Dermatosis**.

Brain Tumor. This can occur in any location of the brain within the cranial cavity, and at any age including very early childhood. In many cases, a benign tumor of the brain can be removed by modern surgical techniques and, when this is possible, the prognosis is good. Unfortunately, the signs and symptoms are variable and depend upon which portion of the brain is affected. Headache is only occasionally the first, and not the most frequent symptom. Other signs are various types of visual disturbance, incoordination, weakness, and paralysis, which may affect one arm, one leg, or half the body. Personality or mental changes are rare.

Arteriography is a diagnostic technique in which the blood vessels are injected with an opaque contrast medium and radiograms are made to observe the flow of the contrast medium through and around the suspected lesion. Various types of tumors and other disorders can thereby be differentiated. In *radiotopography*, the contrast medium is replaced by a radioisotope and a scintillation camera shows the distribution of the isotope around the lesion.

Apart from tumors originating in the brain, neoplasms in other body organs may metastasize to the brain by way of the blood or lymph streams. Primary tumors of the lung are the most likely to metastasize to the brain. Breast and gastrointestinal tumors spread less frequently as do melanotic, thyroid and other tumors. See also **Central and Peripheral Nervous Systems and the Brain**.

Heavy Ions for Cancer Irradiation

In 1984, the Prime Minister of Japan, Yasuhiro Nakasone, announced plans to construct a Heavy Ion Medical Accelerator to be located in Chiba, Japan. Scheduled for dedication in 1994, the $300 million accelerator was the first such installation to be dedicated strictly for medical use, particularly in the treatment of cancers. The facility was designed to treat approximately a thousand cancer patients per year, and thus the initial cost per treatment was be exceedingly high.

Considerable earlier research had demonstrated the superiority of heavy ions over x-radiation and this encouraged Japanese scientists to build the facility. Researchers at the Life Science Division (Lawrence Berkeley Laboratory) also had studied the effects of heavy ions through the use of their Bevatron, but this was closed down in February 1993. Needless to say, these investigators are looking to the Chiba installation with much interest.

Experts, including those in the cancer science community of Japan, hasten to point out that the new facility should not be regarded as the long-sought "magic bullet" for cancer treatment. Setsuo Hirohashi (National Cancer Research Institute of Japan) observes that indeed the heavy ions are expected to shrink primary tumors, "but the most common reason for the failure of cancer treatments (of any kind) has been the presence of metastases at the time of treatment." Sheer radiative power may make a difference.

Heavy ions carry much more destructive power than x-rays. Most of the power is released at the end of the flight of the particles when they have slowed down for interaction with DNA chains. The heavy ions are focused and scanned with electromagnetic fields, making it possible to aim the particles with much greater accuracy than is the case with x- or gamma rays.

The new facility features two synchrotrons, each 130 meters (416.5 feet) in circumference. A linear accelerator furnishes ions to the synchrotrons. In addition to use as a treating facility, the installation will be used for conducting DNA and cell research.

An abridged glossary of terms used to describe conditions and treatment in various cancers would include:

Actinic keratosis: A precancerous condition of thick, scaly patches of skin. Also called solar or senile keratosis.

Anesthetics: Substances that cause loss of feeling or awareness. Local anesthetics cause loss of feeling in a part of the body. General anesthetics put the person to sleep.

Basal cells: Small, round cells found in the lower part, or base, of the epidermis, the outer layer of the skin.

Benign: Not cancerous; does not invade nearby tissue or spread to other parts of the body.

Biological therapy: Treatment to stimulate or restore the ability of the immune system to fight infection and disease. Also used to lessen side effects that may be caused by some cancer treatments. Also called immunotherapy or biological response modifier (BRM) therapy.

Biopsy: The removal of cells or tissues for examination under a microscope. When only a sample of tissue is removed, the procedure is called an incisional biopsy or core biopsy. When the whole tumor is removed, the procedure is called an excisional biopsy. When a sample of tissue or fluid is removed with a needle, the procedure is called a needle biopsy or fine-needle aspiration.

Cancer: A term for diseases in which abnormal cells divide without control. Cancer cells can invade nearby tissues and can spread through the bloodstream and lymphatic system to other parts of the body.

Carcinoma: Cancer that begins in the skin or in tissues that, line or cover internal organs.

Chemotherapy: Treatment with anticancer drugs.

Clinical trial: A research study that evaluates the effectiveness of new interventions in people. Each study is designed to evaluate new methods of screening, prevention, diagnosis, or treatment of cancer.

Cryosurgery: Treatment performed with an instrument that freezes and destroys abnormal tissues. This procedure is a form of cryotherapy.

Curettage: Removal of tissue with a curette, a spoon-shaped instrument with a sharp edge.

Curette: A spoon-shaped instrument with a sharp edge.

Dermatologist: A doctor who specializes in the diagnosis and treatment of skin problems.

Dermis: The lower or inner layer of the two main layers of tissue that make up the skin.

Electrodesiccation: The drying of tissue by a high-frequency electric current applied with a needle-shaped electrode.

Epidermis: The upper or outer layer of the two main layers of tissue that make up the skin.

Fluorouracil: An anticancer drug that belongs to the family of drugs called antimetabolites.

Interferons: Biological response modifiers (substances that can improve the body's natural response to disease). Interferons interfere with the division of cancer cells and thus, slow the growth of the tumor. There are several types of interferons, including interferon alpha, beta, and gamma. These substances are normally produced by the body. They are also made in the laboratory for use in treating cancer and other diseases.

Lymph nodes: Small organs located throughout the body along the channels of the lymphatic system. The lymph nodes store special cells that fight infection and other diseases. Clusters of lymph nodes are found in the underarms, groin, neck, chest, and abdomen. Also called lymph glands.

Malignant: Cancerous; a growth with a tendency to invade and destroy nearby tissue and spread to other parts of the body.

Melanin: The substance that gives the skin its color.

Melanocytes: Cells in the skin that produce and contain the pigment called melanin.

Melanoma: A form of skin cancer that arises in melanocytes, the cells that produce pigment. Melanoma usually begins in a mole.

Metastasize: To spread from one part of the body to another. When cancer cells metastasize and form secondary tumors, the cells in the metastatic tumor are like those in the original (primary) tumor.

Nonmelanoma skin cancer: Skin cancer that arises in basal cells or squamous cells but not in melanocytes (pigment producing cells of the skin).

Photodynamic therapy: Treatment with drugs that become active when exposed to light and kill cancer cells.

Precancerous: A term used to describe a condition that may or is likely to become cancer. Also called premalignant.

Radiation therapy: Radiation therapy (also called radiotherapy) uses high-energy radiation from x-rays, neutrons, and other sources to kill cancer cells and shrink tumors. Radiation may come from a machine outside the body (external-beam radiation therapy) or from materials (radioisotopes) that produce radiation that are placed in or near the tumor or in the area where the cancer cells are found (internal radiation therapy, implant radiation, or brachytherapy). Systemic radiation therapy involves giving a radioactive substance, such as a radiolabeled monoclonal antibody, that circulates throughout the body.

Recur: To occur again. Recurrence is the return of cancer, at the same site as the original (primary) tumor or in another location, after it had disappeared.

SPF: Sun protection factor. A scale for rating the level of sunburn protection in sunscreen products. The higher the SPF, the more sunburn protection it provides.

Squamous cell carcinoma: Cancer that begins in squamous cells, which are thin, flat cells resembling fish scales. Squamous cells are found in the tissue that forms the surface of the skin, the lining of the hollow organs of the body, and the passages of the respiratory and digestive tracts. Also called epidermoid carcinoma.

Squamous cells: Flat cells that look like fish scales under a microscope. These cells cover internal and external surfaces of the body.

Topical chemotherapy: Treatment with anticancer drugs in a lotion or cream applied on the skin.

Tumor: An abnormal mass of tissue that results from excessive cell division. Tumors perform no useful body function. They may be either benign (not cancerous) or malignant (cancerous).

Tumor necrosis factor: A type of biological response modifier that can improve the body's natural response to disease.

Ultraviolet radiation: Invisible rays that are part of the energy that comes from the sun. UV radiation can damage the skin and cause melanoma and other types of skin cancer. UV radiation that reaches the earth's surface is made up of two types of rays, called UVA and UVB rays. UVB rays are more likely than UVA rays to cause sunburn, but UVA rays pass deeper into the skin. Scientists have long thought that UVB radiation can cause melanoma and other types of skin cancer. They now think that UVA radiation also may add to skin damage that can lead to skin cancer and cause premature skin aging. For this reason, skin specialists recommend that people use sunscreens that reflect, absorb, and/or scatter both kinds of UV radiation.

CANCER RESEARCH (The history). "Biology and Cancer Research have developed together. Invariably, at each stage, the characteristics of the cancer cell have been ascribed to some defect in whatever branch of biology happens at the time to be fashionable and exciting." This quotation from John Cairns highlights the main difficulty encountered in writing a history of cancer research: it has occupied such an important place in the work of biologists — in particular during the last century — that its history generally coincides with the history of biology as a whole. Furthermore, cancer was the initial motivation behind many studies that led

to developments unrelated to cancer. Finally a history of cancer research has to include a history of the different therapies used against cancer, since these therapies were based on rationales that had their origins in a specific vision of cancer.

Cancer was described and named first by Hippocrates, then by Galen, the Greek word "crab" referring to the form of the tumor, with the blood vessels irradiating from it. It was initially considered to be the outcome of inflammation due to "black bile." The history of cancer research is therefore extremely long, and it would be pointless to provide a chronological description of all the observations that have been made. Cancer research has continually swung between models viewing cancer as having an exogenous origin (of various kinds) or an endogenous origin, linked to some kind of organic degeneration. This oscillation was not specific to cancer research, but also concerned other diseases, including those we now know to be infectious diseases. Depending on the different theories and models, either the properties of cancer were explained by its origins or, on the other hand, cancer was viewed as a process relatively unrelated to the initial event that generated it. See also **Galen of Pergamum (AD 129–216)**; and **Hippocrates of Cos (460 BC–370 BC)**.

For simplicity's sake, cancer research will be assumed to have been non-existent prior to the advent of cell theory, apart from some very interesting epidemiological observations that will be described later. Three major steps in cancer research will be outlined. First, the view of cancer asdue to cell proliferation, with the progressive characterization of the cancer cell during the nineteenth century. Thirdly, the present vision of cancer as a molecular disease, with the discovery of oncogenes and anti-oncogenes from the 1970s onwards. Between them, during the last decades of the nineteenth century and the first half of the twentieth century, the origin and mechanisms of cancer were sought for in the disciplines that developed atthe time — microbiology, biochemistry, genetics, endocrinology, etc.The models that emerged have since been more or less integrated into the current molecular paradigm. See also **Oncogenes**.

As far as therapy is concerned, the list of useless drugs used over the centuries would be too long — and too depressing — to report. Surgical ablation of the tumor, which was first employed at the end of the eighteenth century for breast cancer, became safe and more effective in parallel with the general development of surgery (in particular of anesthesia and asepsis). It remained the only effective treatment until the beginning of the twentieth century.

Cancer as a Cellular Disease

The vision of cancer as a cellular disease developed rapidly, at the same time as the microscope was extensively used to study the organization of tissues and cell theory was elaborated. In the same year (1838) that Theodor Schwann proposed the cell theory, Johannes Müller, who was Schwann's director, started his studies on the cell structure of tumors. The new vision was a reaction against the conceptions of Xavier Bichat and René Laënnec, who considered that cancer, had its origin in tissues, and that cancer was thus both a local and a general disease. The conception of cancer as a cellular disease was further developed by Rudolf Virchow, a strong supporter of the theory of cell continuity and the popularizer of the famous aphorism "omnis cellula e cellula" [every cell comes from another cell]. This new conception of cancer was responsible for the progressive unification of a range of diseases that were previously dispersed or poorly characterized: after much debate, leukaemias, described by John Hughes Bennett in 1845 and named by Rudolf Virchow, were recognized as cancer. The same was true for lymphomas, discovered by Thomas Hodgkin in 1832, and named in 1856. The steps leading to the progressive formation of a tumor were described by Wilhelm Waldeyer, who developed the very important idea thateach type of tumor derives from the proliferation of one cell type. He was also among the first to distinguish between benign and malignant tumors. Jacob Henle hypothesized that metastases result from displaced cancerous cells. Using the definition of three cell layers that had been given recentlyby embryologists, carcinomas, tumors of epithelial origin, and sarcomas were distinguished. These numerous observations led to the development of histopathology (the study of the morphology of the cancerous cells), and through the determination of the origin and evolution of cancers, the possibility of a diagnosis and a prognosis. In practice, the development of histopathology was very slow, and became commonly used in cancer diagnosis only during the twentieth century. However, despite a general agreement on the cellular processes leading to tumor formation, scientists did not agree on theorigin of tumors: Rudolf Virchow considered that tumor development was the result of a local inflammation of the connective tissue, whereas in 1875 J.Cohnheim proposed that cancers came from cells that had been left aside during the development of the organism. In 1865 C. Thiersch proposed that cancer resulted from a disequilibrium in growth energy, an idea that was to develop during the first part of the twentieth century. See also **Bichat, Marie-Francois-Xavier (1771–1802)**; **Henle, Friedrich Gustav Jakob (1809–1885)**; **Leukemias**; **Schwann, Theodor Ambrose Hubert (1810–1882)**; and **Virchow, Rudolf Carl (1821–1902)**.

Probably the most important experimental consequence of this new cellular vision for cancer research was the first attempt at tumor transplantation by J. Doutrelepont in 1868, followed by M. Novinsky, A. Hanau and H. Morau, and many others. These early studies were not always reproducible. They also had varying objectives: some were aimed at discovering a pathogenic agent associated with the tumors (see below). Most of these studies confirmed the remarkable stability of the properties of cancerous cells, but nevertheless provided interesting clues about the parameters that affect the growth of transplanted tumors, and in particular the relationships between the donor — the organism from which the tumor comes — and the recipient — the organism into which the tumor is transplanted. It was also observed that pregnancy had an influence on tumor development. These early observations were developed in the first half of the twentieth century, opening a highly productive line of research on the role of the immune system and hormones in tumour development (it also led to the characterization of tissue antigens and the development of grafts). See also **Transplantation**.

Finally, tumor growth was interpreted as a Darwinian competition between normal and tumor cells. The vision of cancerous cells as cells that have escaped the control of the organism and act egoistically pervaded biological thought from the end of the nineteenth century, and is still very present in the current conceptions of cancer.

Cancer Research During the First Half of the Twentieth Century

Cancer Caused by Microorganisms. The successes of Robert Koch's and Louis Pasteur's schools of microbiology, and the growing number of microbes shown to be involved in disease, led to the search for cancer-causing germs, despite the fact that cancer isclearly not a contagious disease. Many bacilli were described, as well as protozoa and yeasts. However, the criteria laid down by Koch to ascribe a given microbe a specific role in a pathology were never met, and such studies became rarer in the early years of the twentieth century. As early as 1903, viruses replaced bacteria as causative agents of cancer: involvement of viruses in cancer is another, more brilliant chapter of the history of cancer research. See also **Koch, Heinrich Hermann Robert (1843–1910)**; **Microbiology**; and **Pasteur, Louis (1822–1895)**.

Cancer as a Dysregulation of Metabolism. Otto Warburg, whose work on respiration was at the origin of modern biochemistry, was the first to pinpoint one central biochemical defect affecting cancer cells: they use the glycolytic pathway in conditions of high oxygen supply, whereas normal cells switch off this pathway, which is specifically associated with anaerobiosis. This regulation was known as the Pasteur effect, following its initial description by the founder of microbiology. Not only did Warburg provide strong experimental support for this observation by working on different types of tumors, he also made a model, linking this alteration of metabolism to the formation of cancer cells: for him, the initial event leading to cancer was an alteration of cellular respiration; the cell reacted and adapted to this change by increasing the activity of the glycolytic pathway. This pathway is much used by embryonic tissues, and this cellular adaptation was therefore parallel to the regression of the cancerous cell to a poorly differentiated state. See also **Warburg, Otto Heinrich (1883–1970)**.

Otto Warburg remained firmly convinced by his theory, despite subsequent criticisms. Other biochemists put forward ideas that were more or lessrelated to Warburg's. Ephraim Racker suggested that the initial change in the cell involved acido-basic regulation rather than respiration. Albert Szent-Györgyi, who in 1937 received the Nobel Prize in Physiology or Medicine for his work on vitamin C, considered the cell — and proteins — as conductor, and cancer as an overall perturbation of this circulation of electrons. In the 1960s, his ideas were developed by Bernard Pullman. Linus Pauling's campaign in favor of vitamin C treatment as a way to avoid cancer is a kind of degenerate product of this vision of cancer as a perturbation of oxidative metabolism. Interestingly, the perturbations

of the energetic metabolism of cancerous cells have been confirmed since, but have yet to find a satisfactory explanation at the molecular level. See also **Pauling, Linus Carl (1901–1994)**; and **Szent-Györgyi von Nagyrapolt, Albert (1893–1986)**.

Since protein synthesis is a very important part of cell metabolism, its modification was also thought to be involved in the origin of cancer. At the end of the 1940s, differences were initially noted between normal and cancerous cells, using the new radioactively labeled amino acids. However, these observations were not confirmed, and the scientists involved soon abandoned their initial aim: this research paved the way to understanding the mechanisms of protein synthesis, and the deciphering of the genetic code.

Hormones and Cancer. The discovery by Antoine Lacassagne in 1932 that the injection of estrogen in male mice induced the formation of mammary tumors led to many studies on the effects of hormones, particularly sexual hormones, in tumor development. It was subsequently shown that some forms of breast or prostate cancer responded to hormone treatment (later involving hormone analogues). The fact that Lacassagne's discovery was made at a time when hormones were being given a major role in physiology and in embryology was surely not a coincidence.

Cancer and the Environment. The hypothesis that cancer could result from the action of compounds present in the environment is not new. In 1775, Percivall Pott showed thatscrotal cancer was relatively frequent in chimney sweeps who began work as boys. In 1879, it was observed that lung cancer affected coal miners. Aniline dye was also shown to induce the formation of bladder cancer in workers in the chemical industry. Experiments performed in 1915 on rabbits showed that these animals developed tumors when their ears were painted with coal tar. In the late 1920s, E. Kennaway isolated polycyclic aromatic hydrocarbons from coal tar and demonstrated their carcinogenic power. X-rays were known to have a carcinogenic effect, and radium was also shown to be responsible for tumors. The carcinogenic effect of radiation and radioactive compounds was widely confirmed by medical studies following the atomic bombs dropped on Hiroshima and Nagasaki at the end of World War II. Fears immediately rose as to the potentially deleterious effects of atomic tests on the environment.

The role of cigarette smoke in inducing lung cancer was officially established by two epidemiological studies, one in England in 1962, the second in the United States two years later. In fact, the link between smoking and lung cancer had long been suspected — the first anti-tobacco campaign was launched in the 1930s by Nazi politicians in Germany. In the 1950s and 1960s, more and more compounds produced by the chemical industry, such as asbestos, were shown to be potentially oncogenic.

Genetics and Cancer. The idea that genes were involved in cancer was proposed by Lucien Cuénot in 1908, soon after the rediscovery of Mendel's laws in 1900. At the same time, Theodor Boveri correlated the modifications in cell division of cancerous cells with chromosomal alterations that could be observed in these cells. In the 1920s Hermann Muller showed that X-rays, which had previously been observed to both cure and induce cancer, were mutagenic. This supported the idea that gene mutations were at the origin of cancer. See also **Muller, Hermann Joseph (1890–1967)**; and **Oncogenes**.

However, apart from rare, familial forms of cancers which were described in the twentieth century, observations in human populations do not support a simple genetic model of cancer. The extensive work of Clarence C. Little at the Jackson Memorial Laboratory showed that different pure strains of mice could have very different rates of cancer. In particular, he isolated one strain with an exceptionally high susceptibility to breast cancer. However, further studies by John Bittner in the 1950s showed that these tumors resulted from the transmission of a virus through the mothers' milk. In addition to a general distrust of the eugenic ideas that underlay the use of pure strains of mice, this result led to a shift in favor of the viral origin of cancer, a theory that was in direct competition with the genetic theory of cancer. Despite these ambiguous results, the hypothesis that cancer has its roots in somatic mutations occurring during the life of the organism became relatively well established, as more and more carcinogenic compounds isolated from the environment were shown to be mutagenic, either spontaneously or following their transformation by the organism.

Cancer and Viruses. At the same time, the role of viruses in inducing cancer was taken more and more seriously. The first observations suggesting that viruses wereinvolved in tumor formation were made by Amédée Borrel at the Pasteur Institute (Paris) in 1903. This was a logical development of previous research on the involvement of microbes in tumor formation. In 1908, Vilhelm Ellermann and Oluf Bang showed that leukemia could be transmitted in the chicken by an ultrafiltrating agent, and Peyton Rous obtained the same result for a sarcoma. Similar results were obtained in rabbits and in mice for breast cancer, and further work on leukaemia in mice were carried out by Ludwig Gross in the 1950s. Many RNA viruses ("retroviruses") were isolated from such studies. In the 1970s, the Epstein–Barr virus was the first virus to be shown responsible for a (rare) form of human cancer. See also **Rous, Francis Peyton (1879–1970)**.

A Confused Situation. At the beginning of the 1970s, cancer research was totally confused. Although there were strong arguments in favor of somatic mutations induced by environmental factors being at the origin of cancer, some viruses had been clearly shown to be oncogenic, at least in animals.

On the therapeutic front, surgery remained the major treatment. For breast cancer, which was the focus of major campaigns in the USA after World War II, surgery, on the basis of early diagnosis, was considered to be appropriate, despite the absence of any real experimental support. The conservative or non-conservative nature of the surgery was still a matter of debate. Radiotherapy was also used in cancer therapy. At the end of the nineteenth and the beginning of the twentieth century, newly discovered X-rays and radioactive compounds (radium) were soon used to treat cancer. As earlyas 1906, proliferating tumor cells were shown to be more sensitive to radiation than normal cells. Treatment could be targeted on the tumors — for instance by implanting needles containing radium directly inside the tumor. Simultaneously, statistical studies in all the developed countries reached the same conclusion: cancer mortality was increasing abruptly. These fears, together with the new therapeutic hopes, stimulated the formation of special centers and hospitals for cancer therapy in the early years of the twentieth century. Continual progress was made in the nature of the radiation used, and the way it was delivered to the diseased tissues. By the 1940s, cobalt progressively replaced other treatments in beam therapy. After World War II, radiation sources became increasingly complex, fully justifying the existence of specialized centers for curing cancer. These developments went hand in hand with the rise of professional societies and philanthropic associations, such as the American Cancer Society, which became increasingly influential in cancer research, in particular after World War II. Following the success of penicillin, systematic screening was used after World War II to search for similar compounds that would be active against cancer cells. The rise of chemotherapy was reinforced by the parallel development of a trial culture, with randomization, double-blind tests and statistical analysis. Apart from the sexual hormone analogues, which were used for the treatment of some forms of breast or prostate cancer, all other treatments were nonspecific, aimed simply at killing rapidly dividing tumour cells. See also **Cancer and Oncology**.

During the 1970s, cancer rates were rising again, partly due to changes in the environment, but mainly due to increases in longevity and the disappearance or decline of other diseases. As a result, cancer became of increasing concern for western societies. In 1971, President Nixon launched the US campaign against cancer — the American Cancer Act. The aim was to attack cancer with a similar effort in terms of money and human resources as had been used for the Apollo program to put a man on the moon. It was decided to focus on the isolation of viruses that might be involved in human cancers. Many studies had already described oncogenic viruses in animals. If a virus were to be isolated from human tumors, precedent suggested it would be possible to develop a vaccine against it: in 1970, the first vaccine against a virus responsible for a lymphoma (Marek's disease) in chickens had been developed.

The results of this "crusade" were mixed. Some commentators argued that it was a "medical Vietnam," i.e. a disaster for the U.S. cancer research. A more balanced view would be that the studies carried out did not discover a "magic bullet" against cancer, nor did they find the elusive viruses which might have been responsible for the major forms of human cancers. However, this research was very important because it led to the new molecular vision of cancer which emerged during this period.

Cancer as a Molecular Disease

The Elaboration of a New Consensus Vision of Cancer. From the beginning of the 1980s, a new vision of cancer appeared, centering on the role of a family of genes — oncogenes — which were rapidly joined by the anti-oncogenes — or tumor suppressor genes. Modifications in the expression or function of these genes were thought to be responsible for cell transformation, and tumour formation. See also **Oncogenes**.

As seen earlier, this new vision replaced not one, but many different-models of cancer, which were all partially conflicting. In contrast, whatever their preference for one or another of these models, cancer specialistshad accepted that cancer was a dysregulation, leading to a de-differentiation of cells. These characteristics of the cancer cell played a minor role in the new oncogene model.

Some historians of science have suggested that the new model of cancer was the direct consequence of the entrance of molecular biologists into the field, and of the use of the new technology of genetic engineering. While it is true that studying genetic modifications that might be responsible for cancer was one of molecular biologists' objectives, the nature of the genes involved, and the way their modifications explain cancer, was not. The development of the new model between 1976 and 1984 was simply the consequence of a rapid succession of discoveries. See also **Molecular Biology**.

A Series of Discoveries. In 1976, Dominique Stehelin, Peter Vogt, Harold Varmus and Michael Bishop discovered that the transforming gene present in the oncogenic Rous sarcoma virus was in fact quite similar to a normal gene present in avian cells. For a while, there was some confusion over what the experiment meant: did the avian genome contain silent retroviruses analogous to the oncogenic Rous sarcoma virus? This possibility had been put forward by Robert Huebner and George Todaro, who had proposed in 1969 that tumor formation resulted from the activation of silent retroviruses present within every genome. This model was directly inspired by research on lysogeny in bacteria. See also **Bishop, J Michael (1936–Present)**; and **Varmus, Harold Elloit (1939–Present)**.

The hypothesis was abandoned, however. The gene present in non-infected avian cells turned out not to be a part of a retrovirus: it was a normal gene, which had been highly conserved during evolution. When similar studies were carried out on the numerous oncogenic viruses that had already been characterized, in every example, the transforming gene present in these viruses was found to be homologous to a normal gene, present in non-infected cells, which was not a part of an endogenous retrovirus.

The real breakthrough came when these genes were shown to be involved in oncogenesis using a totally different experimental approach in a completely different situation. In a study aimed at following the fate of oncogenic viruses after their entry into recipient cells, Robert Weinberg's group cut the DNA of these transformed cells, and showed that some of these DNA fragments — those containing the virus following its integration in the genome — were able to transform normal recipient cells. The surprise came when the experiment was done on cancerous cells, produced by a chemical carcinogen: the result was identical. The gene responsible for transformation was rapidly isolated and shown to be identical to one of the genes that had previously been shown to have been hijacked by the oncogenic viruses. Point mutations in the coding part of the gene had transformed a normal gene into an oncogene: these mutations did not alter the regulation of the expression of the gene, but rather its functional properties.

In a few months, the same genes were demonstrated to be responsible for cell transformation in three other situations, which at a first glance appeared to be very different. Some oncogenic retroviruses contain no transforming gene: it was discovered that these retroviruses integrate into the genome close to some of the oncogenic genes that had been characterized in previous studies, and activate their expression. Other cancers, such as Leukemias, are associated with chromosome translocation. As seen earlier, at the beginning of the twentieth century, Theodor Boveri proposed that such effects might cause cancer. It was discovered that the translocation points corresponded precisely to the position of previously characterized oncogenes, and that their expression increased following translocation: translocation stimulates gene expression by placing the oncogene under the control of strong promoters (or enhancers) of transcription. Finally, in some cancers, there is an amplification of some parts of the genome: once again, the amplified sequences corresponded to the same oncogenes.

This limited family of genes, the oncogenes, seemed to be involved in all the forms of known tumors: spontaneous or chemically induced, produced by a viral infection or associated with chromosomal rearrangements. Their functions, which emerged "directly" from sequencing, were particularly revealing: these genes code for growth factors, growth factor receptors, proteins involved in intracellular signal transduction, or proteins interacting with DNA to stimulate cell division. The discovery that oncogenes code for components of intracellular signaling pathways took place at the same time as these pathways and their molecular targets were described.

The rapid pace of these discoveries, the fact that different experimental approaches showed that the same small group of genes was involved in cancer, and that a molecular description provided an immediate clue as to their function — they participate in the signaling pathways which adapt cell division to the needs of the organism — all these characteristics explain the rapid success of the new oncogene theory of cancer. The new model integrated previous visions and models of cancer: a cancer could be due to mutations, to chromosomal rearrangements as well as to infection by oncogenic viruses. In fact, prior to the arrival of the new oncogene vision, the only viruses that had been proved to be oncogenic were responsible for some rare forms of cancer in animals and humans. Subsequently, the hepatitis B and papilloma viruses have been shown to cause common forms of human cancers, hepato carcinoma and cervical cancer, respectively. See also **Hepatitis Viruses**; and **Papillomaviruses**.

However, in one respect these oncogenes did not agree with previous results: the mutations were dominant. The relative rarity of tumors compared with the high frequency of mutations, and studies of familial forms of cancers such as retinoblastoma, suggested that somatic mutations leading to cancer would be recessive. The first "anti-oncogene" or tumor suppressor gene was isolated in 1986 by Robert Weinberg's group: it is involved in the familial forms of retinoblastoma. Interestingly, it was soon found that DNA tumor viruses, which do not harbor oncogenic genes in their genomes, transform by inhibiting the activity of cellular anti-oncogenes. The first anti-oncogenes to be described were also shown to participate in the control of cell division. The description of a limited number of genes raised the legitimate hope that diagnostic precision could improve rapidly and even that new drugs aimed at inhibiting the action of the proteins encoded by these genes might be forthcoming.

The Difficulties Faced by the New Model. Fifteen years have passed since these observations, and the hope that these oncogenes and anti-oncogenes might be used in diagnosis, and as the targets of drug action, has only partially been fulfilled. *BRCA1* and *BRCA2* genes are widely used for estimating the risks of breast cancer, and there are promising new anticancer drugs which act by inhibiting the tyrosine kinase activity of an oncogene that is specifically activated in certain forms of cancer. However, apart from these rare examples, the therapeutic benefits of the massive amount of research on oncogenes and anti-oncogenes is low. Gene therapy essays are still in their infancy. This is rather disappointing, given the high hopes, and the effort that has been expanded over the last two decades.

The main limit to understanding, and the problem involved in applying our knowledge to diagnosis and cure, is the overwhelming complexity that has been revealed. The number of oncogenes and tumour suppressor genes has grown steadily since the middle of the 1980s. At the same time our knowledge of the intracellular signaling pathways that control cell division has improved immensely. But disappointingly, despite all these efforts, nobody understands exactly why only certain links and nodes in these very complex pathways and networks are affected in cancer, why some genes encoding their components are mutation hot spots. Something in the regulation and functioning of these pathways and networks is obviously missing. A full understanding of these networks and their dysfunctions will probably come only when the components have been sufficiently characterized for their functioning to be modeled.

The number of categories of genes, the mutations of which are involved in tumour formation, has also increased. As well as oncogenes, which activate cell division permanently, and anti-oncogenes, which inhibit it, there are genes involved in the control of cell death or apoptosis. Apoptosis enables the organism to eliminate abnormal cells, in particular cells that have accumulated mutations and that might be prone to transformation. The inactivation of genes involved in DNA repair can also contribute to cell transformation. Other genes are also involved in the increased ability of tumor cells to attract blood vessels in order to increase their metabolic supply, or to digest the barriers that prevent their diffusion in the organism

("metastasis"). Recently, mutations have been found which do not directly affect the tumor, but which influence the surrounding tissues and create an environment more favorable to its growth and diffusion.

The molecular description of cancer has become increasingly complex. Apart from a specific form of intestinal tumor, in which the steps leading to transformation have been fully described, in the case of most tumors the genes involved are simply not known. Furthermore, no general rules have emerged from the data we have to hand. This is merely the molecular confirmation of previous observations which showed that each type of tumor has specific characteristics that distinguish it from other tumors. Cancer resultsfrom stochastic events (mutations) and from the selection among these mutations of those that provide the cancerous cell the best conditions for growth. Each cancer is unique, with its own developmental history.

Hopes in a New, Global Approach. This situation explains why the post-genomic era is seen as a source of a new understanding of cancer. The general idea behind these new approaches is that the order that exists in the living world will only be revealed through a global view of its functioning. The cancer cell not only is a cell in which a given gene has been altered, but also a cell that has reached a new functional state, a new equilibrium. In a cancerous cell, many genes have their activity altered as a consequence of the initial mutations in the oncogenes and anti-oncogenes. This new pattern of gene expression isclosely linked to the properties of the cancer cell. It can provide clues as to its future evolution, and therefore help prognosis.

This new approach to cancer has been stimulated by the development of new tools, such as DNA chips — microarrays — which make it possible in a single experiment to estimate the activity of tens of thousands of genes. Initial results from post-genomic approaches to cancer seem promising. Not only can these experiments distinguish different types of tumors by the analysis of molecular data and confirm diagnoses made by more traditional methods, such as histopathology, but some poorly characterized forms of cancers have been shown to have specific molecular profiles, associated with very different prognoses.

On the basis of the preliminary data, we can imagine that, in a few years, cancer diagnosis will be a precise, automatic process, leading to a precise therapeutic protocol. In addition, the new functional state corresponding to the cancer will be modeled. Using this model, it will be possible to predict which links in the network need to be targeted to restore a normal functional state.

Whether such therapeutic hopes will in fact be fulfilled remains open. Whatever the answer, the new vision of cancer which has already emerged from these studies is different from the early oncogenic model. The alteration of oncogenes and anti-oncogenes is still thought to be an important initial event in oncogenesis, but the piece meal approach is not considered as sufficient to understand the new properties of the cancerous cell. The newmodels are reminiscent of the models proposed sixty years ago by the geneticist Conrad Waddington to explain differentiation. Interestingly, recent studies also point again to a similarity between the functional state of a cancerous cell, and the successive functional states that occur during differentiation and development.

Conclusion

Cancer, the dread disease, has always frightened people. Many metaphors have been used to describe the disease and its evolution. "Wars" against cancer have always been lost, and premature hopes have been systematically dashed. This explains why people suffering from cancer regularly turn to quacks and charlatans. The more our knowledge progresses, the more it appears that cancer is intimately linked to life. We will not be able to understand cancer without fully understanding the functioning of cells and organisms. Retrospectively, this explains why research on cancer had such an impact on our understanding of the most fundamental characteristics of organisms, and why the history of cancer research is so closely linked to the history of biology itself.

CANCER (The crab). A small and poorly marked constellation of faint stars that is of importance principally because it is the fourth sign of the zodiac. In cancer (the crab) is found the fine cluster known as Praesepe (or the Beehive). The stars are not so numerous as in some other star clusters, but are of sufficient brightness to make this an interesting object in a small telescope. Galileo counted 36 stars with his telescope but observers using modern equipment have counted over 300. On a clear moonless night the object appears as a faint glow of light, and is frequently used by astronomers as a test of the transparency of the atmosphere. (See map accompanying entry on **Constellations**.)

CANCRINITE. The mineral cancrinite is a complex hydrous silicate (see also **Silicon**) corresponding approximately to the formula $(Na, K, Ca)_{6-8}(Al, Si)_{12}O_{24}(SO_4, CO_3, Cl)_{1-2} \cdot nH_2O$. It is hexagonal, with prismatic cleavage; hardness, 5–6; specific gravity, 2.42–2.50; color, white to gray or may be greenish, bluish, yellow, or flesh red; colorless streak; luster, subvitreous to greasy; transparent to translucent. Cancrinite is found only in the nephelite-syenites and related rock types and is commonly associated with sodalite. It is believed to be in part primary, having crystallized direct from the magma, and in part secondary as a result of alteration of nephelite by solutions of calcium carbonate. It is found in the Ilmen Mountains of the former U.S.S.R., in Rumania, in Norway, in Canada in Hastings County, Ontario, and in the United States in Kennebec County, Maine. This mineral was named for Count Georg Cancrin, a Russian statesman who died in 1845.

CANDELA (CD). A unit of luminous intensity expressed in lumen per steradian ($lm\ sr^{-1}$). The candela was first defined as 1/60 the luminous intensity, in the perpendicular direction, of a 1 cm^2 black body radiator at the freezing temperature of platinum (about 2042 K) and a pressure of 1 atmosphere. It is now defined as the luminous intensity of a light source producing single-frequency light at a frequency of 540 terahertz with a power of 1/683 watt per steradian. It is the standard unit of measure for luminous intensity adopted by the International System of Units (SI). In some texts, it is referred to as the international standard candle.

Originally, each country had its own, and rather poorly reproducible, unit of luminous intensity; it was necessary to wait until 1909 to see a beginning of unification on the international level, when the national laboratories of the United States of America, France, and Great Britain decided to adopt the *international candle* represented by carbon filament lamps. Germany, at the same time, stayed with the *Hefner candle*, defined by a flame standard, and equal to about nine-tenths of an international candle. But a standard based on incandescent lamps, and consequently dependent upon their stability, would never have been fully satisfactory and could therefore be only provisional; on the other hand, the properties of a black body provided a theoretically perfect solution and, as early as 1933, the principle was adopted that new photometric units would be based on the luminous emission of a black body at the freezing temperature of platinum (2045 K).

The units of luminous intensity based on flame or incandescent filament standards in use in various countries before 1948 were replaced initially by the "new candle" based on the luminance of a Planckian radiator (a blackbody) at the temperature of freezing platinum. This modification had been prepared by the International Commission on Illumination (CIE) and by the CIPM before 1937, and was promulgated by the CIPM in 1946. It was then ratified in 1948 by the 9th CGPM which adopted a new international name for this unit, the *candela* (symbol cd); in 1967 the 13th CGPM gave an amended version of the 1946 definition.

In 1979, because of the experimental difficulties in realizing a Planck radiator at high temperatures and the new possibilities offered by radiometry, i.e., the measurement of optical radiation power, the 16th CGPM (1979) adopted a new definition of the candela:

See also **Units and Standards**.

CANDIDIASIS. Traditionally, candidiasis has been described as a relatively common and mild mucocutaneous fungal infection caused by *Candida albicans*, which resides commensally on the mucous membrane of 20–40% of the normal population. Isolation of the organism from normal feces has ranged from 14–17% over a number of past years. Variations of candidiasis infections sometimes have been described as *moniliasis* and *thrush*. Commencing in the early 1960s, candidiasis has progressively emerged from essentially a harmless commensal to an invasive pathogen. Edwards (see reference) likens this evolution to that of coagulase-negative staphylococci, as reported by Klein (see reference). Recent hospital and intensive care unit surveys have indicated that candida species now rival the more familiar *Escherichia coli*, klebsiella, and pseudomonas as pathogens responsible for hospital-acquired sepsis. Because of inadequate diagnostic practices, numbers of patients die with undiagnosed invasive candida infections.

The alarming emergence of these infections obviously is related to surgical and other techniques developed over recent years. These situations have altered the human host relations with the pathogen. Susceptibility to invasive candida infections include those who are iatrogenically immunosuppressed, intravenous drug addicts, infants of low birth weight, burn patients, and those in postoperative recovery units. Persons on life-support equipment are, in particular, exposed to blood infection with candida, facilitating the dissemination to many organs, including the brain, heart, kidney, and eye. Many professionals now recommend more laboratory tests in search of candida septicemia in susceptible patients, as previously mentioned. Edwards reports that permanent bilateral blindness due to hematogenous candida endophthalmitis has resulted from postoperative candidemia.

Further, the candida invasion of deep organs interferes with the use of broad-spectrum bacterial antibiotics, hyperalimentation fluids, systemic steroids, and cytotoxic chemotherapy for cancer or immune suppression after organ transplantation, among other procedures.

Wingard (Emory University School of Medicine) and associates reported in late 1991 on a study of numerous patients who had undergone bone marrow transplantation, some of whom had received fluconazole (introduced as a prophylactic antifungal after bone transplantation) and some patients who did not. This study was prompted by the observance that *Candida krusei* had emerged as the chief candida pathogen among patients with bone transplants. Conclusions: "In patients at high risk for disseminated candida infections, suppression of bacterial flora and the more common candida pathogens may permit some less pathogenic, but natively resistant candida species, such as *C. krusei*, to emerge as systemic pathogens."

The foregoing paragraphs were staff researched.

Also, within the recent past, more has been learned pertaining to the association of oral candidiasis in a complex autoimmune disease referred to as APECED (Autoimmune Polyendocrinopathy-Candidiasis-Ectodermal Dystrophy). Ahonen and associates (Children's Hospital, Helsinki, Finland) describe the disease as a variable combination of failure of certain glands, including the parathyroid and thyroid, chronic mucocutaneous candidiasis, and dystrophy of dental enamel and nails, alopecia, vitilgo, and keratopathy. A study of this complex and variable disease was studied with a sample of 68 patients, ranging from 10 months to 60 years of age. The criteria for inclusion in the study were the unequivocal presence of at least two of the following: (1) hypoparathyroidism, (2) adrenocortical failure, and (3) chronic mucocutaneous candidiasis. Conclusions: "We conclude that the majority of patients with APECED have multiple components of the disorder. The first component, usually candidiasis, developed in most patients in childhood, but other components may develop as late as the fifth decade. Thus, all patients need lifelong follow-up and counseling to facilitate the early detection of new components."

The foregoing portion of this article was staff prepared.

Frequently Encountered Forms of Candidiasis. The different varieties of candidiasis have in common a superficial invasion of epithelium by hyphae of *Candida* and it is usual for the hyphae to penetrate the basement membrane. However, the infection may spread vascularly to the heart, kidneys, and brain. The fungus may produce white patches on the buccal mucosa and at times chronic moniliasis may induce chronic hyperplastic changes that resemble leukoplakia. *C. albicans* frequently causes a mild infection in the vagina presumably because of a heightened glycogen content of the environment. A striking susceptibility to candidiasis of the skin and nails is seen in children with congenital hypoparathyroidism.

Among the several varieties of candidiasis are: *Acute pseudomembranous candidiasis* (thrush) which is commonly seen in infants as well as debilitated adults. Clinically the infection manifests itself as symptomless white papules or cotton-wool-like exudates, which can be rubbed off, leaving an erythematous mucosa. *Acute atrophic candidiasis* may follow the pseudo-membranous variety and is usually associated with broad-spectrum antibiotic therapy; hence it is referred to as "antibiotic sore tongue." It is the only type of candidiasis that is consistently painful, showing a smooth erythematous tongue with angular cheilitis. *Chronic atrophic candidiasis* is better known as "denture stomatitis" because it presents as a diffuse erythema of the palate, limited to denture-bearing mucosa. *Chronic hyperplastic candidiasis* presents as a firm, diffuse white patch or numerous white papules with intervening erythema on the tongue, cheeks, or lips. This may persist for many years or life and should be differentiated from leukoplakia. *Chronic localized mucocutaneous candidiasis* starts in children as an intractable oral moniliasis involving the nails and sometimes the adjacent skin of hands and feet. *Chronic localized mucocutaneous candidiasis with granuloma* is again established in infancy and the clinical manifestations are those of the previous type of candidiasis with the important additional feature of granulomatous masses affecting the face and scalp. *Chronic localized mucocutaneous candidiasis with endocrine disorder* used to be found in children only and the mortality was particularly high in the presence of Addison's disease; but now the disease is also seen in young adults. A strong familial incidence is often found and the candidiasis commonly precedes the endocrine abnormalities. The clinical features are the same as other varieties of candidiasis.

All varieties of oral candidiasis except the chronic hyperplastic type respond readily to topical treatment with antifungal drugs; nystatin is the drug of choice and is administered as lozenges for throat infection and as vaginal suppositories when the genital tract is involved. Chronic mucocutaneous candidiasis, however, does not usually respond to oral treatment and necessitates intravenous administration of amphotericidin B.

As reported by Dismukes (University of Alabama), *Candida albicans* infection may be associated with a chronic hypersensitivity syndrome (fatigue, premenstrual tension, gastrointestinal symptoms, and depression). Traditionally, long-term antifungal therapy has been considered a treatment of choice, notably in women with persistent or recurrent *C. vaginitis*. The study, involving nearly 50 patients over a period of about 8 months, indicated that, in women with presumed candidiasis hypersensitivity syndrome, nystatin does not reduce systemic or psychological symptoms significantly more than placebo does. Conclusion: "Consequently, the empirical recommendation of long-term nystatin therapy for such women appears to be unwarranted."

CANDLE. The original unit of luminous intensity, defined as the luminous intensity of a candle of particular construction. The candle was eventually replaced by the international candle, the new candle in 1939, and finally the candela in 1948. See also **Candela**; and **Units and Standards**.

CANDLE-FLY. A Southern name for moth, equivalent to the Northern miller or moth-miller.

CANGA. A Brazilian term for an iron-rich conglomerate or breccia in which the pebbles or anguclasts are hematite and itaberite cemented by hematite or limonite.

CANINES *(Mammalia, Carnivora)*. The general organization of Canines may be outlined about as follows:

True Canines (*Caninae*)
- Wolves (*Canis*)
- Jackals (*Thos*)
- Foxes (*Vulpes*)
- Fennecs (*Fennecus*)
- Arctic Fox (*Alopex*)
- Gray Fox (*Urocyon*)
- South American Jackals (*Dusicyon*)
- Maned Wolf (*Chrysocyon*)
- Raccoon-Dog (*Nyctereutes*)

False Canines (*Simocyoninae*)
- Dholes (*Cuon*)
- Bush Dogs (*Speothos*)
- Cape Hunting Dog (*Lycaon*)

Bat-eared Foxes (*Otocyoninae*)

Dogs. In this large and diversified group we have, of course, the familiar dog (*Canis familiaris*), one of the most highly diversified of animals as a result of long selection and controlled breeding. While the dog has adapted extremely well to humans and vice versa, it is of interest to note that the dog, compared with many other mammals, is considered primitive, considering the absence of highly specialized structures. Authorities believe that the relationship of humans with dogs dates to the earliest days of human development on this planet. The simple observation is made that the early humans had to grub hard for their food and that they found that early dogs knew where the carrion was as well as other suitable food sources. The humans naturally took to following the dogs and a natural working companionship developed, with the dog ultimately occupying part of the human's shelter and behavior pattern. As with other domesticated animals, the true ancestors of the dog are difficult to trace with any degree of certainty, but many theories have been proposed. Dogs are closely related to jackals, coyotes, dingos, and wolves. It has been observed that once skinned, it is difficult to differentiate between a wolf, coyote, and domestic dog. However, it appears that the modern dog is a descendent of a wolf-like ancestor.

Over the years, over a hundred breeds of dogs have appeared. Generally, these are divided into six categories: (1) *working dogs* for hauling loads and herding grazing animals. Included are Collies, Mastiffs, Schnauzers, Sheepdogs, and the Siberian Husky; (2) *sporting dogs*: (a) pointers, (b) setters, and (c) retrievers; (3) *hounds*; although sporting dogs, the hounds are in a separate category and include Bassets, Bloodhounds, Dachshunds, Foxhounds, and Greyhounds; (4) *terriers*, now essentially pets or house dogs, but once considered sporting dogs — including Fox, Welsh, Scottish Terriers, and Airedales; (5) *non-sporting dogs* — bred originally for sport and working, including Chow Chows, Poodles, Dalmatians, and Bulldogs; (6) *toy dogs*, such as Pekingese and Chihuahuas.

It is interesting to note that dogs, over a period of thousands of years, have formed in essence what some authorities term *nations*; that is, types and varieties that are best suited to given regions and that, in nature, the nations so-called are seldom found mixed. Of course, humans have moved domesticated dogs around the world so much over the centuries that interbreeding has added to the overall complexity of the situation. But, it is of note to observe that the dogs indigenous to the desert areas and temperate zones of the northern hemisphere are all wolves, whereas in the tropics of Asia and Africa, the *jackals* are the indigenous dogs, and whereas in South America, the indigenous dogs are the South American jackals (*Dusicyon*).

One of the earliest records of the existence of the dog was uncovered in exploring an Egyptian tomb (circa 3500 B.C.). Also, a terrier-like dog was found among the remains of a tomb (circa 3066 B.C.). The tomb of the monarch Antafee (3000 B.C.) revealed the presence of four dogs at the feet of the deceased. In diggings made in Denmark dating much further back (6000 B.C.), the bones of dogs were found.

Wolves. Wolves are found in Europe, Asia, and North America. The Antarctic wolf of the Falkland Islands, a species somewhat smaller than the coyote, with a less bushy tail, black at the middle and tipped with white, is the sole representative of the southern hemisphere and most likely may be the result of an importation. Of the true wolves of the genus *Canis*, the coyote or prairie wolf of North America is the smallest form. Seven species ranging over various limited areas from Canada to Texas and from Iowa to California are known indiscriminately as coyotes. They are somewhat more cowardly than the larger wolves and, in settled areas, often persist as annoying predators, robbing poultry roosts and catching small game. The nature of their food supply seems to determine whether they live alone or in a pack. Such patterns of behavior may bear on the question of whether or not they are a threat to livestock. An article by M. Bekoff and M.C. Wells on "The Social Ecology of Coyotes," can be found in *Sci. Amer.*, **242**, 4, 120–148 (April 1980). The common coyote (*C. latrans*) occurs in the northern prairie area; the plains coyote (*C. nebracensis*) is found throughout the Great Plains; and the mountain coyote (*C. lestes*) occurs in the western mountain areas. Generally a coyote will weigh from 25 to 30 pounds (11.3 to 13.6 kilograms) and will attain a length of about 35 inches (89 centimeters), including tail. The body is buff color with white underneath. The legs are reddish-brown. The animal is considered sly and stealthy and is nocturnal. It may attain a speed of 40 miles (64 kilometers) per hour in pursuit of its prey. Favorite dietary items include the rabbit, chipmunk, small animals of almost any kind, mice, all kinds of birds, fowls, and sage hens. The coyote prefers to use burrows that already have been constructed by other animals, such as the prairie dog. A litter consists of from 6 to 8 pups. The life span is about 13 years. The coyote has a distinctive yap, whine, and howl.

Larger wolves are now common only in the wilder parts of North America, Europe, and Asia. Species found in North America include the gray wolf (*C. lycaon*), the southern wolf (*C. floridanus*), the lobo or timber wolf (*C. nubulis*), the Texas red wolf (*C. rufus*), and the American jackal (*C. frustron*) found in Texas and Oklahoma. Hounded by humans from time immemorial, wolves still persist in North America's diminishing wilderness. More detailed coverage of this topic can be found in an article by L. Mech, "Where Can the Wolf Survive?" *National Geographic*, **152**, 4, 518–537 (October 1977).

Foxes. There are over ten species of foxes and these occur widely in the Northern hemisphere. Foxes (*Vulpes*) are of moderate size and slender build, with a sharp muzzle, long bushy tail, and unusually large ears. In addition to the habitats of the wolves, foxes are also found in North Africa north of the great desert regions. They also are found in Iceland. Foxes of certain types are prized for their pelts, the best furs coming from those of the far north. The Silver Fox is bred extensively in captivity for its fur.

The female fox is known as the vixen. The gestation period is 63 days. There usually are 4 to 5 young in a litter and the young are blind at birth with eyes opening at the end of 10 days. The fox has a cunning disposition. For example, a fox may break the line of scent when hunted by leaping onto the back of a sheep. Some of the cleverness of the fox remains to be fully investigated and explained.

Some genera of North American foxes include: Red Fox (*Vulpes*) — with its black fox, silver fox, and cross fox color phases — is bred on a very large scale in so-called fur farms and occurs naturally in all of the colder climes of the United States, Canada, into Alaska and Labrador, and southward into the New Mexican mountain ranges. The Kit Fox (*Vulpes*), also known as the Swift Fox, prefers open country of the Great Plains from Canada southward into Texas. The animal also has been found in the arid regions of Colorado and the Mojave Desert. Favorite dietary items include rats, squirrels, pocket mice, and small desert animals. The fur of the kit fox is not of economic value. The Gray Fox (*Urocyon*) inhabits a range somewhat more southerly of that of the red fox. The animal prefers wooded areas. There are geographic variations of this animal and some of these are found as far south as Florida, Mexico, and Central America. Fur of the gray fox is valued at about half of that of the red fox, but it is used for garment trimming, particularly after it has been dyed. The Arctic Fox (*Alopex*) is found north of the tree limit in the arctic tundra. A favorite food is the lemming, which they store much as a squirrel stores acorns. They also are known to trail polar bears, picking up the remains no longer of interest to the bear. However, polar bears, along with wolves, are natural enemies of the Arctic fox. These animals are known to be particularly friendly to humans, with reports of their trailing explorers and remaining just at the edge of campfires. The Blue Fox is a color phase of the Arctic fox. The blue fox also is farmed for fur on several of the Alaskan islands. By careful breeding, the blue fox will not turn white in winter.

Over eastern Europe, northern India, and Siberia, the gray-colored Hoary Fox (*V. canus*) is found. Further south and in Iraq, Iran, and western India is found the Desert Fox (*V. leucopus*). The Corsac Fox is found in central Asia and Siberia. Sometimes, in error, referred to as fennecs, a small, specialized group of foxes is found in Africa. They are small, with disproportionately large ears. The Kama (*V. cama*) is found in the Kalahari Desert and environs. Ruppell's Fennec (*F. familicus*) is well distributed through the Near and Middle East.

The *Fennec* is a small animal resembling a fox and also has enormous ears; *F. zerda* occurs in northern Africa, and *V. familicus* is found in Syria and adjacent regions. They are desert animals, living underground, and are nocturnal. See Fig. 1.

Fig. 1. Fennec fox, *Fennecus zerda*. (*Photo M.W. Fox.*)

Jackals. As mentioned earlier, the *jackals* are the indigenous dogs of the tropics of Asia and Africa. There are almost innumerable species of jackals, often determined geographically. Generally the jackal is a scavenger and essentially omnivorous. They are hole dwellers, sleeping by day in their holes, or in hot weather, occupying a shallow watery spot to keep cool. They are known to travel in packs and to hunt fairly large game. They are also known to trail large cats and to create a noisy disturbance, whereupon they eat much of the cat's feast during the cat's period of confusion. The common jackal (*C. (Thos) aureus*) ranges from southeastern Europe to Sri Lanka and into northern Africa. The remaining species are African. They are approximately 2 feet (0.6 meter) in length, with a height of about 15 inches (38 centimeters) at the shoulders. The jackal has a dismaying cry, as truly characteristic to it as the hyena's cry is to that animal. The popular use of the term "jackal" does not seem to fit the behavior pattern of the actual jackal, particularly with reference to its association with the big cats. See Fig. 2.

Fig. 2. Asiatic jackal, *Canis aureus*. (*Photo M.W. Fox.*)

The cataloging and, in fact, actual discovery of the South American jackals is far from complete.

False Canines. The false canines are so called because they are not quite so directly related to the true canines, but nevertheless have dog-like qualities. It is believed that this relatively small number of species essentially are relics of major branches that have faced extinction. These include the Dholes which occur in the Oriental region. The Cape Hunting Dog (*Lycaon pictus*) roams regions of Africa south and east of the Sahara. The animal has a large body with long legs, a broad flat head, and large, erect ears. It is of various colors, including brown, yellow, white and black. These animals usually hunt in packs of from 15 to 60 members and feed mostly on small animals. However, they also attack larger animals and are known to be especially damaging to sheep.

The Dingo (*Canis dingo*) is a wild dog found in forested areas of Australia. It is probably descended from dogs introduced to that continent many years ago. The dingo is a serious enemy of sheep and has been killed in large numbers for its depredations. The animal is about $2\frac{1}{2}$ feet (0.8 meter) in length, with a height of about 2 feet (0.6 meter). It has large erect ears, a bushy tail, and has a tawny black coloration. The dog is considered crafty and courageous. When taken from the den at an early age, the dog can be trained to become a trustworthy pet.

CANIS MAJOR (the great dog). Both this constellation and its companion Canis Minor, or the little dog, have been named from remote antiquity as the dogs of Orion. Sirius in Canis Major and Procyon in Canis Minor are both well-known stars, Sirius being the brightest observable. References to these stars are to be found in nearly all ancient classical literature. Sirius, in particular, was of great importance to the Egyptians, because it rose with the sun at the period when the waters of the Nile were due to rise, and was considered as a herald of the returning fertility of the valley. Sirius is not only the brightest, but also the closest star visible to the naked eye in the latitudes of Europe and North America. Intrinsically, Sirius has a brightness of more than 20 times that of our sun. Both Sirius and Procyon have faint companions; that of Sirius is particularly famous as the first of the white dwarfs discovered. (See map accompanying entry on **Constellations**.)

CANKER SORE. A canker sore is an ulcer on the mucous membrane inside your mouth. The medical terms for canker sores are *aphthous stomatitis, ulcerative stomatitis,* or *aphthae*. Recurrent canker sores are one of the most common inflammatory conditions of the mouth, afflicting about 20 percent of the general population. These shallow ulcers in your mouth can make eating and talking uncomfortable. They may occur on your tongue, on your soft palate, inside your cheeks or lips, and at the base of your gums.

Canker sores differ from cold sores in that they occur on the internal soft tissues of your mouth and aren't contagious. Conversely, cold sores almost always start out on the lips and don't often spread to the soft tissues of your mouth. In addition, cold sores are caused by a form of the herpes virus, making them extremely contagious.

It is not known what causes canker sores in all patients, although more than one cause is likely even for individual patients. Canker sores can occur at any age, but often they first appear when you are between 10 and 40 years of age. Attempts to find bacteria or viruses linked with the disease have not proven fruitful, although an allergy to a type of bacteria commonly found in the mouth may cause some people to develop canker sores. The sores also might be an allergic reaction to certain foods eaten. Stress may trigger canker sores as well.

Injury to the mouth — such as scratching by abrasive foods or a stray toothbrush bristle — can trigger outbreaks of canker sores, although these factors probably do not cause the disorder. Hormonal disorders can contribute to canker sores, as can deficiencies of iron, folic acid, or Vitamin B12. There may be an association of canker sores with Helicobacter pylori, the same bacteria that cause peptic ulcers, and they have been associated with the AIDS virus. See also **Ulcer (Acid-Peptic Diseases)**.

Celiac sprue, a disease of the intestines caused by sensitivity to gluten (a group of proteins found in wheat, barley, and rye), has also been associated with development of canker sores.

Canker sores begin as small reddish oval or round swellings, usually on the movable parts of the mouth such as the tongue and the inside linings of the lips and cheeks. These swellings usually rupture within a day, are covered by a thin white or yellow membrane, and become edged by a red halo.

The size of the sores varies from being an eighth of an inch wide in minor infections to an inch and a quarter wide in more severe cases. Fever is rare and rarely there is an association of canker sores with other diseases. Usually a person will only experience a single or a few canker sores at a time. These sores generally heal within two weeks. Severe canker forms of the sore may leave scars. You should consult with your doctor if a canker sores continues or worsens for more than two or three weeks.

There are a number of treatments that reduce the pain and duration of canker sores for individuals whose outbreaks cannot be prevented. These include numbing ointments such as benzocaine, which are available in drug stores without a prescription. Anti-inflammatory steroid mouth rinses or gels can be prescribed for patients with severe sores. A number of medications have been used for canker sores including diphenhydramine suspension (Benadryl and others). This liquid medication can be used as a mouth rinse in adults to provide temporary relief from the pain caused by canker sores. Patients should not swallow the diphenhydramine, but simply use it as a mouth rinse.

Mouth rinses containing the antibiotic tetracycline may reduce the unpleasant symptoms of canker sores and speed healing by preventing bacterial infections in the sores. Clinical studies at the National Institute of Dental Research have shown that rinsing the mouth with tetracycline several times a day usually relieves pain in 24 hours and allows complete healing in 5 to 7 days. The U.S. Food and Drug Administration warns, however, that tetracycline given to pregnant women and young children can permanently stain the children's teeth. Both steroid and tetracycline treatments require a prescription and care of a dentist or physician.

There are other topical medications that a healthcare practitioner can prescribe to ease the discomfort. Medications such as steroids (triamcinolone) or antibiotics (tetracycline) used topically on the ulcers sometimes promote healing. There is no evidence that antibiotics taken orally (swallowed) are helpful. If the canker sores are caused by a yeast infection, a topical anti-fungal medication can be used (nystatin). Some people with AIDS (HIV infection) who have canker sores respond well to thalidomide.

Some doctors recommend applying ice to the canker sore, avoiding food that is irritating, and rinsing your mouth with over-the-counter preparations such as diluted hydrogen peroxide or elixir of Benadryl. Some people find relief by rinsing the mouth with a solution of $\frac{1}{2}$ teaspoon of salt in 8 ounces of water.

Vitamin and other nutrient supplements often prevent recurrence or reduce the severity of canker sores in patients with a nutritional deficiency. Avoidance of foods a patient is allergic to also can reduce the frequency of canker sore recurrence.

Regular dental care, including brushing and flossing, as well as a balanced diet may help reduce the frequency and severity of canker sores.

CANKER WORM *(Insecta, Lepidoptera).* Of two chief species, the canker worm is an economic pest against apple, apricot, plum, as well as elm trees. The spring canker worm (*Paleacrita vernata*) is a moth that emerges in early spring. The caterpillars have only two pairs of prolegs. The fall canker worm (*Alsophila pometaria*) is similar, but the timing of its habits is different. Wingless female moths normally emerge from the ground in late autumn, whereupon they ascend into trees and deposit their eggs, usually on smaller branches. These eggs hatch in mid-spring. The resulting blackish-yellow-striped looping caterpillars proceed to defoliate trees.

Adult male spring canker worms are gray moths; the females are wingless, plump, and gray. The larva is slender, light-to-dark brown and because of their locomotion may be described as "measuring worms." Distribution is the northeastern United States, as well as North Carolina, Missouri, Montana, Colorado, Utah, California, and Texas. Canker worms generally occur in cycles. Their destructive period usually lasts from 3 to 5 years before natural enemies and climatic conditions succeed in bringing about a reduction in numbers. This process may require 10 or more years.

Birds are the most effective natural enemies. Over 40 kinds of birds, chickadees, thrushes, and warblers in particular, feed on these caterpillars, their eggs, and the egg-laden female moths.

CANNABIS INDICA. A variety of common hemp from which is procured the so-called hashish and marijuana, narcotic drugs. See also **Marijuana**.

CANNIZZARO METHOD. See **Chemical Composition**.

CANNIZZARO, STANISLAO (1826–1910). Born in Italy, he extended the research of Avogadro on the molecular concentration of gases, and thus, was able to prove the distinction between atoms and molecules. His investigations of atomic weights helped to helped to make possible the discovery of the periodic law by Mendeleyev. His research in organic

chemistry led to the establishment of the Cannizzaro reaction involving the oxidation reduction of an aldehyde in the presence of concentrated alkali.

CANNON, WALTER BRADFORD (1871–1945). Walter Cannon was an American physiologist, who helped to elaborate the nature and function of the sympathetic nervous system.

Cannon was born in 1871 at Prairie du Chien, Wisconsin, a town built on the site of Fort Crawford where William Beaumont pioneered the study of digestion. In his first year at medical school at Harvard, Cannon used the newly discovered X-rays to study the movements of the stomach during digestion in cats fed a meal mixed with a substance opaque to X-rays, bismuth subnitrate. Cannon found that the movements of the stomach were apt to stop suddenly. This, he argued, was due to heightened emotion, such as fear or distress. In 1911 these findings were summarized in *The Mechanical Factors of Digestion*. See also **Beaumont, William (1785–1853)**.

He graduated in 1900, accepted an instructorship in physiology at the Harvard Medical School, under Henry P. Bowditch; by 1906 he was Professor of Physiology and Chairman of the Department. In his teaching he adapted the case-system of instruction pioneered at the Harvard Law School. He remained at Harvard until his retirement in 1942.

Encouraged by his work on digestion, Cannon began to study the effect of strong emotions on the functions of the body and diseases, examining the sympathetic nervous system. Cannon developed the concept of the emergency function of the sympathetic nervous system, publishing *Bodily Changes in Pain, Hunger, Fear and Rage* in 1915. During the First World War, as a member of the Harvard Hospital Unit, he was sent to France, where he concentrated on the urgent problem of surgical shock. For his efforts he was awarded the CB and the Distinguished Service Medal in 1919. A summary of this research, *Traumatic Shock*, appeared in 1923.

Much of Cannon's subsequent research focused on the adrenal system and its links to the sympathetic nervous system, and how sympathetic nerve impulses were transmitted. In 1921 Otto Loewi demonstrated that a chemical mediator was responsible for the transmission, for which he received the 1936 Nobel Prize for Medicine or Physiology. Cannon had not been far behind, and in 1934, 1935 and 1936 he was considered for the Nobel Prize, as he had been in 1920 for his work on digestion. See also **Loewi, Otto (1873–1961)**, and **Synapse**.

Cannon's work on the sympathetic nervous system led him to suggest that the internal environment of the body was a steady state system. In 1926 he coined the term homeostasis to describe this, and in *The Wisdom of the Body* published in 1932 he applied this notion to the maintenance of social as well as biological systems. His work influenced a generation of social scientists.

Cannon believed that a scientist was a citizen, and should defend freedom. He became involved in the formation of the Medical Bureau to Aid Spanish Democracy and the American Soviet Medical Society, and was accused by some of having communist sympathies. In his latter years he developed mycosis fungoides triggered by over-exposure to X-rays in his early career. He died in 1945.

CANONICAL. This term is used as an adjective to describe a standard form of a function or equation, especially when the form is simple. A canonical matrix, for example, has nonzero elements only on the main diagonal.

CANONICAL TIME UNIT. For geocentric orbits, the time required by a hypothetical satellite to move one radian in a circular orbit of the earth's equatorial radius; 13.447052 minutes.

CANONICAL TRANSFORMATION. A transformation from one set of generalized coordinates and momenta to a new set such that the form of the canonical equations of motion is preserved. This usually involves finding a transformation function S, which is a continuous and differentiable function of the old and new generalized coordinates and the time. The transformation can be defined by

$$L(q, \dot{q}) = L'(Q, \dot{Q}) + \frac{dS}{dt}$$

where L is the Lagrangian function in the original set of coordinates, and L' is the Lagrangian function in the transformed set of coordinates (the dot indicates the first derivative).

CANOPUS (α Carinae). Ranking second in apparent brightness among the stars, Canopus has a true brightness value of 1,500 as compared with unity for the sun. Canopus is a yellow-white, spectral F type star and is located in the constellation Carina south of the ecliptic. Estimated distance from the earth is 100 light years. See also **Constellations**; and **Star**.

CANTERBURY NORTHWESTER. See **Winds and Air Movement**.

CANYON. A long, deep, relatively narrow, steep-sided valley confined between lofty and precipitous walls in a plateau or mountainous area, often with a stream at the bottom; similar to, but larger than, a gorge. It is characteristic of an arid or semiarid area (such as western United States) where stream downcutting greatly exceeds weathering; e.g., Grand Canyon. ("Glossary of Geology," American Geological Institute.)

CAP. See **Meteorology**.

CAPACITANCE. For an electrical system, capacitance may be defined as the ratio of its electric charge to the related change in potential, or by the time integral of the rate of flow of electric charge, divided by the related electric potential. By substitution of the quantities equivalent to electric charge and potential, the concept of capacitance is readily extended to nonelectrical physical systems by a corresponding change in quantities and units. Thus for a thermal system, the quantities equivalent to charge and potential difference are heat and temperature difference; for a pneumatic system the quantities would be mass and pressure.

The electrical capacitance of such a capacitor as a conducting body that is completely isolated, i.e., far removed from other conductors, including the earth, and is surrounded by a homogeneous, perfect dielectric, depends only upon the size and shape of its external surface, and upon the permissibility of the surrounding medium. Very long electric circuits, especially when the wire is surrounded by a conducting sheath, as an ocean cable, have considerable capacitance because of the capacitor — like action of wire and sheath with the insulation between them. The same is true of insulated wire wound in a close coil, adjacent turns of which, being at slightly different potential, act as the conductors of a capacitor — an effect which may be partially avoided by a criss-cross or "honeycomb" winding or by a "banked" winding (in flat spirals).

The *farad* (F) is the SI unit of electric capacitance and is defined as the capacitance of a capacitor between the plates of which there appears a difference of potential of one volt when it is charged by a quantity of electricity equal to one coulomb (C).

For a capacitor made up of two conducting bodies in which charge is taken from one and placed on the other, its capacitance is the ratio of this charge to the difference of potential of the two bodies. The farad is a comparatively large unit and the electrical capacitance is often expressed in microfarads, μF($1\ \mu\text{F} = 10^{-6}$F) or picofarads, pF($1\ \text{pF} = 10^{-12}$F).

For n conducting bodies, their respective potentials, $V_1, V_2, \ldots, V_n$, and charges, $Q_1, Q_2, \ldots, Q_n$, are expressed in terms of a set of algebraic equations

$$V_1 = C_{11}Q_1 + C_{12}Q_2 + \cdots + C_{1n}Q_n$$

$$V_2 = C_{21}Q_1 + C_{22}Q_2 + \cdots + C_{2n}Q_n$$

$$\cdots\cdots\cdots\cdots\cdots\cdots$$

$$\cdots\cdots\cdots\cdots\cdots\cdots$$

$$V_n = C_{n1}Q_1 + C_{n2}Q_2 + \cdots + C_{nn}Q_n$$

$C_{11}, C_{12}, \ldots, C_{nn}$ are called the capacitance coefficients of the set.

Among the special types of capacitance are:

1. The *lumped capacitance* such as the capacitance of a parallel plate capacitor. Its capacitance C in farads is $\in_0 k_e A/d$ where $\in_0$ is the permittivity of free space and is equal to 8.84×10^{-9} farads per meter, k_e is the relative permittivity of the uniform isotropic dielectric between the plates. A is the area of the plate in square meters and d is the plate separation in meters.

2. *Distributed capacitance*, such as the capacitance per meter of a coaxial transmission line. Its capacitance in farads per meter is $2\pi \in_0 k_e / \log_e(D/d)$. D is the inside diameter of the outside conductor and d is the outside diameter of the inner conductor.
3. *Stray capacitance*, such as the unintentional capacitance between a conducting wire or network component and chassis. See also **Capacitor (Electrical)**.
4. *Effective capacitance*, which is the total capacitance between two points on a circuit.
5. *Acoustic capacitance* has been defined as the negative imaginary part of acoustic impedance.

CAPACITANCE RAIN GAUGE. A probe consisting of a stainless steel rod covered by a Teflon sheath set inside a cylindrical rainwater collector. The water surrounding the probe forms the outer plate of a coaxial-type capacitor while the metal rod forms the inner plate. The Teflon sheath serves as the dielectric. As the water height in the collector rises, the surface area of the capacitor increases, increasing the total capacitance. The total capacitance is measured and converted to an analog voltage directly proportional to the height of the water in the collector.

AMS

CAPACITANCE TRANSDUCER. A device whose capacitance is caused to change when exposed to a condition being measured. A simple configuration comprises two parallel plates that are separated by a small distance, with the space between the plates occupied by a dielectric medium. Relationships for such a device are

$$C = m(KA/d)$$

where

C = capacitance, farads
m = proportionality constant
K = dielectric constant
A = effective area of plates
d = distance between plates

Picofarad (equals 10^{-12} farads) is the practical unit used.

In designing a capacitance transducer, one of three properties can be manipulated: (1) effective area, (2) dielectric constant, or (3) distance. All three methods are used and the capacitance principle is found in a number of transducers for various measurements, including displacement, position, velocity, level of fuels in vessels, acceleration, weight, force, and flow.

CAPACITANCE UNITS. See **Units and Standards**.

CAPACITIVE LOAD. An alternating-current circuit in which the current drawn leads the voltage in phase is said to provide a capacitive load. Capacitive loading may be the result of actual capacitors, or of virtual capacitors in the form of long transmission lines, or overexcited synchronous rotating equipment. Most electrical apparatus, such as motors and coils, draws from the line a current that lags the voltage, and the use of some capacitive load is desirable in order to bring the total current and voltage more nearly in phase, and thus raise the power factor.

CAPACITOR (Electrical). An arrangement of conductors and dielectrics used to secure a capacitance for the storage of electrical energy in the electric field. The energy stored in a capacitor is $W = \frac{1}{2}CV^2$ joules where C is the capacitance in farads and V is the voltage in volts. The essential feature of all capacitors is a system of conductors separated by dielectrics. The oldest form of a capacitor is the Leyden jar. Modern capacitors, both fixed and variable, are of many forms, such as those of metal foil and paraffin paper dielectric, metal foil and mica dielectric, metal foil and polystyrene dielectric, metal foil and ceramic dielectric, metal plates with vacuum, compressed gases or air as dielectric, and aluminum and tantalum electrolytes. One finds these in a variety of electrical systems, such as: wire telephony, radio receiving, radio transmitting, television, computers, electrical measuring instruments, servomechanisms, devices for filtering, recording, or transcribing, ignition systems, power factor correcting devices, and motor starting systems.

Well beyond the scope of this encyclopedia are descriptions of the vast number of capacitor constructions, configurations, sizes, performance characteristics, terminals and means of connection into circuits, and ratings, among other factors. An exhaustive summary of the capacitors commercially available to electrical and electronics engineers from a large number of suppliers will be found in the *Electronic Engineers Master Catalog*, Volume A, published annually by Hearst Business Communications, Inc., Garden City, New York. For selection and procurement purposes, the catalog features the following classification of capacitors:

Capacitors, Fixed, Electrostatic
  Ceramic
  Film/Foil (Nonmetallized)
  Metallized Film
Capacitors, Fixed, Electrolytic
  Aluminum
  Tantalum
  Mica
  Paper and Paper/Film
  Glass, Porcelain, Vacuum, Gas-Filled
Capacitors, Variable, Electrostatic

CAPACITY CORRECTION. The correction applied to a mercury barometer with a nonadjustable cistern in order to compensate for the change in level of the cistern as the atmospheric pressure changes. Thus, as the pressure falls, the height of the cistern increases, due to the exchange of mercury between the barometer tube and its cistern. This correction is not required if the scale is calibrated as in the Kew barometer. See also **Barometric Corrections**.

CAP CLOUD. See **Clouds and Cloud Formation**.

CAPE CANAVERAL. See **Spaceports U.S.**

CAPELIN *(Osteichthyes)*. A cold-water pelagic fish, the capelin (*Mallotus villosus*) occurs extensively in the north Atlantic and north Pacific and adjoining regions of the Arctic. The capelin is a soft-rayed fish and, together, with the smelts, comprises the family *Osmeridae*. In the eastern Atlantic, the capelin occurs abundantly from the Trondheim Fjord region of northwestern Norway to Jan Mayen, Spitzbergen, and Novaya Zemyla at the eastern extremity of the Barents Sea. The capelin also occurs sporadically in the White Sea and Kara Sea, but the central part of its range in the eastern Atlantic is the Barents Sea. Iceland also has an abundance of capelin around its shores, as does Greenland, where in the last several decades the center of the capelin distribution has moved north as far as Thule (76°N) on the west and Scoresby Sound (70°N) on the east. In the Canadian Arctic Archipelago, capelin have been reported from the Melville Peninsula, but not from Baffin Island. Individual occurrences of capelin have been reported from the Coronation Gulf, Bathurst Inlet, and the Great Fish River of the Canadian Arctic. Capelin are reportedly very common in the southern half of the Hudson Bay, but rare in the northern portion. They are not known in the western part of Hudson Strait. There is thus a gap in its distribution between eastern Hudson Strait and southern Hudson Bay.

Capelin are relatively small fish, the mature specimens being generally 7 to 8 inches (13 to 20 centimeters) in length, although individual fishes up to nearly 10 inches (24.5 centimeters) in length have been recorded. Growth is greatest during the first two years of life, after which it decreases until, in the fifth year, the size increment is negligible. During the first year, both male and female are the same size, but during the second year a differential growth rate sets in, favoring the male, which is from 0.4 to 1 inch (1 to 2.5 centimeters) larger than the female at sexual maturity. See Fig. 1.

From Saglek south along the Labrador coast, capelin occur in large quantities wherever suitable spawning beaches can be found. The Newfoundland coast, the Grand Bank, St. Pierre Bank, and the Banks of the Labrador Shelf also possess large populations of capelin, but they have not been reported from Flemish Cap, where water temperatures are too warm. In the Gulf of Saint Lawrence, the capelin is most abundant on the northern shore, although in colder years, they also occur extensively around Gasp£. South of the Cabot Strait as far as Cape Cod, the occurrences of capelin

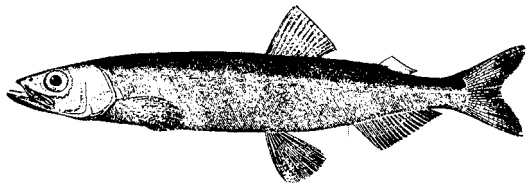

Fig. 1. Capelin (*Mallotus villosus.*)

are rare and are related and restricted to the infrequent influx of cold water into the Gulf of Maine.

In the Pacific, the distribution of the capelin extends from Cape Barrow, Alaska around the Bering Sea south along the Pacific coast to Canada to Juan De Fuca Strait. On the Asiatic coast, it extends from the Sea of Chukotsk south to Hokkaido Island, Japan, and the Tumen River in Korea.

Important Link in Food Chain. In the Barents Sea, the capelin is an abundant fish and forms an important link for many food chains. This is especially true of the cod, which migrates toward the coast in pursuit of the capelin during their spawning migration in early spring, but also of the haddock and redfish. Barents Sea capelin are demersal spawners that deposit their eggs at depths between 164 and 328 feet (50 and 100 meters). The capelin of the Barents Sea are exploited commercially only during the winter-spring spawning period. Capelin represent large catches for both Norwegian and Soviet fishers. The capelin vitally affect the location and productivity of the fishers for demersal fish in the Barents Sea. Iceland, which did not initiate exploitation of its capelin resource until 1963, has expanded the catch progressively since that time. Nearly all of the Norwegian and Icelandic catch, as well as the bulk of the Soviet catch, is reduced to meal and oil. In Newfoundland, capelin have been traditionally used as a source of raw fertilizer and as bait, but these uses have declined in recent years. Although Greenland does not formally report a capelin catch, it is known that large quantities are used as food for human consumption, bait, and as a supplement in the diet of sheep and domestic cattle.

High mortality after spawning has been recorded for the capelin as a result of stranding or wounding during the act of spawning. The pelagic-living capelin enters the tidal zone in order to spawn. The fishes come to the beach in front of the crest of an advancing wave, the spawning act is completed, and they go back with the returning wave. When coming short of the reach of the returning wave, the capelins are stranded. Many others are injured during the vigorous motions that are a part of the act of spawning. In this way, very large numbers are destroyed annually in arctic regions.

See also **Fishes**.

CAPELLA *(α Aurigae).* The third-brightest star visible in the northern latitudes, and the fifth-brightest star in the celestial sphere. Capella is closer to the pole than any of the other bright stars. It has always played an important part in mythological writings, and we find it referred to on an old tablet dating back to 2000 B.C.

Astronomically, Capella is a particularly interesting star, for it is a spectroscopic binary with a period of 104 days, and the angular distance between the components has been measured with the interferometer. There are also two dwarf M stars, making Capella a four-star system. From the complete solution of the orbit, the physical characteristics of the object may be found. It is a giant star of the same spectral class as our sun.

Ranking sixth in apparent brightness among the stars, Capella has a true brightness value of 170 as compared with unity for the sun. Estimated distance from the earth is 47 light years. Capella is classified as a yellow star of spectral type G. See also **Constellations**; and **Star**.

CAPILLARITY. The name given to a class of phenomena, of which the elevating or depression of liquids in fine tubes is representative. When the interface between a liquid and a gas, or between two liquids, is intercepted by a solid surface, an equilibrium is established at the junction among the forces acting along the three surfaces of contact. For example, let a plate of solid *S* be dipped into a liquid *L* having gas *G* above it. See Fig. 1. A molecule at the junction *O* is acted upon by the adhesive attraction *P*, by the forces which give rise to the three surface tensions along the interfaces *OH*, *OE*, and *OD*, and by the reaction *R* of the plate *S* against which it is drawn by the adhesion. (Its weight may be considered negligible.) The flexible interface *OH* adjusts itself so that these forces come into equilibrium; unless, indeed, one of them, *E*, exceeds the sum of *D* and

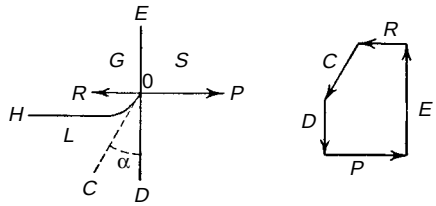

Fig. 1. Capillary force, large adhesion.

C, in which case the liquid "creeps" indefinitely along the surface as oil does over a glass or tin container. The equilibrium polygon at the right is labeled in each case to correspond with the figure representing the surfaces. The "angle of contact" α, between the liquid surface at *O* and the solid surface *OD*, is determined by the aforesaid forces acting at *O*. For most liquids against glass it is acute; for mercury against glass it is obtuse. See Fig. 2. In special cases it may be 90°, and in others it reduces to zero.

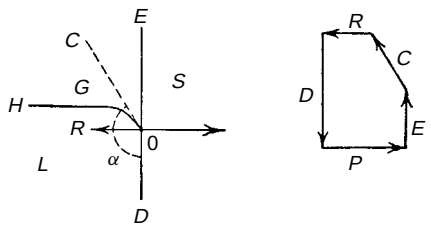

Fig. 2. Capillary force, small adhesion.

If the interface between two media *A* and *B* (Fig. 3) is curved, *A* being on the concave side, the pressure in *A* is greater than in *B* on account of the surface tension; much as the pressure inside a rubber balloon is greater than outside. We can now understand why water rises in a capillary tube. In order to secure equilibrium, the liquid must rise until the pressure inside the surface at *B*, plus the pressure due to gravity at depth *h*, makes the pressure at *L* equal to that at the surface level outside; that is, to the atmospheric pressure. Similar reasoning applies to the depression of mercury in a glass tube. For a circular tube of internal radius *r*, the distance *h* to which capillarity will elevate (or depress) a liquid of density ρ and surface tension *T* (against air) is readily shown to be

$$h = \frac{2T\cos\alpha}{r\rho g}$$

where *g* is gravity. See also **Electrocapillarity**.

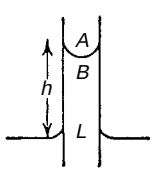

Fig. 3. Rise of liquid in capillary tube.

CAPILLARITY CORRECTION. As applied to a mercury barometer, that part of the instrument correction that is required by the shape of the meniscus of the mercury.

Mercury does not wet glass and consequently the shape of the meniscus is normally convex upward, resulting in a positive correction. For a given barometer, this correction will vary slightly with the height of the meniscus. The capillarity correction can be minimized by using a tube of large bore. See also **Barometric Corrections**; **Capillary Action**; and **Capillary Depression**.

CAPILLARY. 1. Hair-like, especially in application to fine tubes. 2. A minute thin-walled blood vessel intervening between the arteries and veins. See also **Circulatory System**. 3. A cylindrical space of small radius, or

a tube containing such a space. The numerous uses of such tubes has given rise to a number of derived terms. Thus, the capillary correction is a correction applied to mercury barometers, widebore thermometers, etc., for the effect of capillarity on the height of the column. Capillary pressure is a pressure due to capillary force. See also **Capillarity**.

Capillary rise is the elevation of liquid in a capillary tube above the general level. Capillary separation is the separation of gases by flow through a porous medium. In a theory of this process based on the concept of momentum transfer, the actual porous medium is treated as equivalent to a bundle of parallel capillary tubes.

CAPILLARY ACTION. The depression or elevation of the meniscus of a liquid contained in a tube of small diameter due to the combined effects of gravity, surface tension, and the forces of cohesion and adhesion.

When the liquid wets the walls of a container, the meniscus is shaped convex downward; if the liquid does not wet the walls of the container, the meniscus is shaped convex upward. See also **Meniscus**.

CAPILLARY DEPRESSION. The depression of the meniscus of a liquid contained in a tube where the liquid does not wet the walls of the container (as in a mercury barometer). The meniscus is shaped convex upward, and this results in a depression of the meniscus. See also **Meniscus**.

CAPILLARY FRINGE. Above the zone of saturation in the ground, capillary pores may exist which, if filled with water, form a zone or fringe of moisture higher than the true water table. This is the capillary fringe or zone of capillarity.

CAPILLARY SYSTEM (Instrument). Capillary, or small bore tubing, has several uses in instruments. Sometimes the capillarity, or capillary attraction, plays an important functional part, as when such tubing is used in inking systems. In other cases, the capillary is utilized only to provide an optimum volume for the hydraulic transmission of a fluid in amounts proportional to the changes in some measured variable. Capillary tubing also is used to create a resistance to flow between two portions of an instrument so as to improve performance.

CAPPING INVERSION. A statically stable layer at the top of the atmospheric boundary layer. Although the word "inversion" implies that temperature increases with height, the word "capping inversion" is used more loosely for any stable layer (potential temperature increasing with height) at the top of the boundary layer. This inversion is a ubiquitous feature of the atmospheric boundary layer, formed because the troposphere is statically stable on the average, and because turbulence homogenizes air within the boundary layer, which by conservation of heat requires that a stable layer form at the top of the boundary layer. This inversion traps surface-induced turbulence and air pollutants below it, and causes the free atmosphere to not "feel" the earth's surface during fair weather (i.e., no drag, free slip, no heat or moisture from the surface, and winds are nearly geostrophic).

CAPRIC ACID. [CAS: 334-48-5] Also called decanoic, decoic, and decyclic acid, formula $CH_3(CH_2)_8COOH$. The acid occurs as a glyceride in natural oils. Usual form is white crystals having an unpleasant odor. Soluble in most organic solvents and dilute nitric acid; insoluble in water. Specific gravity 0.8858 (40 °C); mp 32.5 °C; bp 270 °C. Combustible. A component of some edible vegetable oils. See also **Vegetable Oils (Edible)**. Capric acid is derived from the fractional distillation of coconut oil fatty acids. The acid is used in esters for perfumes; fruit flavors; a base for wetting agents; as an intermediate in organic synthesis; plasticizer; resins; and used in food-grade additives.

CAPRICORNUS (the sea-goat). A constellation of small stars, not at all striking in appearance, but important because it is the tenth sign of the zodiac. The star Alpha (named Giedi) is one of the more remarkable stars, actually being made up of six components. (See map accompanying entry on **Constellations**.)

CAPRIMULGIFORMES *(Aves)*. This order of birds comprises crepuscular (birds active in the twilight) and nocturnal birds, loosely called the goatsuckers. The beak is broad, cleft rearward beyond the eyes; the head is flat with large eyes at the sides. The feathers are soft and have bark-colored background and markings. There are 10 primaries and 10 tailfeathers, and 14 cervical vertebrae; the thoracic vertebrae are unfused. They scratch their heads by bringing the foot over the wing. Incubation lasts only 16–17 days and is shared by both parents. The newly hatched young are covered with woolly down; they can see, and are ambulatory within a few days. Except for one species, their diet is vegetarian.

The 5 families comprise 22 genera and 96 species: 1. Oilbirds (*Steatornithidae*); 2. Potoos (*Nyctibiidae*); 3. Podargues (*Podargidae*); 4. Owlet Nightjars (*Aegothelidae*); and 5. Nightjars (*Caprimulgidae*). The length of the last two families reaches 20–55 centimeters ($8–21\frac{1}{2}$ inches); the length measured to the tip of the much elongated lateral tailfeathers is 80 centimeters (31 inches).

The Oilbirds (family *Steatornithidae*) comprise only one species, the Oilbird (*Steatornis caripensis*). The length is 45 centimeters (18 inches), the wingspread is 113 centimeters (44 inches), and the weight is 400 grams (14 ounces). The plumage is stiffer than that of the other goatsuckers; the tail feathers are staggered, and there are 10 rectrices. The upper mandible of the stout beak is curved like that of a predator. The legs are very short and without horny scales; the first toe points diagonally forward. The feet are weak and not suited for grasping a branch.

This family of goatsuckers is the smallest and most remarkable one. Oilbirds live in holes, fly out at night, and, unlike all the representatives of the order, feed exclusively on fruits.

The Podargues (family *Podargidae*) are rather large goatsuckers of the Australian-Papuan region and of the southeasterly parts of the Indo-Malayan islands. The length is 21.6–53.4 centimeters ($8\frac{1}{2}–21$ inches). Their beak is large, boat-shaped, and thickly horny. There are two genera: 1. Podargues proper (*Podargus*) with three species, among them the Australian Tawny Frogmouth (*Podargus strigoides*); and 2. Frogmouths (*Batrachostomus*) with nine species, including the Javanese Frogmouths (*Batrachostomus javensis*).

Frogmouths, like nightjars, are softly feathered. Their gray-brown and red-brown marbled color pattern is concealing. They differ considerably from nightjars in their physical structure and their behavior. The arrangement of the feathers in the podargues and in the nightjars is not markedly different. While the tongue in nightjars is more or less degenerate, in the podargues, it is firm, thick-skinned, and leaf-shaped.

The differences between the two genera (*Podargus* and *Batrachostomus*) are only minor. The moult in podargues is "staggered," as it is in potoos and oilbirds. In true goatsuckers and owlet nightjars, on the other hand, the primaries are moulted medially-laterally. Compared to nightjars, the most important differences in behavior are in regard to reproduction. Podargues proper usually lay two eggs, while frogmouths lay one pure white egg in open tree nests. Podargues build loose nests of twigs on a horizontal, forked branch, while frogmouths make a cushion-like structure from their own down and cover the outside with spiderwebs and lichen. Incubation takes about 30 days and so does the nestling period of the young, who at first are covered with long white down. Both sexes share the incubation and the care of the youngsters in the nest.

While the quite frogmouths are to be found only in woodlands, podargues proper inhabit a variety of wooded areas, even the Australian desert with only a sparse tree cover. Nowhere are they especially common; they are also difficult to discover because of their life habits. At night they are as crowded together as are the nightjars of Africa and of tropical South America. They live in pairs and as far as we know they are sedentary: they neither migrate, nor roam like nomads.

The sluggish podargues and frogmouths are in no way aerial hunters, like the nightjars. Most of what they eat is taken from the ground. They fly a short distance from a tree or a pole to pick up such things as ground-dwelling scorpions, centipedes, and insects. They also consume snails, frogs, small lizards, and even birds and mice. The proper podargues also like fruit and occasionally steal grapefruit and other soft fruits from gardens.

The Potoos (family *Nyctibiidae*) are similar to the nightjars in appearance. The wings are very long and, when folded, reach almost to the end of the tail, which is especially long and wide. The beak extends very little beyond the outline of the head; it does, however, extend backward past the ears so that it forms a gigantic maw. The tip of the beak is free and decurved at a right angle. On the edge of the upper mandible a large tooth projects and surrounds the tender lower mandible like a clasp. The eyes are very large, have a vivid yellow color and a reddish reflection when a light is flashed on them in the night. The legs are very short, and the toes

are very long and unusually broad and fleshy at the base, thus forming a large sole (which assures stable sitting on a wide surface).

There is one genus (*Nyctibius*) with five species, which resemble each other closely in their bark-colored plumage. Among them is the Common Potoo (*Nyctibius griseus*). The length is 35 centimeters (14 inches) and the weight is 160 grams ($5\frac{1}{2}$ ounces). It occurs from Mexico to Argentina. The Great Potoo (*Nyctibius grandis*) has a length of 55 centimeters ($21\frac{1}{2}$ inches) and weighs about 550 grams (19 ounces). It occurs from Guatemala to Brazil. During daylight the potoos sit immovably on a tree, not crouching like goatsuckers, but upright. They look so much like the jags on a branch that they can afford to sit on a bare branch in full view, or on a tree stump, or even on a picket fence, looking as if they were part of it. Neither the hot sun nor the rain bothers them. Now and then they droop a little, but immediately straighten up again when something near them stirs. They watch their surroundings through narrow eye slits.

The Owlet Nightjars (family *Aegothelidae*) are closely related to the podargues of the family *Podargidae*. They are smaller than podargues and have a stockier build. The length is 19–28 centimeters ($7\frac{1}{2}$–11 inches). The beak resembles that of a frogmouth, but is shorter and softer than those of podargues and frogmouths, and is extensively hidden by the forehead plumage. On the forehead and between the eye and beak are stiff and partly erectile bristles, and on the chin are some softer ones that are recurved. The coloration of the plumage resembles that of podargues and goatsuckers.

There is only one genus of Owlet Nightjars (*Aegotheles*) with seven species; one of them, the Australian Owlet Nightjar (*Aegotheles cristatus*), is widespread throughout Australia. Four species occur only in New Guinea, one in New Caledonia.

Owlet nightjars inhabit wooded areas and are less sluggish than the podargues. They sit on tree branches in an erect, owl-like posture. They never assume the stiff, "part of the tree" position during the day, but rather stay in tree hollows, from which one can easily chase them by bumping against the tree or shaking the branches. Their feeding habits place them, as indicated by the structure of the palate, between podargues and goatsuckers. Their flight course is straighter than that of goatsuckers; it lacks the latter's characteristic bends and turns. While in flight they catch flying insects. Examinations of the content of their gizzards have shown that ground-living animals, such as weevils, centipedes, and ants constitute the main part of their diet. They brood in tree hollows, occasionally in ground holes in a riverbank, or in buildings. Although they do not build regular nests, the eggs are placed on a soft layer of dry leaves or mammal hairs. Like the eggs of the tawny frogmouth, the egg shell is pure white with occasional brown dots. The clutch consists of three to five eggs. The nestlings, like those of the tawny frogmouth, are covered with pure white down.

The last family of the goatsuckers or nightjars, the Goatsuckers proper (*Caprimulgidae*), derives its name from a legend reaching back to antiquity. Since these birds often flutter around grazing animals at night in order to catch insects near them, it was believed that they sucked the milk from goats. Actually, their very broad and short beak, which can be opened wide, indicates their manner of providing sustenance: they catch hawkmoths and beetles mostly in flight. Their soft plumage with its owl-like markings assures effective camouflage and is superbly adapted to the ground, which is, aside from their hunting flights, their main field of activity. The nightjar's long, slender wings lend flexibility and speed to its flight, and extensions radiating from the vanes make it noiseless.

The length is 20–41 centimeters (8–16 inches). They generally rest during the day and close their eyes down to a slit; they are active at night. They are ground-brooders and lay no nest bedding; both parents relieve each other in the care of the clutch and the young.

There are 17 genera with 69 species; the most important are: the Nightjar (*Caprimulgus europaeus*); the Standard-Wing Nightjar (*Macrodipteryx longipennis*); the Pennant-Wing Nightjar (*Semeiophorus vexillarius*); the White-Throated Poor-Will (*Phalaenoptilus nuttallii*); the Common Nighthawk (*Chordeiles minor*); and the Pauraque (*Nyctidromus albicollis*). See also **Nightjars and Nighthawks**.

Cleere, N. and D. Nurney: *Nightjars: A Guide to the Nightjars, Nighthawks, and Their Relatives*, Yale University Press, New Haven, CT, 1998.

CAPROIC ACID. [CAS: 142-62-1] Also called hexanoic, hexylic, or hexoic acid, formula $CH_3(CH_2)_4COOH$. Present in milk fats to extent of about 2%. Also a constituent of some edible vegetable oils. See also **Vegetable Oils (Edible)**. The acid is oily, colorless or slightly yellow, and liquid at room temperature. Odor is that of Limburger cheese. Soluble in alcohol and ether; slightly soluble in water. Specific gravity 0.9276 (20.4 °C); mp −4.0 °C; bp 205 °C. Combustible. Caproic acid is derived from the crude fermentation of butyric acid; or by fractional distillation of natural fatty acids. Used in various flavorings; manufacture of rubber chemicals; varnish dryers; resins; pharmaceuticals.

CAPROLACTAM. [CAS: 145-60-2] $NH(CH_2)_5CO$, formula weight 112.15, liquid ingredient used in the manufacture of type 6 nylon. See also **Fibers**. Several hundred million pounds of the compound are produced annually. There are a number of proprietary processes for caprolactam production.

In one process, the chargestock is nitration-grade toluene, air, hydrogen, anhydrous NH_3, and H_2SO_4. The toluene is oxidized to yield a 30% solution of benzoic acid, plus intermediates and byproducts. Pure benzoic acid, after fractionation, is hydrogenated with a palladium catalyst in stirred reactors operated at about 170 °C under a pressure of 10 atmospheres. The resultant product, cyclohexanecarboxylic acid, is mixed with H_2SO_4 and then reacted with nitrosylsulfuric acid to yield caprolactam. The nitrosylsulfuric acid is produced by absorbing mixed nitrogen oxides N_2O_3 in H_2SO_4 : $N_2O_3 + H_2SO_4 \rightarrow SO_3 + 2NOHSO_4$. The resulting acid solution is neutralized with NH_3 to yield $(NH_4)_2SO_4$ and a layer of crude caprolactam which is further purified.

A later process utilizes a photochemical reaction in which cyclohexane is converted into cyclohexanone oxime hydrochloride.

The yield of cyclohexanone is estimated at about 86% by weight. Then, in a Beckmann rearrangement, the cyclohexanone oxime hydrochloride is converted to ∈-caprolactam:

$$C_6H_{10}NOH \cdot 2\,HCl \xrightarrow{H_2SO_4} CH_2\text{—}(CH_2)_4\text{—}C(=O)\text{—}NH + 2\,HCl$$

CAPSICUM. See **Spices**.

CAPSULOTOMY. A capsulotomy is an incision that opens the clear, cellophane-like capsule that wraps the natural crystalline lens of the eye. The lens is surrounded by the capsule and separates it from the vitreous, which is the thick fluid in the back of the eye, and the aqueous, which is the thinner fluid in the front of the eye.

A capsulotomy is sometimes necessary following cataract surgery. A cataract occurs when the natural lens of the eye becomes clouded, usually as the result of aging. It is treated by surgically removing the clouded lens and replacing it with an artificial prescription lens. During cataract surgery, the front, or anterior, portion of the lens capsule is removed at the same time that the natural lens is removed. It is then replaced with a plastic prescription lens. The rear, or posterior, portion of the capsule is left in place.

In 30 to 40% of patients, the posterior capsule becomes cloudy following cataract surgery. The cloudiness can appear months or years after surgery. The main symptom is a decrease in vision. Another symptom is difficulty with glare and bright lights. If the cloudiness impairs vision, a posterior capsulotomy is needed. Patients sometimes mistakenly think the cataract has come back, but it cannot return because the natural lens of the eye has been removed.

A posterior capsulotomy is a laser surgical procedure that uses a YAG laser to create an opening in the center of the clouded posterior capsule. The opening allows light to pass freely to the retina, thereby improving vision. The procedure is painless and takes less than five minutes in the ophthalmologist's office. It does not involve anesthesia, other than numbing eye drops, and there is an improvement as soon as the dilated pupil returns to normal size.

As with any surgery, rare complications can occur. With a posterior capsulotomy, there may be swelling. People who have a YAG laser capsulotomy are at a slightly higher risk of developing a retinal detachment in the future. In very rare cases, the intraocular lens can dislocate through the opening in the capsule, requiring surgical repositioning or replacement.

An anterior capsulotomy is a cataract surgery technique used to make a small round opening in the front of the capsule that contains the eye's natural crystalline lens. Through this opening, the ophthalmologist inserts a tiny instrument to break up and remove the cloudy lens. It is then replaced with a plastic prescription lens. See also **Cataract**; and **Vision and the Eye**.

Vision Rx, Inc., Elmsford, NY

CARACARA *(Aves, Falconiformes).* South American birds of several species related to the hawks. They eat carrion but also catch living prey and sometimes rob other birds of their prey. One species, Audubon's caracara, *Polyborus cheriway*, occurs in the extreme southern parts of the United States. The chimachima is found from Panama to southern Brazil. The chimango is found in Tierra del Fuego and the southern part of the continent. See also **Falconiformes**.

CARANGIDS *(Osteichthyes).* Of the order *Percomorphi*, suborder *Percoidea*, the family *Carangidae*, the carangids are very fast and many of the species are excellent food fishes. They are well distributed worldwide in tropical and temperate waters. There are about 200 species, most of which are shaped something like the yellow jack (*Gnathanodon speciosus*). The latter fish occurs in the Indo-Pacific and attains a length of about 3 feet (0.9 meter). It possesses several vertical greenish strips on a pale yellow body. The tail fin is sharply forked. The jack mackerel (*Trachurus symmetricus*) frequents the waters of the American Pacific coast. These fish are characterized by a sharp ridge adjacent the caudal peduncle of the tail. This is formed by a series of bony plates, sometimes called scutes.

Another interesting carangid is the Atlantic pompano (*Trachinotus carolinus*), a valuable food fish. Possessed of spectacular blue coloration on the back, the dirigible-shaped *Elagatis bipinnulatus* (Indo-Pacific rainbow runner) attains a length of about 4 feet (1.2 meters). The yellow-tail (*Seriola dorsalis*) is a highly regarded sporting fish in the waters of Mexico and southern California and attains a length in excess of 3 feet (0.9 meter). The *Naucrates ductor* is the legendary pilot fish, reputed to lead ships and swimmers to safety. The legend has no foundation. The species of jack fishes frequenting the waters of the Palmyra Islands are reputed to be poisonous. However, a related species (*Caranx melampygus*), known as the black ulua, is widely sold in the Hawaiian Islands. The jacks and cavallas found in the Philippines are considered of premium commercial value, particularly when taken from the freshwater lakes on their return to the sea. Jacks are also found in New Guinea.

CARAPACE. A shield-like covering of the upper part of the body. In the crustaceans it is the body wall of the thorax and in the turtles and tortoises it is a complex structure made up of bony plates, including flattened ribs and vertebrae, covered with thin horny plates. The armor of the armadillo, composed of many bony plates developed from the skin and covered with horny plates, is also called a carapace.

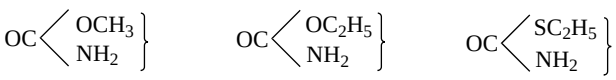
CARAPATO *(Arachnida, Acarina).* Ticks of two species, found in tropical Africa and Central America, respectively. The African species is also called the tampan.

The wounds produced by these creatures are severe in themselves but their transmission of the germs of relapsing fever is a much greater danger.

CARAT. See **Diamond**.

CARAWAY SEED. See **Spices**.

CARBAMATES. Derivatives of the hypothetical carbamic acid, H_2NCOOH, which does not exist. The ethyl derivative urethane is prepared by heating urea in alcohol under pressure, by the reaction $H_2NC(=O)NH_2 + C_2H_5OH \rightarrow H_2NCOOC_2H_5 + NH_3$. The structures of representative carbamates are shown below:



Methyl carbamate Methyl carbamate (urethane) Thiourethane

CARBAMIC ACID. See **Herbicide**; and **Insecticide**.

CARBANION. An ion of the general formula where A, B and D are substituent groups. Their importance in elucidating the mechanism of organic reactions is because a considerable proportion of all organic reactions involve carbanions, as others do carbonium ions and carbon free radicals (including carbene radicals). Many carbanion reactions involve removal of a proton from a carboxylic acid to form a carbanion. Many electrophilic substitution reactions involve carbanions. Carbanions are strong bases or nucleophiles. Many electrophilic substitution reactions that have carbanion intermediates are base-catalyzed since the basic reagent produces the basic carbanion. Because of the negative charge on carbanions, their structures are affected by cations, by attached substituents and particularly by the solvent.

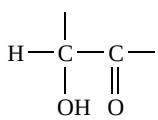
CARBENE. The name quite generally used for the methylene radical,: CH_2. It is formed during a number of reactions. Thus the flash photochemical decomposition of ketene ($CH_2{=}C{=}O$) has been shown to proceed in two stages. The first yields carbon monoxide and $:CH_2$, the latter then reacting with more ketene to form ethylene and carbon monoxide. Carbene reacts by insertion into a C−H bond to form a $C-CH_3$ bond. Thus carbene generated from ketene reacts with propane to form *n*-butane and isobutane. Carbene generated by pyrolysis of diazomethane reacts with diethyl ether to form ethylpropyl ether and ethylisopropyl ether.

Substituted carbenes are also known; chloroform reacts with potassium *t*-butoxide to form dichlorocarbene $:CCl_2$, which adds to double or triple carbon-carbon bonds to form cyclopropane derivatives.

CARBIDES. A binary solid compound of carbon and another element. The most familiar carbides are those of calcium, tungsten, silicon, boron, and iron (cementite). Two factors have an important bearing on the properties of carbides: (1) the difference in electronegativity between carbon and the second element, and (2) whether the second element is a transition metal. Saltlike carbides of alkali metals are obtained by reaction with acetylene. Those obtained from silver, copper, and mercury salts are exlposive. See also **Carbon**; and **Iron Metals, Alloys, and Steels**.

CARBOCYCLIC COMPOUNDS. See **Organic Chemistry**.

CARBOHYDRATES. These are compounds of carbon, hydrogen, and oxygen that contain the saccharose grouping (below), or its first reaction product, and in which the ratio of hydrogen to oxygen is the same as in water.



Carbohydrates are the most abundant class of organic compounds, representing about three-fourths of the dry weight of all vegetation. Carbohydrates are also widely distributed in animals and lower life forms. These compounds comprise one of the three major components (others are protein and fat) of the human diet, and indeed that of most other animals. In a nutrition-conscious era, advocates for both more and fewer carbohydrate calories in the human diet can be found.

Classification of Carbohydrates. Because carbohydrates as components of foods and feedstuffs are not limited to just a few specific classes or types, but essentially run the gamut of the carbohydrate spectrum, it is in order here to review briefly the organization of carbohydrate chemistry, with some examples from the various classes. See also entry on **Organic Chemistry**.

Elementary Terminology. A term synonymous with carbohydrate is *saccharide* (sometimes *saccharose*). When referring to saccharides, the basic molecular formula is considered to be $C_6H_{12}O_6$. Compounds with this general formula, such as glucose, mannose, and galactose, are known as *monosaccharides* because they contain one $C_6H_{12}O_6$. A *disaccharide*, as typified by sucrose, lactose, and maltose, has the general molecular formula, $C_{12}H_{22}O_{11}$ and may be considered as containing two $C_6H_{12}O_6$ groupings that have been joined by one atom of oxygen, with the elimination of one molecule of water. Similarly, the *trisaccharides*, such as raffinose, have the molecular formula, $C_{18}H_{32}O_{16}$. Any larger molecules of the $C_x(H_2O)_y$ configuration are termed *polysaccharides*, and include the starches, celluloses, dextrin, and glycogen. See also **Starch**. An *oligosachharide* is a carbohydrate containing from two up to ten simple sugars linked together (e.g., sucrose, composed of dextrose and fructose). Beyond ten, the term *polysaccharide* is used. Gums and mucilages are complex carbohydrates. See also **Gums and Mucilages**.

Both the terms carbohydrate and saccharide are significant only by way of classifying these compounds, because neither term appears in whole or

TABLE 1. CLASSES OF CARBOHYDRATES (with examples)

Monosaccharides (sugars):
crystalline solids, soluble in water, sweet taste; those that occur in nature are hydrolyzed by certain enzymes.
Tetrose, $C_4H_8O_4$
1. Erythrose
Pentoses, $C_5H_{10}O_5$
2. Arabinose
By boiling gum arabic, cherry gum, corn pith, elder pith with dilute sulfuric acid.
3. Xylose
By boiling substances mentioned under arabinose above.
4. Ribose
5. Lyxose

Hexoses, $C_6H_{12}O_6$
Aldohexoses
6. Glucose, dextrose ("grape sugar"), melting point 146 °C (anhyjeniferdrous).
With the enzyme zymase (of yeast) yields ethyl alcohol plus carbon dioxide. Specific rotatory power — see glucose below.
7. Galactose
Specific rotatory power +83.9°.
8. Mannose
Specific rotatory power +14.1°.
9. Glucose
10. Idose
11. Talose
12. Altrose
13. Allose

Ketohexoses
14. Fructose, levulose ("fruit sugar"), melting point 95 °C. Specific rotatory power −88.5°.
15. Sorbose
16. Tagatose

Disaccharides (sugars), $C_{12}H_{22}O_{11}$: crystalline solids, soluble in water, sweet taste.
17. Sucrose ("cane sugar," "beet sugar"), melting point 170–186 °C (decomposes). With the enzyme invertase, yields glucose plus fructose. Specific rotatory power +66.4°.
18. Lactose ("milk sugar"), melting point 202 °C (anhydrous). With the enzyme lactase yields glucose plus galactose. Specific rotatory power +52.4°.
19. Maltose ("malt sugar"), melting point of $C_{12}H_{22}O_{11} \cdot H_2O$: 100 °C. With the enzyme maltase yields glucose plus glucose. Specific rotatory power +138.5°.
20. Melibiose
With enzymes or dilute acid yields glucose plus galactose.
21. Cellobiose
With the enzymes maltase, or cellase, yields glucose plus glucose.
22. Trehalose

Trisaccharide, $C_{18}H_{32}O_{16}$: crystalline solid, soluble in water, tasteless.
23. Raffinose, melitose, melting point 118 °C (anhydrous). With the enzyme invertase, yields fructose plus melibiose. With the enzyme emulsin, yields sucrose plus galactose.

Polysaccharides (non-sugars), $(C_6H_{10}O_5)_n$: noncrystalline solids, insoluble in water, tasteless.
24. Starches
With the enzyme diastase yield maltose.
25. Celluloses
With hydrochloric acid, heated, yield glucose.
With acetic anhydride plus concentrated sulfuric acid, yield cellobiose.
26. Dextrin
With the enzyme diastase yields maltose.
With the enzyme maltase or with acids yields glucose.
27. Inulin, melting point 178 °C (decom.) $(C_6H_{10}O_5)_n$.
With the enzyme inulase (but not with diastase) yields fructose.
28. Glycogen, melting point 240 °C.
With the enzyme diastase (or ptyalin), yields glucose plus maltose.
29. Pentosans

in part in any of the widely used names of these compounds. About the only point of nomenclature enjoyed in common by several of the saccharides is the termination *-ose*, as found, for example, in cellulose, dextrose, sucrose, and glucose. Any saccharides having the structure of an aldehyde is termed as *aldose*; any saccharide with the structure of a ketone is termed a *ketose*. For those saccharides that contain 4–6 carbons, the number of carbons forms a nomenclature base, as a *tetrose*, $C_4H_8O_4$, a *pentose*, $C_5H_{10}O_5$, and a *hexose*, $C_6H_{12}O_6$.

To be consistent with the relationship between a mono- and a disaccharide, some authorities do not term a tetrose or a pentose a monosaccharide. By combining the *ald-* and *ket-* prefixes, certain compounds then may be called aldohexoses, such as glucose and galactose, or ketohexoses, such as fructose and sorbose.

The mono-, di-, and trisaccharides are also commonly termed *sugars*. A sugar generally is considered to possess the properties of a crystalline solid with a relatively low melting point (below 150 °C), of being soluble in water, and of possessing a sweet taste. Thus, the common names of several saccharides incorporate the term sugar, preceded by the common raw source of the substance, as glucose (grape sugar), sucrose (cane or beet sugar), maltose (malt sugar), and lactose (milk sugar). The crosscurrents of the nomenclature employed for the carbohydrates will be evident from Table 1.

Important Carbohydrates in Foods and Biological Systems

The properties of several carbohydrates that are of particular importance in foods and biological systems are described in the following paragraphs.

Glucose. This may be considered the key carbohydrate. It is the leading member of the aldohexose group, and is formed as one of the products or the only product when the following carbohydrates are hydrolyzed, sucrose, lactose, maltose, cellulose, glycogen. In many of its properties and its structural forms, it is representative of the sugars, and it is therefore discussed in detail here. Glucose is a colorless solid ($C_6H_{12}O_6$), less sweet than sucrose, soluble in water from which it may be crystallized $C_6H_{12}O_6 \cdot H_2O$. Glucose reacts (1) with alkaline cupric salt solution (Fehling's solution or Benedict's solution) to form cuprous

oxide, (2) with ammonio-silver salt solution (Tollens' solution) to form finely divided or mirror film of silver, (3) with phenylhydrazine in acetic acid, to form glucose phenylhydrazone $CH_2OH(CHOH)_4CH{:}NNHC_6H_5$, white solid, melting point alpha 159–160 °C, beta 140–141 °C, with excess phenylhydrazine to form glucosazone

$$CH_2OH(CHOH)_3C : (NNHC_6H_5) \cdot CH : NNHC_6H_5$$

yellow solid, melting point 205 °C decom., (4) with acetic anhydride, to form glucose pentacetate $C_5H_6(OOCCH_3)_5CHO$, melting point alpha 112 to 113 °C, beta 131 to 134 °C, (5) with sodium amalgam, to form sorbitol $CH_2OH(CHOH)_4CH_2OH$, (6) with hydriodic acid, to form 2-iodo-normal-hexane $CH_3(CH_2)_3CHICH_3$, (7) with sodium hydroxide solution, to form yellowish-brown solutions upon warming, (8) with calcium hydroxide solution, to form calcium glucosate $CH_2OH\ (CHOH)_4COCa(OH)$, slightly soluble solid from which glucose is recoverable by action of carbon dioxide (calcium carbonate formed simultaneously). Strontium hydroxide and barium hydroxide react similarly. Any of these three reactions may be utilized to recover glucose, with the limitation that barium soluble compounds are poisonous, (9) with hydroxylamine hydrochloride, to form glucoseoxime $CH_2OH(CHOH)_4CH{:}NOH$, melting point 138 °C, (10) with hydrocyanic acid, to form glucosecyanhydrin

$$CH_2OH(CHOH)_4CHOHCN,$$

(11) by oxidation, to yield with bromine gluconic acid $CH_2OH(CHOH)_4COOH$, and with nitric acid saccharic acid $COOH(CHOH)_4COOH$, (12) with alpha-naphthol dissolved in chloroform and then forming a layer of concentrated sulfuric acid beneath the mixture, to form a red coloration at the junction of the two liquid layers (Molisch's test for carbohydrates). Upon standing, the color changes to purple. (13) With methyl alcohol in the presence of hydrogen chloride, to form methyl glucoside (methyl ether of glucose). See also **Glycosides**.

If a sample of glucose is recrystallized from water, it is found that a freshly prepared aqueous solution of this sample has a specific rotation of +113°, and upon standing, the value steadily changes to +52° and remains there. On the other hand, if a sample of the same glucose is recrystallized from pyridine, a freshly prepared aqueous solution has a specific rotation of +19°, which steadily increases upon standing and levels off at a constant value of +52°. This changing of optical rotation with time is referred to as mutarotation. The fact that the two portions of glucose when recrystallized from different solvents mutarotate and stop at the same position suggests the formation of some equilibrium mixture.

To explain this situation, it must be recognized that glucose contains an aldehyde (−CHO) group and four alcohol groups (−OH). These two kinds of groups can react to form a hemiacetal just as if they were present in different molecules. See Fig. 1.

Glucose and fructose are present in sweet fruits, such as grapes and figs, and in honey. These two are the only hexoses found in nature in the free state. Glucose is normally present in human urine to the extent of about 0.1%, but in the case of those suffering from diabetes glucose is excreted in large amounts. Glucose is formed, as previously mentioned, by the reaction of polysaccharides and water, the reaction with starch in the presence of very dilute hydrochloric acid serving as the industrial source (the hydrochloric acid acts as a catalyzer, and the small percentage present is later neutralized to form sodium chloride). The solution is evaporated to

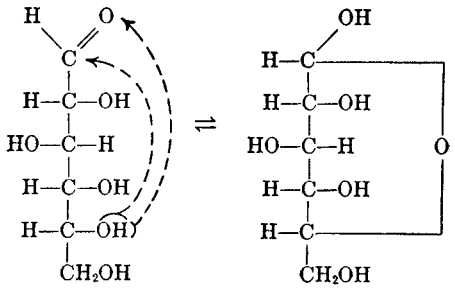


Fig. 1. Mutarotational aspects of glucose.

a syrup or to crystallization, and is used in the manufacture of sweets, and (usually) alcohol, and in foods. The reaction of glucosides with water, by enzymes or acids, produces glucose as one of the products. With sodium hydroxide, under carefully defined conditions, glucose forms lactic acid. Glucose is used as food and for the production of alcohol (wines) from fruit juices. Glucose may be detected by formation of glucosazone, and determination of its melting point.

Industrial process for converting starch into dextrose (glucose) are described under **Starch**.

Fructose. This sugar is present with glucose in sweet fruits and honey, and may be obtained free by reaction of insulin of dahlia tubers or artichokes with water, and with glucose by reaction of sucrose with water, the product being known as invert sugar. Fructose differs from glucose in structure in being a pentahydroxy-2-ketone,

$$CH_2OH(CHOH)_3COCH_2OH$$

instead of aldehyde. The specific rotary power of fructose is −88.5°. Fructose forms the same identical osazone as glucose, and sorbitol plus mannitol by reduction. Fructose may be used as sugar by diabetic patients to advantage instead of glucose or sucrose. Fructose is detected by the violet color its alkaline solution gives with meta-dinitrobenzene.

Sucrose. This is a colorless solid which when heated melts at 170–186 °C, and upon cooling forms barley sugar, which gradually crystallizes. Upon heating above the melting point, it forms caramel, a brown liquid, with decomposition. Caramel is used in confectionery, and in coloring beverages and foods. At higher temperatures decomposition into gaseous and tarry substances occurs, finally leaving a residue of carbon ("sugar charcoal"). Other sugars behave similarly. Sugars are also carbonized by concentration sulfuric acid. Sucrose is very soluble in water, and is obtained from solution by crystallization, usually by vacuum evaporation. The solution has a specific rotatory power of +66.4°, does not exhibit mutarotation, but is converted by acids or invertase into invert sugar (glucose plus fructose), specific rotatory power −19.7°. Sucrose forms with calcium hydroxide calcium sucrosate, a 1% solution of sugar dissolves about 18 times as much calcium hydroxide as does pure water. This behavior is utilized to recover sugar from solutions, as in the case of glucose, and also to determine free calcium oxide in burnt lime, due to the reactivity of calcium hydroxide and non-reactivity of calcium carbonate. Sucrose is nonreactive with dilute sodium hydroxide, with phenylhydrazine, with ammonio-silver salt solution, but, when inverted to glucose plus fructose,

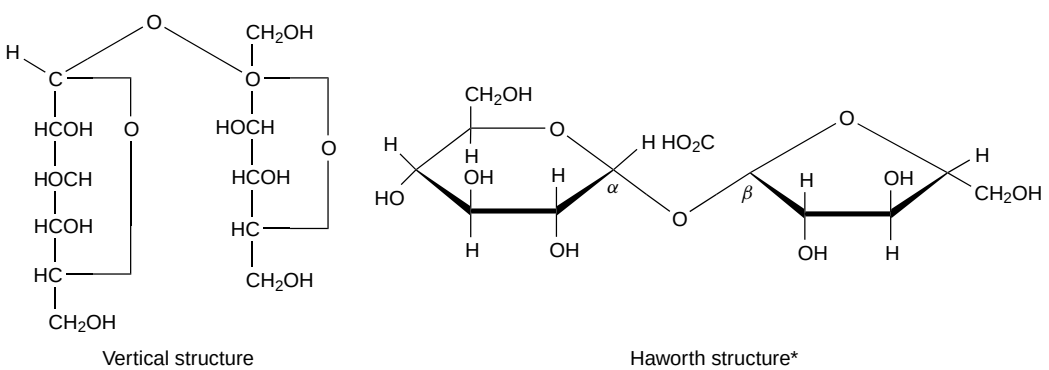

Fig. 2. Sucrose. *Indicates that when the oxygen atom is drawn at the top of the furanose ring, OH groups drawn downward correspond to those on the left side of the vertical structure.

these reactions may be obtained. Sucrose forms with acetic anhydride sucrose octaacetate. The suggested structural formula is as shown in Fig. 2. Sucrose is an important food preservative, food flavor, and a raw material for confectionery and for industrial alcohol.

Sucrose is extensively distributed in the seeds and leaves of plants, and is the most abundant of the sugars. The commercial sources of sucrose are the stems of sugar-cane (11 to 16% sucrose, average 13%), the root of the sugar-beet (average 16% sucrose, selection having raised the sucrose content from 5% to a maximum of 20%), the sap of the sugar maple, and the stems of sorghum-cane. Sucrose is pressed from the stems of sugar cane or sorghum cane, and extracted with the water from the sliced roots of sugar beets. The solutions are purified, evaporated and crystallized to such a degree that commercial sucrose is practically chemically pure (about 99.8% sucrose). The purity of sugar and the concentration or strength of sugar solutions is determined by the rotatory power of the solution, and the special polariscope usually used is called a saccharimeter. Sucrose is reduced with Fehling's solution only after inversion.

The sugar content of some common fruits have been reported by Kulisch:

	SUCROSE	HEXOSES
Apple	1.0–5.4	7.0–13.0
Apricot	6.0	2.7
Banana, ripe	5.0	10.0
Pineapple	11.3	2.0
Strawberry	6.3	5.0

Lactose. This sugar is obtained from the residual water solution (whey) of milk after removal of fat and casein for making butter and cheese. Milk contains about 4.5% of lactose. Lactose forms hard gritty crystals ("sand sugar") $C_{12}H_{22}O_{11} \cdot H_2O$, loses water at 140 °C, melting point 202 °C (anhydrous) with decomposition; is less sweet than sucrose, reduces ammoniocupric salt solution, ammoniosilver salt solution, forms osazone, melting point 200 °C, turns yellow when warmed with sodium hydroxide solution. Lactose is the source of galactose, and undergoes, with the proper enzymes, fermentation into lactic acid and butyric acid.

Maltose. This sugar is found in soybean, and is produced by the action of the enzyme diastase of germinated barley (malt) on starch at 50 °C, and is thus an intermediate product in the transformation of starch into alcohol. Maltose $C_{12}H_{22}O_{11} \cdot H_2O$, melting point 100 °C, when rapidly heated, may be crystallized from the concentrated malt syrup after removal of proteins and insoluble material. Maltose reduces ammonio-cupric salt solution, and forms osazone.

Starch. This is a white powder, odorless and tasteless, insoluble in cold water, forming an emulsion ("starch paste") or gel with hot water, the consistency of which depends upon the ratio of starch to water used. When boiled starch emulsion is cooled and treated with a solution of iodine in alcohol or potassium iodide, a blue coloration is produced, which is a sensitive and characteristic test. The blue color is associated with the adsorption of iodine on the surface of the starch, and disappears in the presence of alkalis. When boiled with dilute acid, starch is first changed into a soluble gummy mixture known as dextrin, and finally into glucose. When starch, either alone or in the presence of a slight amount of nitric acid, is heated to 120° to 200 °C, dextrin is formed; at higher temperatures starch behaves similarly to sucrose. With concentrated nitric acid, starch forms esters, similar to cellulose nitrates. By the action of the enzyme diastase, starch is converted into maltose, which, with the enzyme maltase, yields glucose. Starch is nonreactive with ammonio-cupric salt solution, and with phenylhydrazine. See also **Starch**.

Dextrin. This is a white-to-yellow solid, forming an adhesive with water, nonreactive with ammonio-cupric salt solution, reactive with iodine in alcohol or potassium iodide, usually forming red, brown, or blue color. Formed when starch is (1) heated to 120° to 200 °C either alone or in the presence of a slight amount of nitric acid. Dextrin is formed when bread is toasted and is present in well-baked bread crust, and on the surface of starched goods that have been ironed hot. Dextrin is used in adhesives.

Inulin. This is a white solid, soluble in warm water, specific rotatory power −40°, with iodine in alcohol or potassium iodide gives yellow color. Inulin is present in tubers of dahlia to the extent of about 10%. Inulin reacts with water in the presence of the enzyme inulase or of acids to form fructose. The enzyme diastase does not produce this change.

Glycogen. Also known as *animal starch*, this is a white solid, soluble in water, specific rotatory power +197°, with iodine in alcohol or potassium iodide solution, forming brown color. Glycogen is found as reserve carbohydrates in the animal body, more particularly in the liver. Horse flesh, oysters and beef are sources of glycogen.

Pentosans. These compounds are polysaccharides which may be considered as anhydrides of pentose sugars, after the manner of the hexosans, sucrose, starch, from glucose, fructose. When pentosans or pentoses are heated with hydrochloric or sulfuric acid, furfural $C_4H_3O \cdot CHO$ is formed, and addition of aniline produces a red color. Pentosans are present in gummy carbohydrates, in bran of wheat seed, and in woods.

By means of the cyanhydrin reaction, higher sugars of the heptose, octose, and nonose types have been prepared. A monosaccharide such as an aldohexose may be converted into the next lower monosaccharide, such as an aldopentose, by oxidation to the acid, which corresponds to the aldohexose, then treating the calcium salt solution of this acid with a solution of ferrous acetate plus hydrogen peroxide. Carbon dioxide is evolved and aldopentose formed.

For a description of cellulose, see **Cellulose**.

Carbohydrate Metabolism

Carbohydrates are utilized by the cells as a source of energy and as precursors for the manufacture of many of their structural and metabolic components. In the mammal, for example, D-glucose is the carbohydrate primarily used for this purpose. certain microorganisms, in contrast, can grow on a medium containing some other hexose or a pentose as the principal source of carbon. Green plants obtain their carbohydrates by photosynthesis, while animals receive most of their carbohydrates by ingestion and digestion. See also **Photosynthesis**.

The complete oxidation of glucose to carbon dioxide and water yields 689 kcal of heat per mole of glucose. When this oxidation occurs in a cell, the energy is not all dissipated as heat. Some of the evolved energy is conserved in biochemically utilizable form of "high-energy" phosphates, such as adenosine triphosphate (ATP) and guanosine triphosphate (GTP). In addition to enzymes concerned with energy metabolism, there are enzymes in biological systems which catalyze the transformation of glucose into various carbohydrates, fatty acids, steroids, amino acids, nucleic acid components, and other necessary biochemical substances. The entire network of reactions involving compounds that interconvert carbohydrates constitutes *carbohydrate metabolism*. By convention, some reactions involving compounds which are not carbohydrates, but which are derived from them, may also be included in this area of metabolism.

Anaerobic Oxidation of Glucose. Historically, the first system of carbohydrate metabolism to be studied was the conversion by yeast of glucose to alcohol (fermentation) according to the equation: $C_6H_{12}O_6 \rightarrow 2CH_3CH_2OH + 2CO_2$. The biochemical process is complex, involving the successive catalytic actions of 12 enzymes and known as the *Embden-Meyerhof pathway*. This series of reactions is summarized in the entry on **Glycolysis**.

In order for the cell to carry out a "controlled" oxidation of D-glucose and conserve some of the energy derived from the process, it is first necessary to add phosphate to the hexose with the expenditure of energy. The necessary energy and the phosphate per se is supplied by ATP in two separate reactions of the system. Since each molecule of glucose can yield two molecules of triose phosphate for oxidation, the conversion of glucose to pyruvic acid nets two molecules of ATP per molecule of hexose utilized.

Approximately 30% of the evolved energy is conserved as ATP, but only about 8% of the total energy in glucose is made available in this anaerobic oxidation of glucose to pyruvic acid. Since nicotinamide adenine dinucleotide (NAD^+), also called diphosphoryidine nucleotide (DPN^+), which is involved in the oxidation of glyceraldehyde-3-phosphate, is present in the cell in small quantities only, this coenzyme must constantly be regenerated for the oxidative process to continue. This regeneration is accomplished by the reduction of *acetaldehyde* to *ethanol*. Since oxygen plays no role in this process, the system can obviously proceed anaerobically. In fact, the presence of oxygen decreases the net disappearance of glucose (*Pasteur effect*).

Fermentation occurs in many microorganisms, but not all organisms reoxidize the reduced nicotinamide adenine dinucleotide (NADH) through the formation of ethanol. In certain organisms, for example, *pyruvic acid* is converted to *acetoin*, which is then reduced with NADH to 2,3-butylene glycol. In other organisms and in animal tissues, NADH is oxidized in the reduction of *pyruvic acid* to *lactic acid*. In insects, and possibly in

some animal tissues, the reduction of *dihydroxyacetone phosphate* to *alpha-glycerol phosphate* may serve to regenerate NAD^+. The conversion of glucose to lactic acid in animal tissues is termed *glycolysis*. This term arose from the initial understanding that this process was markedly different from the microbial fermentation process. Fermentation and glycolysis are now known to differ primarily in the further anaerobic utilization of pyruvic acid.

Aerobic Oxidation of Pyruvic Acid. Pyruvic acid can be oxidized completely to carbon dioxide and water in a cyclic enzymatic system known as the *Krebs citric acid cycle*, or the *tricarboxylic acid cycle (TCA cycle)*. In this system, a two-carbon unit in the form of acetyl coenzyme A (acetyl = CoA), derived from the NAD^+ mediated oxidative decarboxylation of pyruvic acid in the presence of coenzyme A, is condensed with oxalacetic acid to form citric acid. This tricarboxylic acid is then converted back to oxalacetic acid in a stepwise manner with the formation of $2CO_2$ and $2H_2O$. In addition to this formation of CO_2, one reduced nicotinamide adenine dinucleotide phosphate (NADPH), two NADH, one reduced flavin, and one GTP arise per two-carbon unit oxidized in the cycle. Since in the aerobic oxidation of the reduced flavin and the reduced nicotinamide adenine nucleotides, ATP is formed, the oxidation of a molecule of "acetate" results in the conservation of energy in the form of 12 molecules of triphosphate. In the complete oxidation of glucose through glycolysis and the citric acid cycle, about 40% of the energy originally present in the glucose can be retained as triphosphate. The ubiquitous distribution of this cycle in nature suggests that the citric acid cycle is a major energy-yielding pathway in biological systems.

Certain microorganisms have a modification of this cycle in which isocitric acid is cleaved to succinic acid and glyoxylic acid. The latter acid is condensed with acetyl-CoA to form malic acid. In this modification (the *glyoxylic acid cycle*), oxalsuccinic acid and alpha-ketoglutaric acid are not involved. This is sometimes referred to as the "glyoxylate shunt" pathway.

Since in the citric acid cycle there is no net production of its intermediates, mechanisms must be available for their continual production. In the absence of a supply of oxalacetic acid, "acetate" cannot enter the cycle. Intermediates for the cycle can arise from the carboxylation of pyruvic acid with CO_2 (e.g., to form malic acid), the addition of CO_2 to phosphenolpyruvic acid to yield oxalacetic acid, the formation of succinic acid from propionic acid plus CO_2, and the conversion of glutamic acid and aspartic acid to alpha-ketoglutaric acid and oxalacetic acid, respectively. See Fig. 3.

The utilization of carbohydrate intermediates for the biosynthesis of amino acids, fatty acids, steroids, etc. occurs at various stages of the cycle and its related reactions. See Fig. 4. See also **Coenzymes**.

Other Carbohydrate Interconversions. Two systems, as shown in Fig. 5, are available for the synthesis of ribose-5-phosphate, a precursor of the pentose moiety of ribonucleic acid, ATP, and other substances. The formation of ribose-5-phosphate from glucose-6-phosphate by formation and decarboxylation of 6-phosphogluconic acid and isomerization of the resulting ribulose-5-phosphate is termed the *hexose monophosphate oxidative pathway*. The scheme, together with the system involving the

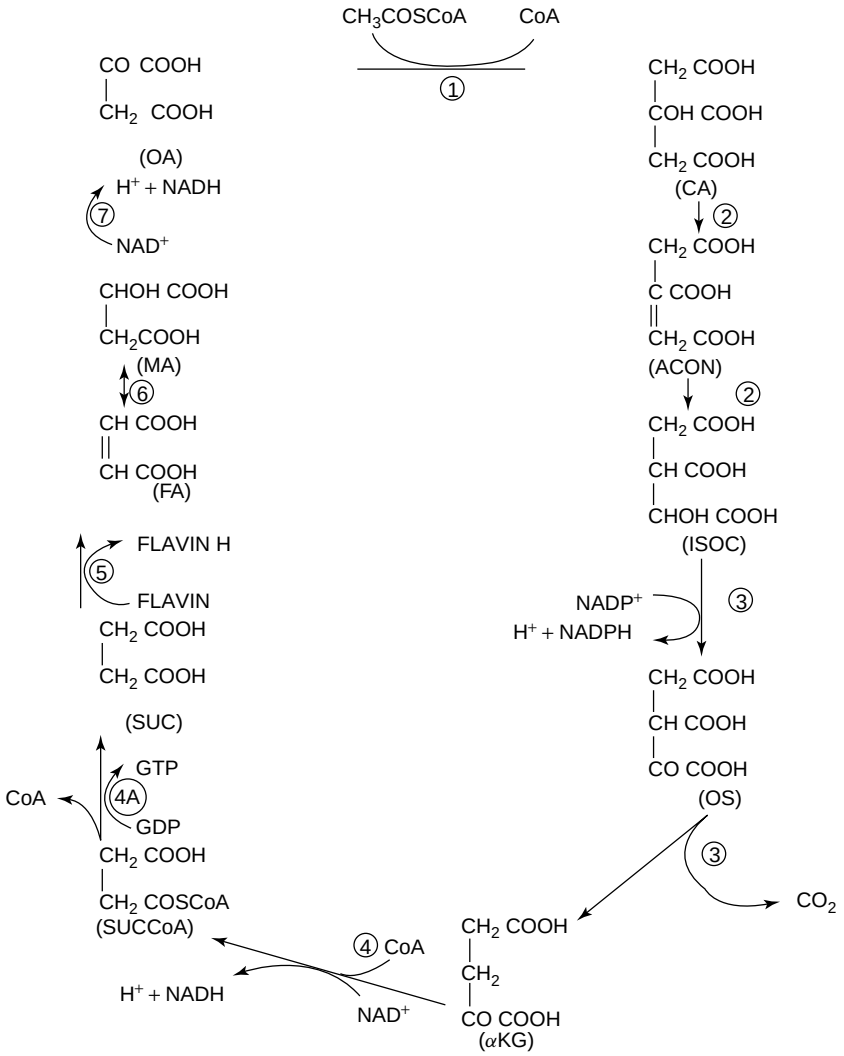

Fig. 3. Krebs citric acid cycle. *Enzymes involved*: (1) Condensing enzyme; (2) aconitase; (3) isocitric acid; (4) α-ketoglutaric acid dehydrogenase; (4) α-succinic acid thiokinase; (5) succinic acid dehydrogenase; (6) fumarase; (7) malaic acid dehydrogenase. *Abbreviations*: CA = citric acid; ACOM = *cis*-aconitic acid; KG = α-ketoglutaric acid; SIC = succinic acid; FA = fumaric acid; MA = malic acid; OA = oxalacetic acid.

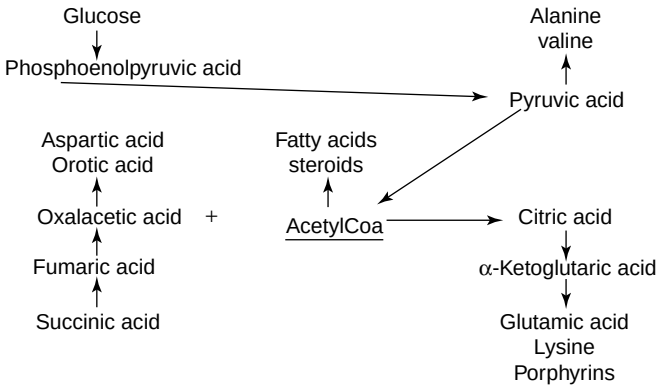

Fig. 4. Representative conversions of carbohydrates to other substances.

enzymes *transketolase* and *transaldolase* (which also can synthesize pentose) that act to form hexose phosphate from pentose phosphate, is called the *pentose phosphate cycle*. This cycle represents an alternative pathway to glycolysis for the formation of triose phosphate from glucose-6-phosphate. The relative importance of the two pathways seems to be different among the various organisms and tissues.

In a certain group of bacteria, still another pathway (*Entner-Doudoroff pathway*) for the utilization of glucose has been studied. Here glucose-6-phosphate is oxidized to 6-phosphogluconic acid which is dehydrated to 2-keto-3-deoxy-6-phosphogluconic acid. This substance is then split to pyruvic acid and glyceraldehyde-3-phosphate (which also can be converted to pyruvic acid).

The formation of deoxyribose, the pentose moiety of deoxyribonucleic acid, can occur directly from ribose while the latter is in the form of a nucleotide diphosphate. Deoxyribose-5-phosphate can also be formed by condensation of acetaldehyde and glyceraldehyde-3-phosphate.

Transglycosylation. An enzymatic process, transglycosylation, plays an important role in carbohydrate metabolism. Figure 6 represents the formation of the disaccharide, sucrose, as an example of this mechanism. In the upper reaction of Fig. 6, glucose-1-phosphate is the glycosyl donor and fructose is the acceptor. In the lower reaction, the sugar nucleotide, uridine diphosphoglucose (UDP-glucose) is the glycosyl donor. With UDP-glucose as donor and glucose-6-phosphate as acceptor, trehalose-6-phosphate may be formed. Polysaccharides may also be formed by this process. The donor residues provided by sugar nucleotides are added to preexisting polysaccharide chains (known as "primers") acting as glycosyl acceptors. In the formation of glycogen, for example, UDP-glucose donates the glucose moiety which is added to the end of a previously synthesized chain by a 1,4-linkage, thereby lengthening the chain by one glucose unit.

Digestion, Absorption and Storage of Carbohydrates

In the mammal, complex polysaccharides which are susceptible to such treatment, are hydrolyzed by successive exposure to the amylase of the saliva, the acid of the stomach, and the disaccharidases (e.g., maltase, invertase, amylase, etc.) by exposure to juices of the small intestine. The last mechanism is very important. Absorption of the resulting monosaccharides occurs primarily in the upper part of the small intestine, from which the sugars are carried to the liver by the portal system. The absorption across the intestinal mucosa occurs by a combination of active transport and diffusion. For glucose, the active transport mechanism appears to involve phosphorylation. The details are not yet fully understood. Agents which inhibit respiration (e.g., azide, fluoracetic acid, etc.) and phosphorylation (e.g., phlorizin), and those which uncouple oxidation from phosphorylation (e.g., dinitrophenol) interfere with the absorption of glucose. See also **Phosphorylation (Oxidative)**. Once the various monosaccharides pass through the mucosa, interconversion of the other sugars to glucose can begin, although the liver is probably the chief site for such conversions. Even though many organs and tissues store carbohydrates as glycogen for their own use, the liver provides the main source of glucose for all tissues, through conversion of its glycogen (and other substances) to glucose-6-phosphate, hydrolysis of this ester by the specific liver glucose-6-phosphatase, and transport of the free glucose in the bloodstream throughout the body.

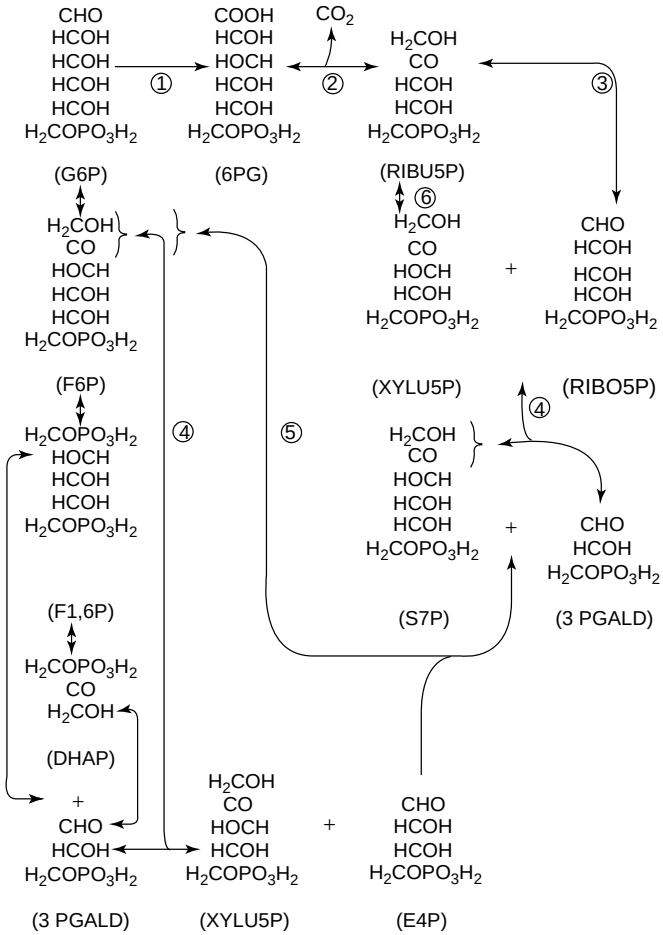

Fig. 5. Pentose phosphate cycle. *Enzymes involved*: (1) Glucose-6-phosphate dehydrogenase; (2) 6-phosphogluconic acid dehydrogenase; (3) pentose phosphate isomerase; (4) transketolase; (5) transaldolase; (6) pentose phosphate epimerase. *Abbreviations*: G6P = glucose-6-phosphate; 6PG = 6-phosphogluconic acid; RIBIUP = ribulose-5-phosphate; 3PGALD = glyceraldehyde-3-phosphate; E4P = erythrose-4-phosphate; F1,6P = fructose-1-6-diphosphate; DHAP = dihydroxyacetone phosphate; F6P = fructose-6-phosphate. Enzymes not named are those of glycolysis. $NADP^+$ is reduced in reactions (1) and (2).

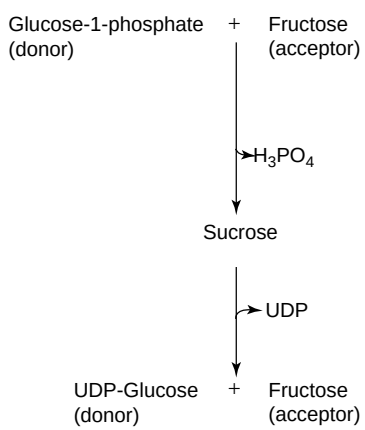

Fig. 6. Examples of transglycosylation.

A common cause of *osmotic diarrhea* is the ingestion of carbohydrates that a person cannot digest. Retention of a disaccharide, such as lactose or sucrose, within the intestinal lumen occurs because of the absence of the appropriate disaccharidase at the intestinal surface membrane. Unless they are converted to monosaccharides, these sugars cannot be transported. Their retention in the lumen can cause a significant diarrheal water loss per day. As an added complication, bacteria in the lower small intestine and

colon may catabolize the 12-carbon sugars to 3-carbon fragments, further aggravating the osmotic effect. Infants and very young children usually have sufficient lactase and sucrase, but there is a tendency among some people to become lactase deficient between the ages of 3 and 14 years. Once such a condition is fully recognized, the ingestion of milk and other dairy products should be eliminated. It should be pointed out, however, that the so-called *irritable bowel syndrome* is attributable to lactase deficiency in a relatively small percentage of cases. Carbohydrates that can cause diarrhea in some persons include: lactose and sucrose, already mentioned; stachyose and raffinose, contained in many legumes; mannitol and sorbitol, contained in artificial sweeteners (which contain sugar alcohols); glucose and galactose, present in all dietary sugars; and lactulose, contained in nondietary disaccharides as parts of certain medications. See also **Diarrhea**.

Endocrine Influences. A number of hormones are known to influence carbohydrate metabolism in the mammal. Insulin seems to increase oxidation of glucose, lipogenesis, and glycogenesis. Its primary mode of action may be to facilitate the entry of glucose into the cell. The extremely important role of carbohydrate metabolism in connection with diabetes is described in entry on **Diabetes Mellitus**.

Vitamin Influences. The involvement of NAD^+ and $NADP^+$ in many carbohydrate reactions explains the importance of nicotinamide in carbohydrate metabolism. Thiamine, in the form of thiamine pyrophosphate (cocarboxylase), is the cofactor necessary in the decarboxylation of pyruvic acid, in the *trans*-ketolase-catalyzed reactions of the pentose phosphate cycle, and in the decarboxylation of alpha-ketoglutaric acid in the citric acid cycle, among other reactions. Biotin is a bound cofactor in the fixation of carbon dioxide to form oxalacetic acid from pyruvic acid. Pantothenic acid is a part of the CoA molecule. There are separate alphabetical entries in this volume on the various specific vitamins as well as a review entry on **Vitamin**.

Photosynthesis. The formation of carbohydrates in green plants by the process of photosynthesis is described in the entry on **Photosynthesis**. The synthetic mechanism involves the addition of carbon dioxide to ribulose-1,5-diphosphate and the subsequent formation of two molecules of 3-phosphoglyceric acid which are reduced to glyceraldehyde-3-phosphate. The triose phosphates are utilized to again from ribulose-5-phosphates by enzymes of the pentose phosphate cycle. Phosphorylation of ribulose-5-phosphate with ATP regenerates ribulose-1,5-diphosphate to accept another molecule of carbon dioxide. See also **Phosphorylation (Photosynthetic)**.

Carbohydrates in Foods

Sugar is discussed in several entries in this volume, including **Beet; Fiber; Gums and Mucilages**; and **Sugarcane**.

Statistics on the carbohydrate content of diets of various peoples throughout the world have not been very reliable because of the scores of variables involved, the great difficulties in establishing reliable sampling procedures, lack of past records, among other factors. One summary, for example, that breaks down food energy from protein, fat, and carbohydrates shows a downward trend for carbohydrates in the American diet — from 56% in 1911 to 46% in the mid-1970s. These figures were based upon U.S. Department of Agriculture statistics of food disappearance at the retail level, but they do not take into consideration food spoilage, cooking waste, plate waste, and other factors that affect actual consumption. Since protein remained quite constant at 11–12% throughout this time span, the drop in carbohydrates was made up by an increase in fats — from 32% in 1911 to 42% in the mid-1970s. In another study, of the 46% carbohydrate energy intake as of 1977, 24% is attributed to sugar and 22% to complex carbohydrates. In a controversial U.S. government study that attempted to set new dietary goals for the nation, it was suggested that the traditional 12% protein be retained, but that fat be reduced from 42% and carbohydrates upped to 58%, but with a major difference, namely, cutting the sugar portion of carbohydrates from 24% to 15%. Thus, the dietary goal would require 40–45% complex carbohydrates in the diet. It has been suggested that to achieve the projected carbohydrate goals, there would have to be a 66% increase in the consumption of grain products; a 25% increase of vegetables and fruit; and a 50% reduction in sugar and sweets.

Even though much visibility had been given by the various news media to the dietary role of sugar, it was obvious that, as of the late 20th Century, a great deal of fundamental research remained to be done to prove or disprove many conclusions, often conflicting and confusing, in order to establish reliable dietary guidance in this area.

CARBON. [CAS: 7440-44-0] Chemical element symbol C, at. no. 6, at. wt. 12.011, periodic table group 14, mp 3,550 °C (approximate), bp 4,289 °C (approximate), density 3.52 g/cm^3 (diamond at 20 °C), 2.25 g/cm^3 (graphite at 20 °C). The specific gravity of amorphous carbon at 20 °C ranges from 1.8 to 2.1. There are two stable isotopes of the element, ^{12}C and ^{13}C, and four known radioactive isotopes, ^{10}C, ^{11}C, ^{14}C, and ^{15}C. Because the half-life (about 5,760 years) of ^{14}C has been established, this isotope is useful for dating ancient documents and materials.

The first ionization potential of carbon is 11.264 eV; Second, 24.28 eV; third, 47.7 eV. Other important physical characters of carbon are given in article on **Chemical Elements**.

Traditionally, the principal forms of carbon have (1) *diamond*, with its tetrahedral arrangement of atoms; (2) *graphite*, whose structure resembles layers of chicken wire; and sometimes (3) *amorphous*, a poorly defined grouping of carbons. This latter classification was chosen more out of convenience than grounded scientifically. However, by recent consensus, a third form of carbon is now officially recognized: *fullerene*, of which the C_{60} so-called *buckminsterfullerene* or "buckyball" is the most thoroughly investigated example of its class.

Diamond, the hardest of natural materials, consists of a lattice of carbon atoms arranged in a tetrahedral structure at equal distances apart (1.544 Å) and bonded by electron pairs in localized molecular orbitals formed by overlapping of the sp^3 hybrids. See article on **Diamond**.

Graphite, a very soft material, consists of carbon atoms arranged in laminar sheets, 3.40 Å apart and composed of carbon atoms in hexagonal arrangement 1.42 Å apart. Each atom is bonded to three others in its sheet

by electron pairs in localized molecular orbitals formed by overlapping of the sp^2 hybrids. The remaining p-electrons form a mobile system of nonlocalized pi bonds that permit electrical conductivity between the lamina. See also **Graphite**.

The familiar carbon blacks are formed by such methods as combustion of carbon-containing materials with sufficient oxygen. These carbons are found to have x-ray diffraction patterns that are suggestive of graphite, but with more diffuse rings, thus indicating a much lower degree of crystallinity. When carbon black is heated, its diffraction pattern develops new rings indicative of a structure more like that of graphite. When so heated, the properties of the carbons as absorbent materials deteriorate. See also **Carbon Black and Coal**.

Because of the comparatively recent demonstration of the geometry of C_{60} and cousins of both lower and higher carbon atom content, this giant molecule is ushering in a new concept to the chemistry of carbon and organic chemistry. This discovery, which later may have profound implications for practical industrial and scientific usage, provides insights into other scientific fields, such as astrochemistry, and serves as a source of yet unknown chemical derivatives; it has been likened by some scientists to the first practical suggestion by Kekulé (1825) on the structure of the benzene ring. The carbon atoms in Kekulé's design have dangling bonds which usually are accommodated by hydrogen. In contrast the three-dimensional configuration of C_{60} has exactly 60 carbon atoms in a single molecule that is inert, in the absence of dangling bonds. The molecule, however, appears to tolerate the insertion of certain ions and thus may make possible large numbers of derivatives.

Traditional Carbon Chemistry

The probable importance to high-temperature behavior of the $-C\equiv C-$ triple bond, most familiarly encountered in acetylene, was proposed in the late 1960s. The essence of the proposal is that high-temperature carbon forms are made up of chains of triple-bonded carbon atoms, termed *carbynes*. See Fig. 1. It will be noted that at high temperatures, a single bond in the structure may break. This shifts an electron into each of the adjacent double bonds, forming a triple bond. Completion of the process transforms the sheet of atoms into a chain of carbynes. The chains can be variously stacked. In 1973, at least five such forms had been reported. Researchers in 1977 reported that the transformation from the carbyne form to graphite involves a reaction between acetylene-like molecules (acting rapidly and exothermically), whereas the reverse reaction (breaking of single bonds) can be expected to be a much slower process. Thus, the conventional carbon phase diagram may be deficient because it does not consider the carbyne forms. One scientist pointed this out because it had been difficult to reconcile high-pressure results with the low-pressure data available on the vapor pressure of carbon. See Fig. 2.

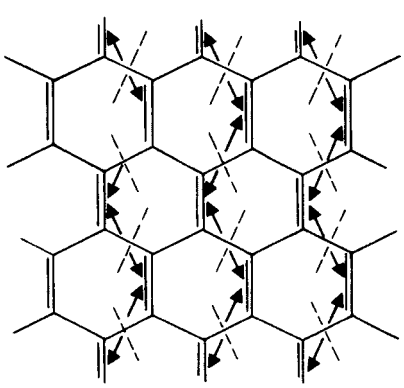

Fig. 1. Mechanisms suggested for transformation of a graphite basal plane sheet of atoms into carbyne chains.

Research pertaining to carbynes, in way, was a prelude to further molecular carbon research and the now well-known buckyball.

Carbon Compounds

With the exception of hydrogen, carbon forms more compounds than any of the other chemical elements. Traditionally, carbon compounds fall into two fundamental classes: (1) *inorganic* compounds and (2) *organic* compounds.

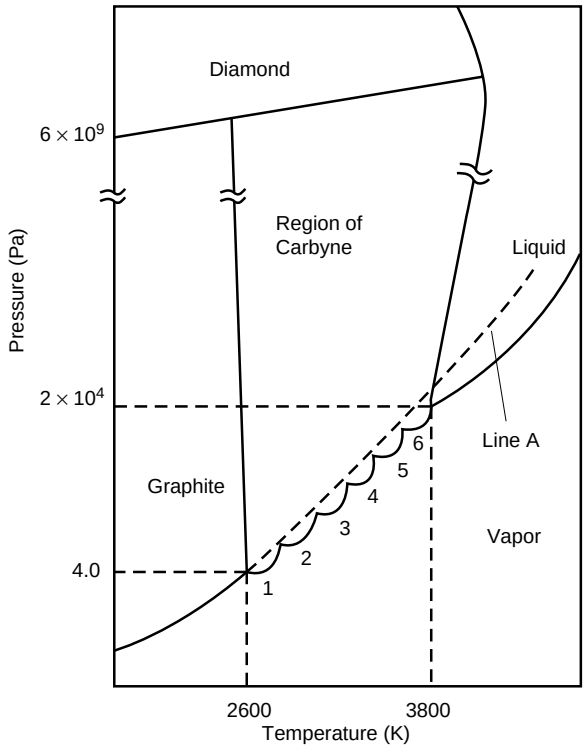

Fig. 2. Carbon phase diagram (suggested by Whittaker) to accommodate region of carbyne. Dashed line A is vapor pressure graphite would have if it were the stable form above 2600 K. Whittaker notes: (1) graphite is not stable above 2600 K at any pressure; (2) the solid-liquid-vapor triple point occurs at 3800 K and 2×.

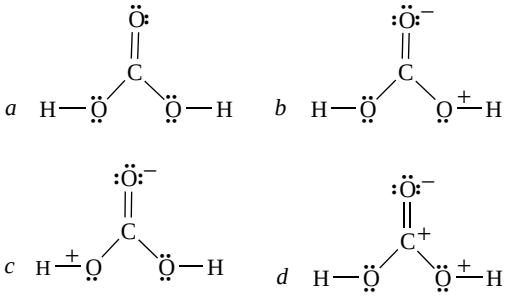
The main subclasses of inorganic carbon compounds include:

1. The *carbon oxides*, notably CO (carbon monoxide) and CO_2 (carbon dioxide).
2. The *carbonates*—CO_3, which occur widely in nature—minerals, rocks, ores, and mineral waters—and include such compounds as Na_2CO_3, $CaCO_3$ (limestone), $MgCO_3$ (magnesite), $MgCa(CO_3)_2$ (dolomite), etc.
3. Some carbon-sulfur compounds, such as CS_2 (carbon disulfide), the thiocyanides, and thiocyanates —CNS, such as HCNS (thiocyanic acid), $Pb(CNS)_2$ (lead thiocyanate), etc.
4. The *carbides*, such as Na_2C_2, Cu_2C_2, WC, ZrC, etc.
5. The *carbonyls*—CO, such as $Cr(CO)_6$, $Fe(CO)_5$, $Ni(CO)_4$, etc.
6. The *halides*, such as CCl_4 (carbon tetrachloride), CBr_4, etc.

The subclasses of organic compounds comprise the realm of organic chemistry and are described under **Organic Chemistry**. There are several subclasses of organic compounds that include oxygen along with hydrogen and carbon in their structure—e.g., acid anhydrides, alcohols, aldehydes, carbohydrates, carboxylic acids, esters, ethers, fatty acids, furans, ketones, lactides, lactones, phenols, quinones, and terpenes. Some of the main subclasses of nitrogen-bearing organic compounds include the amides, amines, amino acids, anilides, azo and diazo compounds, carbamates, cyanamides, hydrazines, polypeptides, proteins, purines, pyridines, pyrroles, quaternary ammonium compounds, semicarbazones, ureas, and ureides. The addition of the halogens to the structure yields chlorine organics, brominated compounds, fluorocarbons, etc. Most of the metals combine with carbon compounds to form organometallics. Sulfur-bearing organics include the sulfonic acids, sulfonyls, sulfones, thioalcohols, thioaldehydes, sulfoxides, etc. Silicones are silicon-bearing carbon compounds. See also **Chlorinated Organics**.

Carbides: As might be expected from its position in the periodic table, carbon forms binary compounds with the metals in which it exhibits a negative valence, and binary compounds with the non-metals in which it exhibits a positive valence. A convenient classification of the binary compounds of carbon is into ionic or salt-like carbides, intermediate carbides, interstitial carbides, and covalent binary carbon compounds.



The ionic or salt-like carbides are formed directly from the elements, or from metallic oxides and carbon, carbon monoxide, or hydrocarbons. This last reaction is reversible, and this group of carbides may be further subdivided into acetylides, e.g., Li_2C_2, Na_2C_2, K_2C_2, Rb_2C_2, Cs_2C_2, Cu_2C_2, Ag_2C_2, Au_2C_2, BeC_2, Mg_2C_2, CaC_2, SrC_2, BaC_2, ZrC_2, CdC_2, Al_2C_6, Ce_2C_6, and ThC_4: methanides, e.g., Be_2C and Al_4C_3; and the allylides, primarily magnesium allylide, Mg_2C_3, according to the hydrocarbon or the principal hydrocarbon formed upon hydrolysis. By the term intermediate carbides is meant compounds intermediate in character between the ionic carbides and the interstitial carbides. The intermediate carbides, such as Cr_3C_2, Mn_3C, Fe_3C, Co_3C, and Ni_3C are similar to the ionic carbides in that they react with water or dilute acids to give hydrocarbons, and they resemble the interstitial carbides in their electrical conductivity, opacity, and metallic luster. The interstitial carbides have these properties, and are uniformly chemically inert. They include those having cubic close-packed structures, such as TiC, ZrC, HfC, VC, NbC, TaC, MoC, and WC, and those having hexagonal close-packed structures such as V_2C, Mo_2C, and W_2C. In both, the carbon atoms occupy interstitial positions in the crystal lattices of the metals, giving hardness, high melting points, and chemical inertness, as well as electrical conductivity with a positive temperature coefficient and metallic luster. The covalent binary compounds of carbon range in character from hard, chemically inert solids, such as silicon carbide, SiC, to volatile liquids, such as carbon disulfide and carbon tetrachloride, CS_2 and CCl_4, and even to gases such as carbon tetrafluoride, carbon dioxide and methane, CF_4, CO_2 and CH_4, varying in thermal stability. With several of these elements carbon forms a series of compounds, or as with hydrogen, a number of series of hydrocarbons, consisting of both compounds based upon chains and branched chains of carbon atoms, variously saturated (i.e., joined by single, double, or triple bonds), and also of ring connected carbon atoms, with or without side chains, with varying degrees of saturation, and capable of replacement of the hydrogen atoms with other atoms or radicals.

Carbonates: Carbonic acid H_2CO_3 is present to the extent of 0.27% of the total CO_2 present in the solution that is formed by dissolving CO_2 in H_2O at room temperature. The CO_2 may be expelled fully upon boiling. The solution reacts with alkalis to form carbonates, e.g., sodium carbonate, sodium hydrogen carbonate, calcium carbonate, calcium hydrogen carbonate. The acid ionization constant usually cited for carbonic acid (4.2×10^{-7}) is actually for the equilibrium $CO_2(aq) + H_2O \leftrightarrow H^+ + HCO_3^-$. The true ionization constant, i.e., for the equilibrium $H_2CO_3 \leftrightarrow H^+ + HCO_3^-$ is about 1.5×10^{-4}. The carbonate ion is a resonance hybrid of the three structures shown *a*, *b*, and *c* as well as structures of the type *d* which give a partial ionic character to bonds. This resonance is somewhat inhibited in the acid and its esters, but is complete, or much more nearly complete, in many other derivatives and in the carbonate ion. Esters of both metacarbonic, $(RO)_2CO$, and orthocarbonic acid, $(RO)_4C$, are known. The esters also exhibit resonance.

Metallic carbonates are (1) soluble in H_2O, e.g., sodium carbonate, potassium carbonate, ammonium carbonate (2) insoluble in H_2O and excess alkali carbonate, e.g., calcium carbonate, strontium carbonate, barium carbonate, magnesium carbonate, ferrous carbonate (3) insoluble in H_2O but soluble in excess alkali carbonate forming carbonate complexes, e.g., compounds of uranium and ytterbium $U(CO_3)_2$, UO_2CO_3, $Yb_2(CO_3)_3$. Metallic bicarbonates are known in solution and on warming are converted into ordinary or normal carbonates, e.g., bicarbonates of sodium, potassium, calcium, barium. These are preferably named as "hydrogen carbonates," e.g., $NaHCO_3$ = sodium hydrogen carbonate. Basic carbonates are important in such cases as lead ("white lead"), zinc, magnesium, and copper. Carbonates of very weak bases, such as aluminum, iron(III), and chromium(III), are now known.

The carbonates are found in nature as the carbonates, calcite, iceland spar, limestone and various forms of impure calcium carbonate $CaCO_3$, as magnesite (magnesium carbonate, $MgCO_3$), as dolomite (various compositions of calcium and magnesium carbonates), as witherite $SrCO_3$, as strontianite $SrCO_3$, as azurite and malachite (various compositions of cupric hydroxycarbonates), in various natural waters as carbonic acid, calcium and magnesium hydrogen carbonates, in blood, as sodium hydrogen carbonate.

Many esters of carbonic acid are known, e.g., diethyl carbonate, ethyl ester of metacarbonic acid, $(C_2H_5O)_2CO$, made by reaction of ethyl alcohol and carbonyl chloride; dimethyl carbonate, $(CH_3O)_2CO$; methyl ethyl carbonate, $(CH_3O)CO(OC_2H_5)$; dipropyl carbonate, $(C_3H_7O)_2CO$; tetraethyl carbonate, ethyl ester of orthocarbonic acid, $(C_2H_5O)_4C$, bp 158 °C.

Peroxycarbonic acid exists only in its compounds. Alkali peroxycarbonates are obtained by electrolysis of concentrated solutions of the carbonates, the anodic reaction being written as

$$2CO_3^{2-} \longrightarrow C_2O_6^{2-} + 2e^-$$

The peroxycarbonates are relatively stable only in concentrated alkaline solutions. On dilution they decompose to give the bicarbonate and hydrogen peroxide

$$Na_2C_2O_6 + 2H_2O \longrightarrow 2NaHCO_3 + H_2O_2$$

when acidified, the peroxycarbonate ion gives, correspondingly, CO_2 and hydrogen peroxide

$$C_2O_6^{2-} + 2H^+ \longrightarrow 2CO_2 + H_2O_2$$

Carbonyls: The metal carbonyls are strongly covalent in character, as shown by their volatility, their solubility in many nonpolar solvents, and their insolubility in polar solvents. They also behave in many reactions like mixtures of carbon monoxide, CO, and the metal. Those of group 6b elements, $Cr(CO)_6$, $Mo(CO)_6$, and $W(CO)_6$ are more stable and less reactive than the others, especially those of group 8 elements. Group 7b carbonyls are $Mn_2(CO)_{10}$, $Tc_2(CO)_{10}$, and $Re_2(CO)_{10}$, while group 8 elements form $Fe(CO)_5$, $Fe_2(CO)_9$, $Fe_3(CO)_{12}$, $Co_2(CO)_8$, $Co_4(CO)_{12}$, $Ni(CO)_4$, $Ru(CO)_5$, $Ru_2(CO)_9$, $Ru_2(CO)_{12}$, $Rh_2(CO)_8$, $Rh_3(CO)_9$, (and multiples), $Rh_4(CO)_{14}$, (and multiples), $Os(CO)_5$, $Os_2(CO)_9$, $Ir_2(CO)_8$, and $Ir_3(CO)_9$ (and multiples). The carbonyls form a wide variety of addition compounds; they are dissolved in alcoholic potassium hydroxide or other strong alkalies to form hydrides which are acids, and can be used to form a wide variety of more complex compounds. Although $H_2Fe(CO)_4$ is a moderately weak acid, $pK_1 = 4.44$, $pK_2 = 14.0$, $HCo(CO)_4$ appears to be comparable with HCl in acidity. The carbonyl compounds have zero charge number on the metal. The mononuclear carbonyls are spin-paired complexes, and are formed only by metals having even atomic numbers. However, metals having odd atomic numbers can form carbonyl compounds with other atoms or radicals, as exemplified by the nitrosyl compound of cobalt carbonyl, $Co(CO)_2NO$, where the —NO radical contributes the electron necessary to complete the 3*d* level of the cobalt atom. More than one NO group may occur in a metal carbonyl, as, for example, in $Fe(CO)_2(NO)_2$. This is isostructural with $Co(CO)_3NO$ and $Ni(CO)_4$.

Halides: The four tetrahalides of carbon are symmetrical, planar compounds, with the general property of marked stability to chemical reactions, although the tetraiodide undergoes slow hydrolysis in contact with water to form iodoform and iodine. It also decomposes under the action of light and heat. The stability of these four compounds decreases in order of descending periodic table position. Their properties are given below:

NAME	FORMULA	MP	BP
Carbon tetrafluoride	CF_4	−184 °C	−128 °C
Carbon tetrachloride	CCl_4	−23.0°	−76.8°
Carbon tetrabromide	CBr_4	α48.48 / β90.18	−189.5°
Carbon tetraiodide	Cl_4	171° dec	

The same relation of reactivity and stability to periodic position is exhibited by such other carbon halides as hexachloroethane $CCl_3 \cdot CCl_3$ and hexabromoethane, $Br_3 \cdot CBr_3$, as well as by hexachloroethylene, $CCl_2 = CCl_2$ and hexabromoethylene, $CBr_2 = CBr_2$. Carbon also forms halides containing more than one halogen. See also **Carbon Tetrachloride**.

It is well established that hydrogen forms more than one covalent binary compound with carbon. Fluorine behaves similarly. Thus, fluorine forms CF_4, C_2F_4, C_2F_6, C_3F_8 and many higher homologs, as well as the definitely interstitial compound $(CF)_n$. The other halogens form some similar compounds, although to more limited extent, and various polyhalogen compounds have been prepared. They exhibit the maximum covalency of four and are therefore inert to hydrolysis and most other low temperature chemical reactions.

Carbon Oxides: See also **Carbon Dioxide**; **Carbon Monoxide**; and **Carbon Suboxide**.

The Fullerenes

The less-than-scientific ring ascribed to the comparatively recent discovery of a third form of carbon, the *fullerenes*, is reminiscent of *flavors* used a few years ago to describe the various kinds of quarks in the field of high-energy physics. The technical literature on fullerenes, as of early 1994, features such terms as bucky-ball, buckminsterfullerene, buckytube, carbon cage, dopey ball, hairy ball, Russian doll, et al., some of which terms are synonymous; others have specific connotations. Considered as an entity, fullerene chemistry constitutes a major breakthrough in the science of physics and chemistry of materials at the molecular level.

The absence of a formal nomenclature at this juncture is accompanied by a somewhat fuzzy chronology pertaining to the discovery and early research on the fullerenes. However, the isolation and confirmation of the C_{60} all-carbon molecule sans any dangling bonds, as first conjectured in 1985, was pivotal to subsequent research.

Setting the Stage for Carbon 60 Research. The pathways that ultimately led to the geometric visualization of the C_{60} molecule were several and varied.

(1) A growing interest in cluster configurations extends back to the 1950s. The sophistication of instrumentation for investigating once exotic substances has improved many times over during recent years, and numerous schemes of molecular geometry have been proposed. Thus, in retrospect, the efforts made to visualize the structure of the C_{60} molecule were not exclusively of a pioneering bent.

(2) For many years, astrophysicists have been interested in the role of carbon molecules, both as building blocks and as photofragments of carbonaceous materials. As early as 1972, *polyyne* chain molecules ($\cdots C{\equiv}C{-}C{\equiv}C{-}C{\equiv}C\cdots$) were proposed as being present in interstellar space and in the atmospheres of carbon stars. This material, in the form of HC_5N was prepared in the laboratory and later was found, by way of radio astronomy, to exist in space. The structural geometry of the compound, however, could not be explained satisfactorily.

(3) Over a number of years, researchers engaged in the study of carbon (fuel) combustion reactions sought a better understanding of such reactions at the molecular level and, in particular, those processes that produced soot (carbon particles). Thus, carbon particles became a major target of their research. Because of concerns with air pollution, efforts were made to make carbon particle determination an exact science.

Carbon Sixty Research Chronology

In 1984, scientists (Rohlfing, Cox, and Caldor at Exxon Research and Engineering) created clusters of carbon (soot) by the laser vaporization of a carbon target rod in connection with a supersonic nozzle. By means of mass spectroscopy, the researchers determined the relative abundance of the carbon clusters produced. Small, 20- to 40-atom clusters of carbon were expected inasmuch as these had been produced a number of times by earlier investigators working on the soot problem. In such experiments, an interesting but unexplained question always arose — Why were only even-numbered carbon clusters produced in the complete absence of odd-numbered clusters? See Fig. 3.

In 1985, similar experiments were conducted at Rice University. In a 1988 paper, Curl and Smalley (Rice University) outlined their experiments with carbon cluster beams, essentially using the cluster-generating apparatus previously described by the Exxon researchers. Initially, this experimentation was motivated by an interest that had been shown by the astrophysicist, Kroto (University of Sussex), who had been modeling the formation of carbon molecules in circumstellar shells. As a consequence, the Rice University team concentrated its studies on the smaller (2- to 30-atom) carbon clusters. As pointed out in the Curl-Smalley paper, the objective was to "determine if some or all of the species had

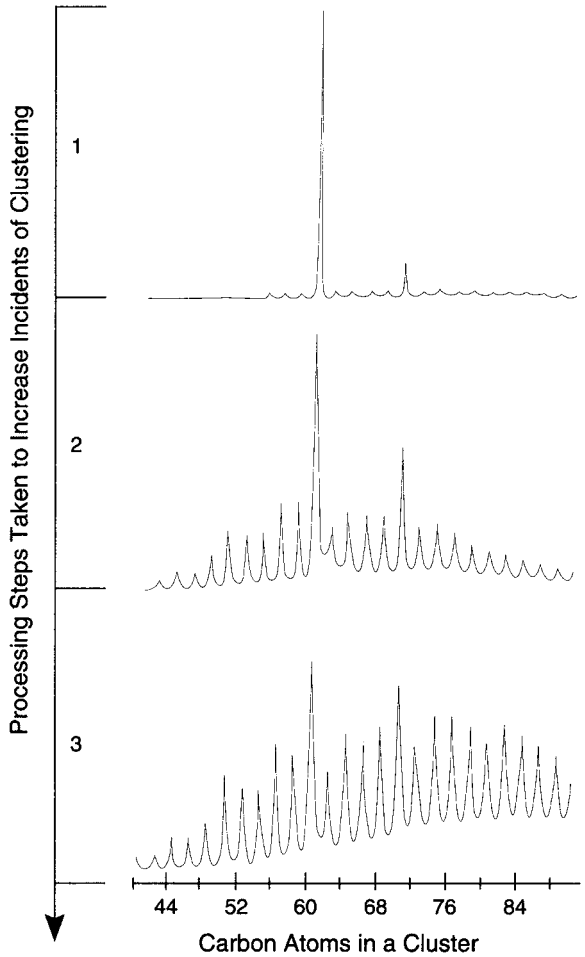


Fig. 3. Reasonable facsimiles of mass spectra produced by laser vaporization of carbon in a supersonic beam, indicating three stages in the process for increasing the extent of clustering. Experiment was carried out by Rohlfing, Cox, and Kaldor (Exxon Research and Engineering). Original diagrams were featured in *Nature* (1985).

the same form as the long linear carbon chains known to be abundant in interstellar space."

Over time, the research interests of the Rice University team and of Kroto were directed increasingly to developing a suitable structural explanation of the even-numbered carbon clusters and, notably, of the C_{60} molecule.

It has been reported that, over a period of at least several months, Kroto and the Rice University team had formed a sort of research camaraderie, which developed out of their common interests in learning more about the structure of C_{60}. There are, however, some differences in opinion as to how the buckyball was visualized initially.

In a 1988 article, Kroto observed, "Initially, cluster reactions were probed which showed that C_n ($n > 30$) clusters did indeed react with H and N to form polyynes, which had been detected in space, a result satisfyingly consistent with the idea of a stellar source of interstellar chains. The larger clusters were totally inert, and as the experiments progressed, it became impossible to ignore the antics of the C_{60} peak which varied from relative insignificance to total dominance, depending on the clustering conditions.

"After much discussion we conjectured that the bizarre behavior, particularly of the dominance of C_{60}, could be the result of stabilization by closure of a graphite net into a hollow chicken-wire cage similar to the geodesic domes of Buckminster Fuller.[1] Such closure would eliminate all 20 or so reactive edge bonds of a 60-atom sheet. This led to the realization that there was a most elegant and, at the time, overwhelming solution — the *truncated icosahedron cage*." See Fig. 4.

[1] Architect, Buckminster Fuller, probably is most famous for his design of the United States exhibit building for the 1967 Exposition in Montreal.

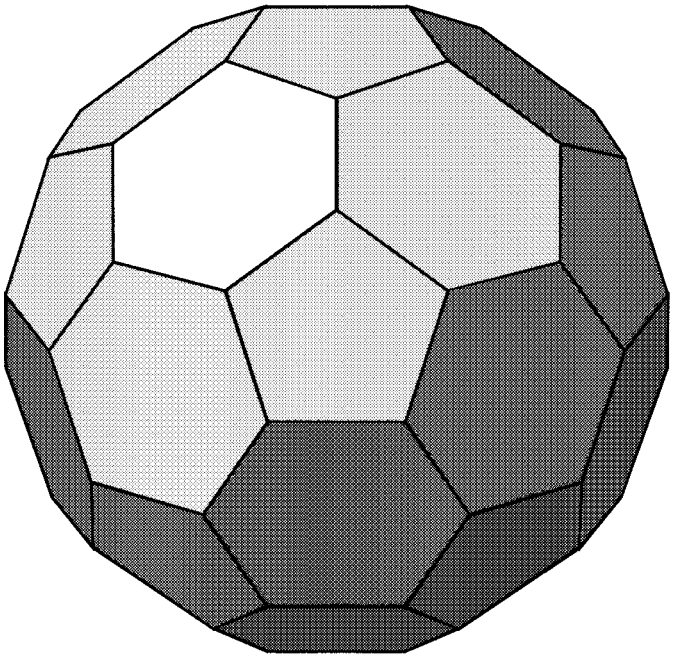

Fig. 4. Frontal view of truncated icosahedral structure of C_{60} cluster.

"The structure necessitated the throwing of all caution to the wind (the Greek icosahedron) and it was proposed immediately by Kroto, Heath, O'Brien, Curl, and Smalley: *Nature*, **318**, 162 (1987). After all, it was surely too perfect a solution to be wrong. We named C_{60} after Buckminster Fuller, which has turned out to be a highly appropriate name."

The diagram (Fig. 5) shows a full accounting of the 60 carbon atoms that fully close the cage without any dangling bonds. Because the molecule resembles a soccer ball, it has been called the "buckyball."

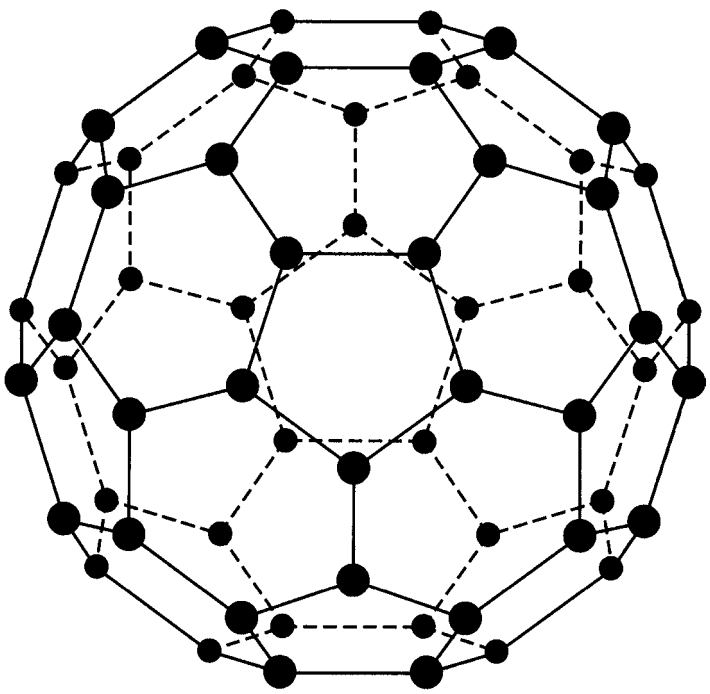

Fig. 5. C_{60} shown as transparent to indicate all sixty carbon atoms.

Smalley's description of how the geometry of C_{60} was revealed varies somewhat from Kroto's accounting. This is explained partially by Philip Yam (reference listed), who writes in a short biography of Smalley, "Neither individual probably would have discovered buckyballs had they not collaborated, and both agree that it was a serendipitous finding." Ironically, it is interesting to note that David Jones (writing under the pseudonym, Daedalus) previously had proposed such cages as early as 1982.

Ensuing Fullerene Research

In the 1990s, fullerene research continued apace. Hundreds of new papers appeared each quarter pertaining to the properties of C_{60} and its cousins, and the prospects for developing new materials based upon this new dimension of carbon chemistry. (A sampling list of additional reading is given at the end of this article.)

Researchers J.M. Hawkins, et al. (University of California, Berkeley), for example, studied infrared, Raman, ^{13}C nuclear magnetic resonance, and photoelectron spectra of C_{60}, and found the data to be consistent with icosahedral symmetry and thus highly supportive of the original proposed structure. However, the researchers did not strictly prove the soccer ball framework or provide atomic positions through the studies of spectra. Therefore, the investigators added an osmyl unit to C_{60} in order to break its pseudospherical symmetry and give an ordered crystal. The crystal structure of this derivative, C_{60} (OsO_4) (4-*tert*-butylpyridine)$_2$, revealed atomic positions within the carbon cluster, thus essentially confirming the soccer ball framework.

Scientists Y.Z. Li, R.E. Smalley, et al. (Rice University) have used scanning tunneling microscopy to study monolayer and multilayer structures of C_{60}. Detailed studies of potassium incorporation in crystalline C_{60} show highly ordered structures in the K_3C_{60} metallic state, but disordered nonmetallic structures for high potassium concentrations.

Researcher R.C. Haddon (AT&T Bell Laboratories) reports that there seems to be no doubt that the C_{60} molecule is highly electronegative, but that recent research has characterized C_{60} as that of an electron-deficient polyalkene without significant delocalization. Fullerenes are without boundary conditions; just as in an ideal graphite sheet, there are no peripheral atoms to serve as sites of preferred activity. "Without curvature, the fullerenes would be no more reactive than an ideal graphite sheet. The chemistry of the fullerenes is best described as that of a class of strained and continuous aromatic molecules. C_{60} is of ambiguous magnetic properties but with the reactivity of a continuous aromatic molecule moderated only by the tremendous strain inherent in the spheroidal structure."

J.E. Fischer and a team of researchers (University of Pennsylvania) report, "The recent discovery of an efficient synthesis of C_{60} and C_{70} ... has facilitated the study of a new class of molecular crystals ('fullerites') based on these molecules ('fullerenes')." In the Fischer reference listed, a study of the compressibility of solid C_{60} is described.

In the S. Chakravarty (University of California, Los Angeles) et al. reference, "A theory of the electronic properties of doped fullerenes is proposed in which electronic correlation effects, within single fullerene molecules play a central role and qualitative predictions are made, which, if verified, would support this hypothesis. Depending on the effective intrafullerene electron-electron repulsion and the interfullerene hopping amplitudes (which would depend on the dopant species, among other things), the calculations indicate the possibilities of singlet superconductivity and ferromagnetism."

As described by V.P. Dravid (Northwestern University) et al., "Transmission electron microscopy (TEM) observations of graphite tubules (*buckytubes*) and their derivatives have revealed not only the previously reported buckytube geometrics but also additional shapes of the buckytube derivatives. Detailed cross-sectional TEM images reveal the cylindrical cross section of buckytubes and the growth pattern of buckytubes as well as their derivatives. ... Based on the TEM observations, it is proposed that buckytubes act as precursors to closed-shell fullerene (buckyball) formation."

The NEC Corporation, when examining deposits of soot on a carbon electrode used for generating fullerenes, found miniscule (up to a micron long) fibers which were tiled in hexagonal arrays. The arrays appear to tightly bind the carbon atoms and terminate in faceted, conical caps. The fibers immediately were referred to as "buckytubes." Iijama observes, "It (buckytube) could be the strongest fiber that can exist. Its strength flows from the nature of carbon-carbon bonds, on the one hand, and the nearly flawless structure of the tubular crystals, on the other." A scientist at the Massachusetts Institute of Technology has observed, "Buckyfibers have very few defects and so in that sense are better than graphite."

Materials engineers are becoming very interested in buckytubes because they may perform better than graphite in carbon-carbon composite materials, as currently used in aircraft.

Fullerenes in nature have been reported by a team of scientists, including P.R. Buseck (Arizona State University). High-resolution transmission electron microscopy images of poorly graphitized material in carbon-rich (coaly) rock, taken from an area near Karelia, Russia, are similar to those produced by synthetic fullerenes. The presence of C_{60} and C_{70} was confirmed by mass spectrometry. Needless to say, the finding was a surprise because the natural conditions for producing the fullerenes differ so much from the high-temperature processes of the laboratory. This finding may contribute in some way to future fullerene research.

CARBONADO. The mineral carbonado is an opaque massive black variety of diamond, often crystalline to granular or compact and without cleavage. In thin splinters it appears greenish-black by transmitted light. It is found chiefly in Bahia, Brazil. Carbonado is used for rock-drilling apparatus.

Carbonado also is known as *black diamond*.

CARBONATE. A compound resulting from the reaction of either a metal or an organic compound with carbonic acid. The reaction with a metal yields a salt (calcium carbonate) and that with an alphatic or aromatic compound forms an ester, e.g., diethylcarbonate, diphenyl carbonate. The latter are liquids used as solvents and in synthesizing polycarbonate resins. See also **Calcium Carbonate**.

CARBON BLACK. Finely divided carbonaceous pigments of a wide variety are termed carbon blacks. Over 90% of the carbon black manufactured is consumed as reinforcing and compounding agents for rubber, mainly for motor vehicle and aircraft tires. Most users of tires do not realize that the effective use of these agents extends the life of a tire in normal usage by eight to ten times. The addition of as little as 1 to 2% carbon black to plastics greatly minimizes the effects of sunlight in degrading the

materials. Most carbon blacks are derived from the pyrolysis of hydrocarbon gases and oils. The permanent and penetratingly deep black coloration obtainable with carbon blacks also makes the materials attractive for paints, inks, protective coatings, and as colorants for paper and plastics.

Two properties of carbon blacks are most significant for commercial applications: (1) particle size and (2) surface area. The particle sizes range from 100 to 5,000 micrometers. Surface areas will range from 6 to 1,100 m^2/g of material. Under electron microscopic examination, the carbon particles appear as rough spheres, usually as clusters of spheres rather than as individual spheres. The clustering characteristics stem from both chemical and physical bonding forces. Classically, the arrangement of the carbon particles may be likened to hexagonal nets of carbon atoms, which are *paracrystalline* in nature. The particle size and surface area characteristics essentially are at the microscopic level-hence control over carbon black production is exacting. In terms of coloration, for example, the human eye can resolve 260 shades of blackness. The blackest of commercially produced carbon particles will have a diameter of about 100 micrometers. The grayest particle will have a diameter of about 5,000 micrometers. The blackness characteristic sometimes is referred to as *masstone* (mass-tone). The particles with the smaller diameters and hence greater surface area exhibit the highest masstone.

Lampblacks have been made for many centuries. Early methods involved the burning of petroleum-like substances or coal-tar residues with a minimum of air, thus producing large amounts of unoxidized carbon particles. The earlier settling chambers in which the particles collected have been replaced by cyclones, bag filters, or electrical precipitators. Modern installations use oil furnaces to create the particles.

Channel or *impingement carbons* are produced from burning natural gas (sometimes containing oil vapors) in many hundreds of small burners. The flames from the burners impinge upon flat surfaces called channels. The carbon deposits are periodically removed by scraping into a collector. The burning equipment is contained within a large burner house, which has means for carefully regulating bottom and top drafting of air.

Thermal blacks also are derived from natural gas, but by thermal decomposition completely in the absence of air. Large furnaces first are preheated to a temperature ranging from 1,100–1,650 °C. When the checkerwork is at the proper temperature, natural gas is bled into the furnace, whereupon the gas decomposes into carbon and hydrogen. This is a batch process, requiring pairs of furnaces, one furnace preheating, while the other furnace is decomposing the gas feed. Frequently, the hydrogen byproduct is recycled as fuel to heat the furnaces. Where very fine thermal blacks are produced, the byproduct hydrogen is used as a diluent for the gas feed.

Furnace carbons also are derived from natural gas, but in a process in which a slight excess of air is introduced to support combustion. The hydrocarbon feedstock or liquid oil is injected into the furnace at a location where the so-called blast-flame gases are circulating at their greatest velocity. Injection of the feed at this point causes an instant high rise in temperature, which results in practically instantaneous decomposition of the feed into carbon black. For coarse particles, the oil/air ratio is greater, furnace gas velocities are lower, and residence time in the furnace is longer. There is a wide range of furnace carbon particle sizes. The very fine particles go into tire treads, whereas the coarser particles are used in tire carcasses.

Acetylene black is derived from feeding acetylene into high-temperature retorts whereupon the acetylene dissociates into carbon and hydrogen. This reaction is exothermic (other carbon black processes are endothermic). Temperature control of the furnace is effected by throttling the acetylene feed.

CARBON COMPOUNDS. See **Carbon**; and **Organic Chemistry**.

CARBON CYCLE (Nuclear). In physics and astronomy, a series of thermonuclear reactions, releasing great quantities of energy (by conversion from mass and by radiation) that are believed to furnish the energy radiated by some of the stars. This scheme was developed from theoretical considerations by H.A. Bethe in 1939 (and simultaneously by C.F. von Weizsäcker). Various possibilities were tried but the following series was the only one that gave results in agreement with the experimental facts:

$$C^{12} + H^1 \longrightarrow N^{13} + \gamma$$
$$N^{13} \longrightarrow C^{13} + e^+ + v$$
$$C^{13} + H^1 \longrightarrow N^{14} + \gamma$$
$$N^{14} + H^1 \longrightarrow O^{15} + \gamma$$
$$O^{15} \longrightarrow N^{15} + e^+ + v$$
$$N^{15} + H^1 \longrightarrow C^{12} + He^4$$

where e^+ indicates a position, v indicates a neutrino, and γ indicates a gamma ray.

The overall reaction results in the production of a helium atom, two positrons, two neutrinos and 4×10^{-5} ergs from four protons, the carbon atom that reacted initially being regenerated at the end of the process. There are, of course, other probable side reactions.

The mass rate of energy generation is given by

$$\epsilon_C = \rho X (100\alpha_N) f_N E_N$$

where ρ is the density, X is the fraction of hydrogen by mass, α_N is the fraction of nitrogen by mass, f_N is the shielding factor for nitrogen, and E_N is a function dependent upon temperature.

CARBON DATING. See **Radioactivity**.

CARBON DIOXIDE. [CAS: 124-38-9] CO_2, formula weight 44.01, colorless, odorless, nontoxic gas at standard conditions. High concentrations of the gas do cause stupefaction and suffocation because of the displacement of ample oxygen for breathing. Density 1.9769 g/l (0 °C, 760 torr), sp gr 1.53 (air = 1.00), mp −56.6 °C (5.2 atmospheres), solid CO_2 sublimes at −79 °C (760 torr), critical pressure 73 atmospheres, critical temperature 31 °C. Carbon dioxide is soluble in H_2O (approximately 1 volume CO_2 in 1 volume H_2O at 15 °C, 760 torr), soluble in alcohol, and is rapidly absorbed by most alkaline solutions. The solubility of CO_2 in H_2O for various pressures and temperatures is given in Table 1.

TABLE 1. SOLUBILITY OF CARBON DIOXIDE IN WATER

Pressure (atmospheres)	Parts (Weight) CO_2 Soluble in 100 Parts Water				
	18 °C	35 °C	50 °C	75 °C	100 °C
25	3.7	2.6	1.9	1.4	1.1
50	6.3	4.4	4.0	2.5	2.0
75	6.7	5.5	4.5	3.4	2.8
100	6.8	5.8	5.1	4.1	3.5
200	—	6.3	5.8	5.3	5.1
300	7.4	—	6.2	5.8	5.7
400	7.8	7.1	6.6	6.3	6.4
700	—	—	7.6	7.4	7.6

Carbon dioxide plays several roles: (1) as a *raw material* for several processes, as in the Solvay process for the manufacture of sodium bicarbonate and sodium carbonate. (2) as a *byproduct* from many processes, notably as a product of combustion of fossil fuels, (3) as an *ingredient* of products, for example, carbonated beverages, (4) as a *product* for direct consumption, for example, CO_2 fire extinguishers and dry ice refrigerants, and (5) as a *pollutant* of the atmosphere. Carbon dioxide is useful in all three of its physical phases-gas, liquid, and solid. Although not toxic, the presence of CO_2 in the atmosphere disturbs the environmental energy balance. The latter aspects of CO_2 are discussed under **Climate**; and **Pollution (Air)**. Normally, CO_2 is present in the air at sea level to the extent of about 0.05% by weight.

Transportation Uses. Solid carbon dioxide (dry ice) is an effective refrigerant for transportation uses. Refrigeration of moving vehicles may be derived from (1) mechanical systems which, of course, require a continuous input of energy, (2) water ice and ice-salt mixes which require water (often briny) removal, and are corrosive and subject to

algae formations, and (3) dry ice, the end-product of which is simply gaseous CO_2, which is easily removed. To maintain a cool temperature in a railroad refrigerator car for a trip between California and New York, about 1,000 pounds (~454 kg) of dry ice would be required. To maintain the same conditions with water ice and salt would require 10,000 pounds of ice.

Specially designed rail cars have replaced on-board diesel-powered refrigeration units, with a CO_2 injection system and ceiling-mounted bunker. These bunkers carry sufficient quantities of dry ice snow to provide sufficient refrigeration for long trips. There are similar applications where perishables are moved by truck. Particularly in truck shipments, CO_2 systems not only refrigerate the cargo, but the inert atmosphere (CO_2 in gaseous phase) retards bacterial growth and thus prevents spoilage. The system is widely used for local route deliveries where frequent and lengthy door openings are needed. Automatic temperature controllers are used. Airlines, hotels, and restaurants keep prepared foods fresh during transport by dispensing CO_2 snow into the bunker portion of customized food service carts.

Fire-Fighting Uses. The fact that CO_2 is heavier than air makes it particularly effective for fighting fires in low places, such as pipe trenches and hard-to-reach low corners and basements, where the CO_2 tends to roll under the air required to maintain combustion. Both manually and automatically controlled CO_2 fire-fighting systems are available. These can be actuated by heat-sensitive systems — just as a conventional water-sprinkling system. CO_2 is effective for fires involving electrical and electronic gear because, if a fire is not fully out-of-hand, the CO_2 often can quickly quench the fire source without leaving any residual damage, as often is the disastrous consequences of using water or sand.

Food Industry Uses. Large quantities of CO_2 are used in food processing, ranging over a wide variety of cooling and freezing operations. A number of freezer designs have been developed, including tunnel, cabinet, spiral, flighted, and drum designs. For example, wide usage of CO_2 in the baking industry includes chilling pneumatically conveyed dry ingredients, such as flour and powdered sugar, to controlling the temperature of dough during the mixing process.

Carbon dioxide is used for carbonating soft drinks. The wine industry also uses CO_2 to add effervescence to sparkling burgundies, rose wines, and some champagne.

The use of CO_2 atmosphere systems in greenhouses has been found to increase plant growth. During winter months, heating costs are markedly reduced and crop yields are increased.

Oil Production Enhancement. For a number of years, depending upon the geopolitics of crude oil production, considerable interest has been shown in the use of carbon dioxide for increasing the recovery of oil from old wells. In the United States alone, it is estimated that there are more than 300 billion barrels of oil left in known formations, which are incapable of recovery through the use of traditional recovery enhancement techniques, such as steam flooding and the use of surfactants. Supercritical fluid carbon dioxide is an impressive solvent for fats and hydrocarbons. The problems of geological formations underground and their varying characteristics (permeability, etc.) present difficulties as with past methods, but it has been established that the dense fluid CO_2 will contribute to recovery wherever it contacts oil. Consequently, some major oil firms already have expended large sums to ready pipelines and other facilities for bringing CO_2 to oil fields as, for example, those in the Permian basin of western Texas and New Mexico. Although carbon dioxide has been a useful material for other purposes, oil recovery usage may require the gas in huge quantities not heretofore contemplated. The target, of course, is to capture the needed CO_2 mainly from wastes to the atmosphere, as from power plants. Although authorities still consider oil recovery as a long-range goal, the short-term pace is affected by the fluctuating price of crude oil on world markets. More detail concerning the use of supercritical CO_2 for this purpose is given in entry on **Petroleum**.

Sources of Commercial Carbon Dioxide. Although carbon dioxide must be generated on site for some processes, there is a trend toward CO_2 recovery where it is a major reaction byproduct and, in the past, vented to the atmosphere. For example, very large quantities of CO_2 are generated by various fermentation processes and in cement production. If the CO_2 must be removed from stack gases because of pollution control regulations, it is only one more step to purify the gas and sell it, usually in compressed liquid form. There are, of course, several economic tradeoffs that must be considered. Where the gas is recovered, it usually is first absorbed in sodium or potassium carbonate solutions, followed by steam-heating the solutions to free a reasonably pure CO_2. The last step is compression of the gas into steel cylinders. The ethanolamines also are excellent absorbents of CO_2.

Carbon Dioxide in Biological Systems. Carbon dioxide, which is a byproduct of the metabolic activity of all cells, is one of the most important chemical regulators in the human body. It can be said that human life without carbon dioxide would be impossible. In less specialized forms of life, carbon dioxide is essentially a waste product. In the more highly developed animals, such as humans, the gas is used to regulate the activity of the heart, the blood vessels, and the respiratory system.

As mentioned, CO_2 is normally present in air at sea level at about 0.05% (weight). A poorly ventilated room may contain as much as 1% (volume). Concentrations of the gas from about 0.1–1% (volume) induce languor and headaches; concentrations of 8–10% (volume) bring about death by asphyxiation. High concentrations of the gas are toxic. See also **Basal Metabolism**.

As a general rule, the respiration of individual cells decreases as the concentration of carbon dioxide in the medium increases. Fish show a lessened capacity to extract oxygen from their environment with increasing amounts of carbon dioxide present. On the other hand, many invertebrates show marked increases in respiratory rate (or ventilation) with increased amounts of the gas in their surroundings.

Photosynthetic and autotrophic bacteria reduce carbon dioxide, which is assimilated into complex molecules for use in synthesizing various cellular constituents. The gas is apparently assimilated, at least to a small extent, by the heterotrophic bacteria. Certainly it is required for any growth in these forms. Many pathogenic bacteria required increased carbon dioxide tension for growth immediately after they are isolated from the body. The production of hemolysins and like substances is greatly enhanced by adding 10–20% of CO_2 in the air that comes in contact with the cultures.

The oxygen dissociation curve for blood is shifted to the right when the partial pressure of carbon dioxide is increased. This is referred to as the "Bohr Effect." It means that for a given partial pressure of oxygen, hemoglobin holds less oxygen at high concentration of carbon dioxide than at a lower concentration. It is evident, then, that the production of carbon dioxide by actively metabolizing tissues favors the release of oxygen from the blood to the cells where it is urgently needed. Moreover, at the alveolar surfaces in the lungs, the blood is losing carbon dioxide rapidly, which loss favors the combination of oxygen with hemoglobin. In males, the average amount of CO_2 in the alveolar air is about 5.5% (volume); during the breathing cycle, this concentration varies only slightly. In females and children, somewhat lower mean values obtain.

In every 100 milliliters of arterial blood, there is a total of 48 milliliters of free and combined CO_2. In venous blood of resting humans, there is about 5 milliliters more than this. Only about 1/20 of the carbon dioxide is uncombined, a fact which indicates that there is a specialized mechanism, aside from simple solution, for the transport of CO_2 in the blood.

About 20% of the CO_2 in the blood is carried in combination with hemoglobin as *carbaminohemoglobin*. The balance of the combined carbon dioxide is carried as bicarbonate. A CO_2 dissociation curve for blood can be prepared just as for oxygen, but the shape is not the same as for the latter. As the partial pressure of CO_2 in the air increases, the amount in the blood increases; the increase is practically linear in the higher ranges. Oxygen exerts a negative effect on the amount of CO_2 which can be taken up by the blood.

In working muscles large amounts of CO_2 are produced. This causes local vasodilation. The diffusion of some of the CO_2 into the bloodstream slightly raises the concentration there. It circulates through the body and the capillaries of the vasoconstrictor center, where it excites the cells of the center, resulting in an increase of constrictor discharges. Regarding the stimulating effect of CO_2 on cardiac output, it is evident that a most effective mechanism exists for increasing circulation through active muscles: more blood is pumped by the heart per minute, and the arterial pressure is increased by the general vasoconstriction; blood is forced from the inactive regions, under increased pressure, through the widely dilated vessels of the active muscles.

The partial pressure of CO_2 is important in connection with a number of physiological problems. For example, respiratory acidosis is the result of an abnormally high $p \ldots CO_2$. The value of arterial pCO_2 varies directly with changes in the metabolic production of CO_2 and indirectly with the

amount of alveolar ventilation. The problem is more commonly the result of decreased alveolar ventilation caused by abnormally low CO_2 excretion by the lungs (alveolar *hypo*ventilation).

On the other hand, primary respiratory alkalosis occurs as a result of alveolar *hyper*ventilation. This condition is associated with a number of pulmonary diseases, but also may appear during pregnancy, liver disease, and salicylate intoxication, among others. The sequence of events proceeds along these lines: (1) Ventilation removes CO_2 faster than the gas is produced by metabolism, causing a decrease in pCO_2 in the blood and body fluids, including a reduction of venous pCO_2. This reduces the gradient for excretion of CO_2 by the lungs. (2) Pulmonary excretion and metabolic production ultimately balance out at a lower pCO_2 level for all body fluids. (3) The lower pCO_2 level causes a lower carbonic acid concentration and consequently an increase in pH. The latter is relative to the reduced level of pCO_2, but the pH change also alters bicarbonate concentration. The steplike process is quite complex. See also **Blood**.

Narcosis due to CO_2 is characterized by mental disturbances which may range from confusion, mania, or drowsiness to deep coma, headache, sweating, muscle twitching, increased intracranial pressure, pounding pulse, low blood pressure, hypothermia, and sometimes papilloedema. The basic mechanisms by which carbon dioxide induces narcosis is probably through interference with the intracellular enzyme systems, which are all sensitive to pH changes.

See also **Photosynthesis**.

Carbon Dioxide and Enzymes. Dr. Harland Wood (Case Western Reserve University) has made major contributions to the understanding of carbon dioxide cycles and enzyme reactions within living organisms. While investigating the process of bacterial fermentation, Wood discovered that some heterotrophic organisms (non-plant forms that require organic compounds for growth) can use carbon dioxide along with organic compounds to build essential compounds. This was in 1935, when it was considered that only plants could use carbon dioxide and that, in heterotrophs, carbon dioxide was a waste product. Wood also researched the role of carbon dioxide in the metabolism of carboydrates, fats, and amino acids by forming the required intermediate compounds. In 1985 Wood found that certain bacteria produce organic compounds entirely from carbon dioxide by a pathway that differs from that of photosynthesis. Certain parts of the cycle involving use of carbon dioxide and hydrogen were found to exist within many organisms.

Wood also has worked with transcarboxylase, a complex, biotin-containing enzyme important in the use of carbon dioxide within heterotrophs. As of the early 1990s this pathway had not been fully delineated.

CARBON GROUP (The). The elements of group 14 of the periodic classification sometimes are referred to as the Carbon Group. In order of increasing atomic number, they are carbon, silicon, germanium, tin, and lead. The elements of this group are characterized by the presence of four electrons in an outer shell. The similarities of chemical behavior among the elements of this group are less striking than that for some of the other groups. e.g., the close parallels of the alkali metals or alkaline earths. However, as more knowledge is gained of silicon, including the element's ability to form "carbon-like" chains with alternating silicon and oxygen atoms, to polymerize, and to form silicones, silanes, etc., the similarity of silicon and carbon emerges more sharply. The semiconductor properties of silicon and germanium in this group are striking, but such properties are not limited to elements in this group. Although some of the elements of the group have valences in addition to +4, all do have the +4 valence in common. Unlike the alkali metals or alkaline earths, for example, the elements of the carbon group are not so similar chemically that they comprise a separate group in classical qualitative chemical analysis separations.

CARBONITRIDING. A surface hardening process for steels involving the introduction of carbon and nitrogen into steels by heating in a suitable atmosphere containing various combinations of hydrocarbons, ammonia, and carbon monoxide followed by a quenching to harden the case.

CARBONIUM ION. An ion of the general formula where A, B and D are substituent groups. It is important in elucidating the mechanism of organic reactions because a considerable proportion of all organic reactions involve carbonium ions, as others do carbanions and carbon free radicals (including carbene radicals). Nucleophilic substitution at saturated carbon atoms includes most of carbonium ion chemistry. Carbonium ions are usually powerful acids or electrophiles, and thus many nucleophilic substitution reactions that involve carbonium ions are acid-catalyzed. For example, the tertiary-butyl carbonium ion offers a clear understanding of the probable course of the conversion of isobutylene to its dimers and trimers.

$$(CH_3)_2C{=}CH_2 + H^+ \longleftrightarrow (CH_3)_3C^+$$

$$(CH_3)_3C^+ + (CH_3)_2C{=}CH_2 \rightleftharpoons (CH_3)_2C{-}CH_2C(CH_3)_3$$

The larger carbonium ion thus formed cannot continue to exist, but may depolymerize, unite with the catalyst, or stabilize itself by the attraction of an electron pair from a carbon atom adjacent to the electronically deficient carbon (C^+) with its proton. This establishes a double bond involving the formerly deficient atom. Thus a proton is expelled to the catalyst or attracted to the catalyst. If this takes place with one of the methyl groups, the product is  . If the methylene group is involved, the product is $(CH_3)_2C{=}CHC(CH_3)_3$.

CARBONIZATION (Coal). See **Coal**.

CARBON MONOXIDE. [CAS: 630-08-0]. CO, formula weight 28.01, colorless, odorless, very toxic gas at standard conditions, density 1.2504 g/l (0 °C, 760 torr), sp gr 0.968 (air = 1.000), mp −207 °C, bp −192 °C, critical temperature −139 °C, critical pressure 35 atmospheres. Carbon monoxide is virtually insoluble in H_2O (0.0044 part CO in 100 parts H_2O at 50 °C). The gas is soluble in alcohol or solutions of cupric chloride. Because carbon monoxide has an affinity for blood hemoglobin that is 300 times that of oxygen, exposure to the gas greatly reduces or fully hinders the ability of hemoglobin to carry oxygen throughout the body, causing death in excessive concentrations. Engines and stoves in poorly ventilated areas are especially hazardous.

Carbon monoxide plays several roles: (1) as a raw material for chemical processes (a) particularly as an effective reducing agent in various metal smelting operations, (b) in the manufacture of formates: CO + NaOH → HCOONa, (c) in the production of carbonyls, such as $Ni(CO)_4$ and $Fe(CO)_5$, which are useful intermediate compounds in the separation of certain metals, (d) in combination with chlorine to form $COCl_2$ (phosgene), (e) as an ingredient of several synthesis gases, as for the production of methanol and ammonia; (2) as a *fuel* where CO is a major ingredient of such artificial fuels as coal gas, producer gas, blast-furnace gas, and water gas; (3) as a byproduct of numerous chemical reactions, notably combustion processes where there is insufficient oxygen

for complete combustion — the fumes from internal-combustion engines may contain in excess of 7% CO, and (4) as a dangerous air pollutant, particularly in industrial areas and where there are high concentrations of automotive vehicles and aircraft. The latter aspects of CO are discussed under **Pollution (Air)**.

Summary of Chemical Reactivity. Chemically, carbon monoxide is (1) reactive with oxygen to form CO_2 accompanied by a transparent blue flame and the evolution of heat, but the fuel value is low (320 Btu per ft^3), (2) reactive with chlorine, forming carbonyl chloride $COCl_2$ in the presence of light and a catalyzer, (3) reactive with sulfur vapor at a red heat, forming carbonyl sulfide COS, (4) reactive with hydrogen, forming methyl alcohol, CH_3OH or methane CH_4 in the presence of a catalyzer, (5) reactive with nickel (also iron, cobalt, molybdenum, ruthenium, rhodium, osmium, and iridium) to form nickel carbonyl, $Ni(CO)_4$ (and carbonyls of the other metals named), (6) reactive with fused NaOH, forming sodium formate, HCOONa, (7) reactive with cuprous salt dissolved in either ammonia solution or concentrated HCl, which solutions are utilized in the estimation of carbon monoxide in mixtures of gases, e.g., flue gases of combustion, coal gas, exhaust gases of internal combustion engines, (8) reactive with iodine pentoxide at 150 °C. For the reaction of carbon monoxide with oxygen to form CO_2 finely divided iron or palladium wire is used as a catalyzer; for the reaction of carbon monoxide with H_2O vapor to form CO_2 plus hydrogen ("water gas reaction") important studies have been made of the conditions; and for the reaction of CO_2 plus carbon (hot) similar important studies have been made (at 675 °C, 50% CO_2 plus 50% CO; at 900 °C, 5% CO_2 plus 95% CO). The reaction of carbon plus oxygen at such a temperature as produces carbon monoxide (say 900 °C, 95% CO plus 5% CO_2) and *evolves heat*; while the reaction of carbon plus CO_2, producing carbon monoxide at the same temperature *absorbs heat*. Accordingly it is possible to arrange the oxygen (free or as air) and CO_2 supply ratio in such a way that the desired temperature may be continuously maintained. The reduction of CO_2 by iron forms carbon monoxide plus ferrous oxide.

In valence bond terms, carbon monoxide is considered as a resonance compound with the structures

In molecular orbital terms the CO molecule is described as $CO(KK(z\sigma)^2(y\sigma)^2(x\sigma)^2(w\pi)^4)$, one $(z\sigma)$ pair being formed from the oxygen 2*s* electrons, and one $(y\sigma)$ pair held by the carbon *sp* hybrid. This $(y\sigma)^2$ pair offsets the dipole moment of the π electrons, and also accounts for the readiness with which the CO molecule coordinates with metals to form the carbonyls.

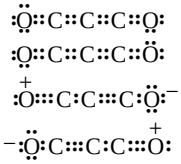
CARBON SUBOXIDE. C_3O_2, formula weight 68.03, colorless, toxic, gas at room temperature, very unpleasant odor, sp gr 2.10 (air = 1.00), 1.24 (liquid at −87 °C), mp −107 °C, bp 7 °C (760 torr), burns with a blue smoky flame, producing CO_2. When condensed to liquid, the oxide slowly changes at ordinary temperature to a dark red solid, soluble in water to a red solution. Reacts with water to form malonic acid, with hydrogen chloride to form malonyl chloride, with ammonia to form malonamide. Made by heating malonic acid or its ester at 300 °C under diminished pressure, and separation from simultaneously formed carbon dioxide and ethylene by condensation and fractional distillation.

Carbon suboxide has a linear structure, probably a resonance of four structures of which the last two below probably make a smaller contribution to the normal state of the molecule than the first two.



CARBON SULFIDES. See **Sulfur Compounds**.

CARBON TETRACHLORIDE. [CAS: 56-23-5] (tetrachloromethane), CCl_4, formula weight 82.82, heavy, colorless liquid with a characteristic nonirritant odor, nonflammable. Carbon tetrachloride contains 92 wt% chlorine. When in contact with a flame or very hot surface, the vapor decomposes to give toxic products, such as phosgene. It is the most toxic of the chloromethanes and the most unstable upon thermal oxidation. The commercial product frequently contains added stabilizers. Carbon tetrachloride is miscible with many common organic liquids and is a powerful solvent for asphalt, benzyl resin (polymerized benzyl chloride), bitumens, chlorinated rubber, ethylcellulose, fats, gums, rosin, and waxes. Dry carbon tetrachloride is noncorrosive to common metals except aluminum. When wet, CCl_4 hydrolyzes and is corrosive to iron, copper, nickel, and alloys containing those elements. About 90% of all CCl_4 manufactured goes into the production of chlorofluorocarbons:

$$2\ CCl_4 + 3\ HF \xrightarrow{\text{catalyst}} CCl_2F_2 + CCl_3F + 3\ HCl$$

Carbon tetrachloride was first made by chlorinating chloroform (1839). Later, CCl_4 was made by chlorinating carbon disulfide, CS_2, in the first commercial process, developed by Müller and Dubois (1893). See also **Carbon Disulfide**. In the 1890s, commercial manufacturing processes were being investigated by the United Alkali Co. in England. At the same time it was also produced in Germany, exported to the United States, and retailed as a spotting agent under the trade name Carbona. Large-scale production of carbon tetrachloride in the United States commenced in the early 1900s. By 1914, annual production fell just short of 4500 metric tons and was used primarily for dry cleaning and for charging fire extinguishers. During World War I, U.S. production of carbon tetrachloride expanded greatly; its use was extended to grain fumigation and the rubber industry. In 1934 it was supplanted as the predominant dry-cleaning agent in the United States by perchloroethylene, which is much less toxic and more stable. During the years immediately preceding World War II, trichloroethylene began to displace carbon tetrachloride from its then extensive market in the United States as a metal degreasing solvent. Carbon tetrachloride is more difficult to recover from degreasing operations, more readily hydrolyzed, and more toxic than trichloroethylene [CAS: 127-18-4] C_2HCl_3. The demands of World War II stimulated production and marked the beginning of its use as the starting material for chlorofluoromethanes, by far the most important application for carbon tetrachloride.

By the late 1940s, carbon tetrachloride was rapidly losing in competition not only with trichloroethylene but with perchloroethylene as well. In 1948 only 33% of the solvent used by the dry-cleaning industry was carbon tetrachloride and 60% was perchloroethylene; two years later the ratio of perchloroethylene to carbon tetrachloride was three to one. This technological change was not reflected in past sales of carbon tetrachloride, which exhibited a steady increase following World War II. It was at this time, ca 1950, that carbon tetrachloride found a new and rapidly expanding use as the starting material in the manufacture of fluorinated refrigerants, an application that by 1954 accounted for about half the total demand for carbon tetrachloride and over 95% of the demand today.

Physical and Chemical Properties

The physical properties of carbon tetrachloride are listed in Table 1.

Carbon tetrachloride readily dissolves stannic chloride, [CAS: 7646-78-8], $SnCl_4$, but not ferric chloride, [CAS: 7705-08-0], $FeCl_3$. Carbon tetrachloride forms a large number of binary and several ternary azeotropic mixtures; a partial list of the former is shown in Table 2.

Many polymer films, eg, polyethylene and polyacrylonitrile, are permeable to carbon tetrachloride vapor. Carbon tetrachloride vapor affects the explosion limits of several gaseous mixtures, eg, air-hydrogen and air-methane. The extinctive effect that carbon tetrachloride has on a flame, mainly because of its cooling action, is derived from its high thermal capacity.

As chlorination proceeds from methyl chloride to carbon tetrachloride, the length of the C−Cl bond is decreased from 0.1786 nm in the former to 0.1755 nm in the latter. At ca 400 °C (752 °F), thermal decomposition

of carbon tetrachloride occurs very slowly, whereas at 900–1,300 °C (1,652–2,372 °F) dissociation is extensive, forming perchloroethylene and hexachloroethane and liberating some chlorine. Subjecting the vapor to an electric arc also forms perchloroethylene and hexachloroethane, as well as hexachlorobenzene, elementary carbon, and chlorine.

A cold mixture of carbon tetrachloride and water, seeded with crystals of chloroform hydrate, yields crystals of a hydrate that decomposes at 1.4–1.49 °C (34.5–34.7 °F) and 101.3 kPa (760 mm Hg). Carbon tetrachloride is the chloromethane least resistant to oxidative breakdown. One gram of CCl_4 mixed with air and heated to 335 °C (635 °F) in the presence of iron produces 375 mg of phosgene. Only 2.4 mg of phosgene is produced from 1 g of chloroform under the same conditions. When mixed with excess water and heated to 250 °C (482 °F), carbon tetrachloride decomposes to carbon dioxide and hydrochloric acid; if the quantity of water is limited, phosgene is produced. This decomposition also occurs when wet carbon tetrachloride is exposed to uv irradiation (253.7 nm) at ordinary temperatures. Chloromethanes, hexachloroethane, and perchloroethylene are formed with steam at high temperatures. A similar decomposition occurs when carbon tetrachloride vapor is heated with some metallic oxides, eg, aluminum and magnesium oxides. An aqueous suspension of carbon tetrachloride droplets exposed to ultrasonic irradiation at ordinary temperature decomposes to carbon dioxide, chlorine, hydrogen chloride, perchloroethylene, and hexachloroethane. Dry carbon tetrachloride does not react with most commonly used construction metals, eg, iron and nickel; it reacts very slowly with copper and lead. Like the other chloromethanes, carbon tetrachloride is reactive, sometimes explosively, with aluminum and its alloys. The presence of moisture is probably a necessary requirement for the reaction with aluminum. When carbon tetrachloride is in contact with metallic sodium or potassium, or with a liquid alloy of both metals, shock may produce an explosion. On heating with sodium amalgam, decomposition takes place with the formation of sodium chloride and the liberation of carbon; at 400 °C (752°F) an analogous reaction takes place with mercury alone.

Carbon tetrachloride can be reduced to chloroform using a platinum catalyst or zinc and acid. With potassium amalgam and water, carbon tetrachloride can be totally reduced to methane. It is widely employed as an initiator in the dehydrochlorination of chloroethanes at 400–600 °C (752–1,112°F):

$$CH_2ClCH_2Cl + \xrightarrow{CCl_4} CH_2 = CHCl + HCl + CCl_4$$

When treated with aluminum bromide [CAS: 7727-15-3], $AlBr_3$, at 100 °C (212°F), carbon tetrachloride is converted to carbon tetrabromide [CAS: 558-13-4], CBr_4; reaction with calcium iodide [CAS: 10102-68-8], CaI_2, at 75 °C (167°F) gives carbon tetraiodide [507-25-5], Cl_4. With concentrated hydroiodic acid [CAS: 10034-85-2, HI, at 130 °C (266°F), iodoform [CAS: 75-47-8], CHI_3, is produced. Carbon tetrachloride is unaffected by gaseous fluorine at ordinary temperatures. Replacement of its chlorine by fluorine is brought about by reaction with hydrogen fluoride [CAS: 73602-61-6] at a temperature of 230–300 °C (392–572°F) and a pressure of 5.17–6.89 MPa (750–1000 psi), producing mainly dichlorodifluoromethane. Replacement of more than two chlorine atoms in carbon tetrachloride with fluorine from hydrogen fluoride requires other techniques.

Carbon tetrachloride forms telomers with ethylene and certain other olefins. The mixture of liquid products derived from ethylene telomerization may be represented $CCl_3(CH_2CH_2)_nCl$ in which n is a small number. Reaction of ethylene and carbon tetrachloride takes place under pressure and is induced by the presence of a peroxygen compound, eg, benzoyl peroxide [CAS: 94-36-0] or metal carbonyls.

Benzene [CAS: 71-43-2] reacts with carbon tetrachloride in the presence of anhydrous aluminum chloride to give triphenylchloromethane; no tetraphenylmethane is formed. At elevated temperatures, carbon tetrachloride attacks silica gel forming a silicon oxychloride.

Manufacture

For many years chlorination of carbon disulfide was the only process used to manufacture carbon tetrachloride. In the 1950s, chlorination of hydrocarbons, particularly methane, became more popular in the United States. Many hydrocarbons and chlorinated hydrocarbons are now used to feed chlorination reactors to make carbon tetrachloride.

Carbon Disulfide Chlorination. The chlorination of carbon disulfide [CAS: 75-15-0] is a very old method of producing carbon tetrachloride that is still practiced commercially in the United States. In this process CS_2 reacts continuously with chlorine in an annular reactor at 105–130 °C (221–266°F). Product CCl_4 is separated by distillation to a CS_2 content of 0–5 ppm. By-product S_2Cl_2 is reduced in a reactor at 450 °C (842°F) with hydrogen without a catalyst to give sulfur of 99.985% purity. Other processes use ferric chloride as a catalyst.

Chlorination of Hydrocarbons or Chlorinated Hydrocarbons. Chlorination at pyrolytic temperatures is often referred to as chlorinolysis because it involves a simultaneous breakdown of the organics and chlorination of the molecular fragments. A number of processes have been described for the production of carbon tetrachloride by the chlorinolysis of various hydrocarbon or chlorinated hydrocarbon waste streams, but most literature reports the use of methane as the primary feed. The quantity of carbon

tetrachloride produced depends somewhat on the nature of the hydrocarbon starting material but more on the conditions of chlorination. The principal by-product is perchloroethylene with small amounts of hexachloroethane, hexachlorobutadiene, and hexachlorobenzene. In the Hüls process, a 5:1 mixture by volume of chlorine and methane reacts at 650 °C (1,202°F); the temperature is maintained by control of the gas flow rate. A heat exchanger cools the exit gas to 450 °C (842°F), and more methane is added to the gas stream in a second reactor. The use of a fluidized-bed-type reactor is known. Carbon can be chlorinated to carbon tetrachloride in a fluidized bed.

Oxychlorination of Hydrocarbons. Methane was oxychlorinated with HCl and oxygen over a 4:3:3 $CuCl–CuCl_2–KCl$ molten mixture to give a mixture of chlorinated methanes, 60 mol % of which was carbon tetrachloride. Aqueous 20% HCl was used in the multistep process as the source of the acid. Anhydrous HCl is more typically used. Other oxychlorination processes can be made to yield high percentages of carbon tetrachloride starting from any of several hydrocarbon feeds. The typical reaction temperature is 400–600 °C (752–1, 112°F).

Standards and Analysis

The most widely used method of analysis for carbon tetrachloride is gas chromatography. A capillary column medium that does a very good job in separating most chlorinated hydrocarbons is methyl silicone or methyl (5% phenyl) silicone. The detector of choice is a flame ionization detector. Typical molar response factors for the chlorinated methanes are methyl chloride, 2.05; methylene chloride, 2.2; chloroform, 2.8; and carbon tetrachloride, 3.1, where methane is defined as having a molar response factor of 2.00. Most two-carbon chlorinated hydrocarbons have a molar response factor of about 1.0 on the same basis.

A good technical grade of carbon tetrachloride contains not more than the following amounts of impurities: 1 ppm acidity as HCl, 1 ppm carbon disulfide if manufactured by carbon disulfide chlorination, 20 ppm bromine, 200 ppm water, and 150 ppm chloroform. The residue should not exceed 10 ppm on total evaporation. The product should give no acid reaction with bromophenol blue, and the starch iodine test should indicate the absence of free chlorine.

When heated with pyrocatechol [CAS: 120-80-9], $C_6H_6O_2$, copper powder, and alcoholic sodium hydroxide, carbon tetrachloride gives a blue color that changes to red on addition of hydrochloric acid. This color reaction is not produced by chloroform. Quantitative analysis of carbon tetrachloride may be done by first decomposing the sample free of organic and inorganic chlorides, heating in a sealed tube with alcoholic potash, and subsequently determining the potassium chloride formed as the silver halide. The Zeiss interference refractometer has been used to determine the concentration of carbon tetrachloride vapor in air.

Health and Safety

Carbon tetrachloride is the oldest and was the most extensively used chlorinated solvent in degreasing and dry-cleaning operations for many years. Consequently, its narcotic and toxic properties have been the subject of much investigation. Careful investigations have repeatedly shown carbon tetrachloride to be one of the most harmful of the common solvents.

Carbon tetrachloride is toxic by inhalation of its vapor and oral intake of the liquid. Inhalation of the vapor constitutes the principal hazard. Exposure to excessive levels of vapor is characterized by two types of response: an anesthetic effect similar to that caused by compounds such as diethyl ether and chloroform; and organic injury to the tissues of certain organs, in particular the liver and kidneys. This type of injury may not become evident until 1–10 days after exposure. The nature of the effect is determined largely by the vapor concentration but the extent or severity of the effect is determined principally by the duration of exposure.

Organic injury may result from single prolonged exposure to carbon tetrachloride vapor or from repeated short duration exposures. Serious and fatal injuries are usually the result of a single prolonged exposure. Vapor concentrations of only a few hundred parts per million may be sufficient to cause injury. Symptoms of exposure include nausea and vomiting, headache, burning of eyes and/or throat, drowsiness, abdominal pain or discomfort, weakness, and muscle stiffness and soreness. Prolonged or repeated exposure to carbon tetrachloride vapor or liquid may result in subacute or chronic poisoning. Consequently, a threshold limit value of 5 ppm by volume of carbon tetrachloride in air has been established by ACGIH as a maximum safe concentration for daily eight-hour exposure. The OSHA permissible exposure level is 2 ppm.

Occasional brief contacts of liquid carbon tetrachloride with unbroken skin do not produce irritation, though the skin may feel dry because of removal of natural oils. Prolonged and repeated contacts may cause dermatitis, cracking of the skin, and danger of secondary infection. Carbon tetrachloride is apparently absorbed through the skin but at such a slow rate that there is no significant hazard of systemic poisoning in normal industrial operations.

In most situations, adequate, usually forced, ventilation is necessary to prevent excessive exposure. Persons who drink alcohol excessively or have liver, kidney, or heart diseases should be excluded from any exposure to carbon tetrachloride. All individuals regularly exposed to carbon tetrachloride should receive periodic examinations by a physician acquainted with the occupational hazard involved. These examinations should include special attention to the kidneys and the liver. There is no known specific antidote for carbon tetrachloride poisoning. Treatment is symptomatic and supportive. Alcohol, oils, fats, and epinephrine should not be given to any person who has been exposed to carbon tetrachloride. Following exposure, the individual should be kept under observation long enough to permit the physician to determine whether liver or kidney injury has occurred. Artificial dialysis may be necessary in cases of severe renal failure.

Toxicity. The experimental exposure of laboratory animals to the vapors of CCl_4 has shown it to be very toxic by inhalation at concentrations easily obtainable at ambient temperatures. An overexposure to carbon tetrachloride has been known to cause acute but temporary loss of renal function.

Uses

Carbon tetrachloride was formerly used for metal degreasing, dry-cleaning fluid, fabric spotting fluid, fire extinguisher fluid, grain fumigant, and reaction medium. However, as its toxicity became recognized, it was replaced by less toxic chlorinated hydrocarbons in metal and fabric cleaning applications. During the 1950s the demand for carbon tetrachloride as a raw material in the manufacture of chlorofluorocarbons increased and the net result was continued growth for the product. In 1970, carbon tetrachloride was banned from all use in consumer goods in the United States. Its current principal applications include chlorofluorocarbon production (CFC-11 and -12) and some small use as a reaction medium or chemical intermediate. Chlorofluorocarbons 11 and 12, trichloromonofluoromethane [CAS: 75-69-4], and dichlorodifluoromethane [CAS: 75-71-8], respectively, are made by the catalytic reaction of hydrogen fluoride with carbon tetrachloride. These products will decline significantly long term as the Montreal Protocol takes effect. See also **Montreal Protocol**.

CARBONYLS. See **Carbon**.

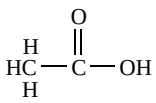
CARBONYLS (Chlorinated). See **Chlorinated Organics**.

CARBORANE. A crystalline compound composed of boron, carbon, and hydrogen. It can be synthesized in various ways, chiefly by the reaction of a borane (penta-or deca-) with acetylene, either at high temperature in the gas phase or in the presence of a Lewis base. Alkylated derivatives have been prepared. Carboranes have different structural and chemical

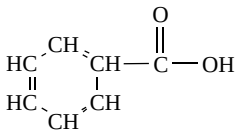
characteristics and should not be confused with hydrocarbon derivatives or boron hydrides. The predominant structures are the cage type, the nest type, and the web type, these terms being descriptive of the arrangement of atoms in the crystals. Active research on carborane chemistry has been conducted under sponsorship of the U.S. Office of Naval Research. http://www.onr.navy.mil/

CARBORUNDUM. See **Silicon**.

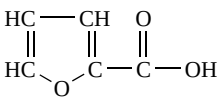
CARBOXYLIC ACIDS. The general formula for a carboxylic acid is  . In terms of structure, a carboxylic acid may be aliphatic, carbocyclic, or heterocyclic:



Aliphatic
acetic acid

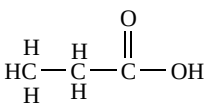


Carbocyclic or
aromatic benzoic acid



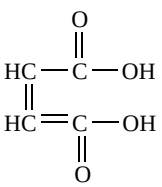
Heterocyclic
pyromucic or furoic acid

Or, a carboxylic acid may be classified in terms of the number of carboxyl (−COOH) groups which it contains. If one carboxyl group, it is designated as *mono*carboxylic; if two groups, as *di*carboxylic; if three groups, as *tri*carboxylic; and if four groups, as *tetra*carboxylic:



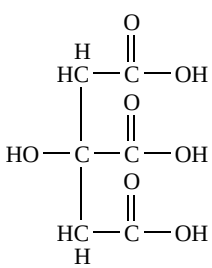
Propionic acid

(*mono*)



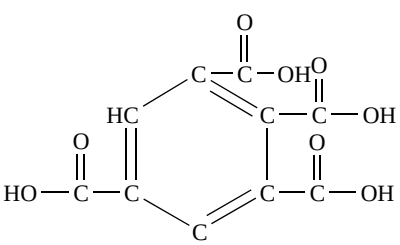
Maleic acid or
cis-ethylene dicarboxylic acid

(*di*)



Citric acid

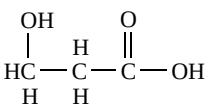
(*tri*)



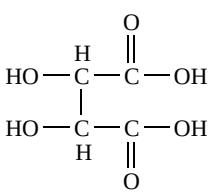
1,2,3,5-Benzenetetracarboxylic acid
or mellophanic acid

(*tetra*)

When a carboxylic acid contains a hydroxyl group in addition to that of the principal −COOH grouping, the term *hydroxy* is sometimes used. If there is only one additional hydroxyl group, the acid may be designated simply as a *hydroxycarboxylic* acid; if two groups, a *di*hydroxycarboxylic acid; if three groups, a *tri*hydroxycarboxylic acid.



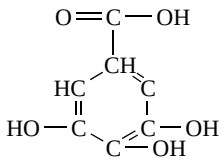
Hydracrylic acid or
β-hydroxypropionic acid
A hydroxymono-
carboxylic acid



Tartaric acid
A dihydroxycarboxylic acid

A carboxylic acid may be classified in accordance with the number of available hydrogens for salt formation. If only one hydrogen is available, the acid is *monobasic*; if two hydrogens are available, the acid is *dibasic*; if three or more hydrogens are available, the acid is *polybasic*.

A carboxylic acid also may be classified from the standpoint of other groups it contains. An *aldehydic* carboxylic acid contains the CHO group. An example is glyoxalic acid, $CHO \cdot COOH$. An *amino* carboxylic acid contains the NH_2 group. An example is carbamic or amino-formic acid, NH_2COOH. A *ketonic* carboxylic acid contains the CO group. An example is benzoylacetic acid, $C_6H_5 \cdot CO \cdot CH_2 \cdot COOH$. In the case of a *phenolic* carboxylic acid, the acid is structurally derived from benzoic acid, with uniting of the OH group with a carbon of the nucleus.



Gallic or pyrogallol carboxylic acid
or 3,4,5-trihydroxybenzoic acid
A trihydroxymonocarboxylic acid

There are several homologous series of carboxylic acids, including:

$C_nH_{2n}O_2$	Saturated monobasic fatty acids
$C_nH_{2n-2}O_2$	Unsaturated monobasic fatty acids
$C_nH_{2n-4}O_2$	Propioloic acid series
$C_nH_{2n}(COOH)_2$	Dicarboxylic acids, where $n = 0$ for oxalic acid
$C_nH_{2n}(OH)(COOH)$	Hydroxymonocarboxylic acids, where $n = 0$ for carbonic acid

Fatty Acids. The simplest or lowest member of the fatty acid series is formic acid, HCOOH, followed by acetic acid, CH_3COOH, propionic acid with three carbons, butyric acid with four carbons, valeric acid with five carbons, and upward to palmitic acid with sixteen carbons, stearic acid with eighteen carbons; and melissic acid with thirty carbons. Fatty acids are considered to be the oxidation product of saturated primary alcohols. These acids are stable, being very difficult (with the exception of formic acid) to convert to simpler compounds; they easily undergo double decomposition because of the carboxyl group; they combine with alcohols to form esters and water; they yield halogen-substitution products; they convert to acid chlorides when reacted with phosphorus pentachloride; and their acidic qualities decrease as their formula weight increases.

Monohydroxy Fatty Acids. Structurally, these acids may be considered as the monohydroxy derivatives of the fatty acids. Included among these acids are hydroxyacetic acid (glycollic acid) and β-hydroxypropionic acid (β-lactic acid). These acids generally are syrupy liquids that tend to give up water readily and form crystalline anhydrides; they decompose when volatilized, and they are soluble in water and usually in alcohol and ether.

Polyhydric Monobasic Acids. Structurally, these acids are considered to be the oxidation products of polyhydric alcohols. However, a number of them can be formed from the oxidation of sugars. The careful oxidation of glycerol will yield a syrupy liquid, glyceric acid, an example of a dihydroxymonobasic carboxylic acid.

Aromatic Carboxylic Acids. In many ways, these acids are similar to the fatty acids. Generally, they are crystalline solids that are only slightly soluble in water, but most often they dissolve easily in alcohol or ether. The simpler aromatic acids may be distilled (or sublimed) without decomposition. The more complex acids, such as the phenolic and polycarboxylic aromatic acids, break down when heated, yielding carbon dioxide and a simpler compound. As an example, salicylic acid degrades to carbon dioxide and phenol. In nature, the aromatic acids are found in balsams, animal organisms, and resins.

The monobasic saturated aromatic acids include benzoic, hippuric, toluic acids (three structures), phenylacetic, phenylchloracetic, and dimethylbenzoic acid. Among the monobasic unsaturated acids are cinnamic, atropic, and phenylpropionic acids. The saturated phenolic acids include gallic and

salicylic acids. The alcohol acids include amygdalic, tropic, and mandelic acids. One example of an unsaturated monobasic phenolic acid is coumaric acid.

Formation of Carboxylic Acids. Commercially, these acids are produced in several ways: (1) oxidation of relevant alcohol — e.g., acetic acid from ethyl alcohol; (2) oxidation of relevant aldehyde — e.g., acetic acid from acetaldehyde; (3) bacterial fermentation of dilute alcohols; (4) reacting a methyl ketone with sodium hypochlorite (haloform reaction); (5) carbonation of Grignard reagents; (6) hydrolysis of nitriles; (7) malonic ester synthesis route; (8) oxidation of relevant alkylaromatic — e.g., benzoic acid from toluene; (9) reaction of an alkali metal phenolic with carbon dioxide; and (10) hydrocarboxylation of olefins — e.g., butyric acid from propylene.

CARBUNCLE (Geology). A term applied to that variety of garnet, almandine, which was much used formerly for jewelry, when cut en cabochon. It is derived from the Latin, *carbunculus*, a small spark, in reference to the glowing effect of that style of cutting. In the early part of the Christian Era, the term seems to have been used for red stones of all sorts.

CARBURETION. The fuel for an internal combustion engine must be well mixed with the air required for combustion. This is particularly true of the Otto cycle engine, inasmuch as thorough distribution of particles of fuel in the air is essential to rapid and complete explosive combustion of the fuel in that cycle. One of the most effective means of mixing the particles of a liquid fuel with air is by vaporization. The vaporizing and mixing of a liquid fuel with air in the correct proportions is called *carburetion*; the device used is called a *carburetor*.

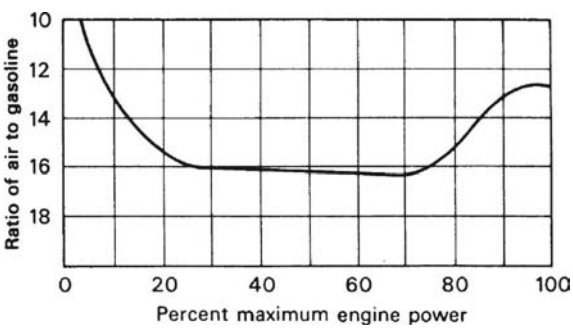

Fig. 1. Optimal carburetor performance for gasoline engine.

By using multiple jets, adjustable orifices, and other intricacies, commercial carburetors attain mixture control approximating the desirable performance for a gasoline engine as shown in Fig. 1. Increasing air pollution standards have exacted greater demands on carburetor performance and most of these demands have been met by utilizing solid-state controls over carburetor optimization.

CARBURIZING. Machine parts requiring high strength, hardness, and toughness can often be made by either of two methods, one based on the use of a medium-carbon steel (0.30–0.50% carbon) heat treated to the required properties, and the other based on the use of a low-carbon steel (0.08–0.25% carbon) carburized to give a high-carbon surface layer and then heat treated. The carburized part will have a harder, more wear-resistant surface and a tougher core than the heat-treated medium-carbon steel. Transmission gears, camshafts, and piston pins are typical parts which can be made advantageously of carburizing grade steels.

The process consists of heating the fully machined part in an atmosphere rich in carbon monoxide or hydrocarbon gases at a temperature in the range 1650–1800 °F (899–982 °C). Reactions at the surface of the metal liberate atomic carbon which is readily dissolved by the steel and diffuses inward from the surface. In a typical carburized case a depth of penetration of 0.05 inch (0.13 centimeter) was obtained in 4 hours at 1700 °F (927 °C). The maximum carbon content at the surface was 1.10%. Shallow cases under 0.02 inch (0.05 centimeter) are useful for many purposes and very deep cases over 0.10 inch (0.25 centimeter) thick are required for gears for heavy machinery and for armor plate.

The process is most often carried out in sealed containers in which the parts are packed in carburizing compound consisting of a mixture of charcoal, coke, and other carbonaceous solids, together with barium carbonate and other compounds which act as energizers. At high temperatures these solids burn slowly, maintaining a supply of carbon monoxide. Carburizing is also carried out in batch-type and continuous-type furnaces in an atmosphere of natural gas, propane, butane, or specially mixed gases. Liquid baths consisting mainly of molten cyanide and chloride salts are also used for surface hardening. These baths supply both nitrogen and carbon to the surface of the steel, and where nitrogen is the principal hardener the process is known as cyaniding. Nitrogen hardens steel by forming hard compounds with iron and with certain alloying elements that may be present such as aluminum, chromium, and vanadium. See also **Nitriding**. In general, the salt-bath methods give shallower but harder cases than regular solid-pack carburizing. The pieces are quenched for hardening directly from the bath.

Carburized steels may also be quenched in oil or water directly from the box or furnace, or they may be cooled and reheated for hardening. A low temperature tempering treatment is given for relief of quenching stresses. A surface hardness of 60 Rockwell "C" is readily obtained, and when medium alloy steels of fine grain size are used, the strength and ductility of the core is exceptionally high, for example, 165,000 psi (11,224 atmospheres) tensile strength and 18% elongation.

CARCINOGENS. A carcinogen may be defined as a substance, normally not present in the body that, when absorbed by the body in some manner (breathing, eating, drinking, injecting, skin contact, etc.), will induce the formation of malignant neoplasms (cancers); that is, a carcinogen initiates and nurtures tumor growth.

Progress of the ensuing carcinogenesis is dependent upon many factors, such as the frequency of exposure to the carcinogen (single, multiple, continuous), the concentration of the carcinogen when absorbed (ranging from parts per billion to parts per million and greater), as well as the poorly understood "natural resistance" of individual organisms to expel a given carcinogen. Very important is the total length of time over which exposure has occurred (ranging from seconds to years). Because of these extreme variations, group studies of environmental carcinogenicity are difficult and frequently unreliable. Consequently, the dangers of carcinogens can be over- or underestimated.

In terms of exposure to carcinogens by the average individual, particular attention should be given (1) to the *habitat* (water and air contamination; use of household chemical products), (2) the *workplace* (industrial chemicals), and, of course, (3) the *general environment*, particularly in industrialized urban areas.

There is much the average person can do to minimize exposure to carcinogens as, for example, carefully selecting garden chemicals and using gloves to prevent exposure of the skin when hazardous materials, including paint solvents, are handled — and in assuring good ventilation and air conditioning of living quarters to remove airborne particles. Within practical limitations, it is good practice to consider the local neighborhood environmental quality to avoid locating near known sources of air pollution. A check on possible radon pollution at a given site may be in order. See also **Radon**.

Millions of people are avoiding exposure to the carcinogenic substances in tobacco. Millions of others are checking their dietary intake to avoid any substances that are suspected of promoting forms of carcinogenesis within the body, which often are of a long-term nature.

Until the early 1950s, the concept prevailed that the activity of carcinogenic chemicals was somehow related to the fact that they were synthetic "unnatural" substances that, since they are not present in the natural environment, were not factors of selection during developing life processes; hence, contemporary living organisms were not equipped for effective metabolic "detoxification" of these compounds. In the intervening years, however, a number of carcinogenic compounds of plant and fungal origin have been identified, including: safrole [CAS: 94-59-7] $C_{10}H_{10}O_2$ in sassafras; capsicine in chili peppers; various tannins; cycasin [14901-08-7] $C_8H_{16}N_2O_7$ in the cycad groundnut; parasorbic acid in mountain ash berry; pyrollizidine alkaloids in *Senecio* shrubbery; and patulin, griseofulvin, penicillin G, and actinomycin produced by various molds. It also appears that liver cancer in Africa and the Peoples Republic of China is caused by interaction of aflatoxin and the co-carcinogen, hepatitis B virus. The number and variety of identified naturally occurring carcinogens continues to increase at a rapid rate.

Grouping of Carcinogens

Chemically identified carcinogens may be grouped in many ways, including a division into inorganic ions and organic compounds. The inorganic carcinogens contain the elements beryllium [CAS: 7440-41-7], cadmium [CAS: 7440-43-9], iron [CAS: 7439-89-6], cobalt [CAS: 7440-48-4], nickel [CAS: 7440-02-0], silver [CAS: 7440-22-4], lead [CAS: 7439-92-1], zinc [CAS: 7440-66-6], and possibly arsenic [CAS: 7440-38-2]; these can form coordination compounds and/or react with sulfhydryl groups. Also asbestos powder is a powerful carcinogen toward the lung upon inhalation (asbestos cancer of miners). See also **Asbestos**. In recent years, the characteristics of asbestos and related substances have caused much controversy in connection with the pollution of certain waters, notably Lake Superior, by taconite processing waste products which contain fibers that have been compared with asbestos fibers. Most likely this situation will require some years for full scientific and legal resolution. Distinction must be made, however, between the supposed carcinogenic properties of asbestos materials and the silicosis engendered by the inhalation of other silicate dusts. There appears no reason to believe that in this latter instance the lesions are related to lung cancer per se.

The organic carcinogens may be subdivided in several ways, including: (a) condensed polycyclic aromatic hydrocarbons and heteroaromatic polycyclic compounds; (b) aromatic amines and *N*-aryl hydroxylamines; (c) amino-azo dyes and di-arylazo compounds; (d) aminostilbenes and stilbene analogues of sex hormones. Further breaking down the aliphatic carcinogens, these include: (1) alkylating agents (such as sulfur and nitrogen mustards, derivates of ethyleneimine [CAS: 151-56-4], lactones, epoxides, alkane-*α*-*ω*-*bis*-methanesulfonates, certain dialkylnitrosamines, and ethionine [CAS: 13073-35-3]; (b) lipophilic agents and hydrogen-bond reactors; this class comprises a wide variety of agents, such as chlorinated hydrocarbons (chloroform [CAS: 67-66-3], carbon tetrachloride [CAS: 56-23-5], and compounds used as pesticides under the names aldrin [CAS: 309-00-2] and dieldrin [CAS: 60-57-1]), bile acids, certain water-soluble high polymers, certain phenols [CAS: 64743-03-9], urethane [CAS: 51-79-6] and some of its derivatives, thiocarbonyls, and cycloalkynitrosamines; (c) naturally occurring carcinogens.

Until the mid-1970s, most studies in chemical carcinogenesis were experimental, i.e., suspect materials were placed continuously on the skin or in the diets of laboratory animals who were then observed to see if any neoplasms developed. While such work was invaluable in identifying materials which should be removed from the environment, or otherwise avoided, it did not provide any major understanding of the basis of chemical carcinogenesis. Indeed, many of the dermal tests merely indicated allergic reactions and many of the dietary tests showed that some animals thrived on trace additives.

Over the past decade, however, emphasis has been placed upon the molecular biology of carcinogenesis and it has been demonstrated that, in the first steps of carcinogen interaction, most carcinogens must be activated by the host cell's metabolism. Cell culture techniques have demonstrated that normal healthy cells can be transmuted into malignancies by certain chemicals. This in vitro work, however, has yet to transform human cells in the same way.

There is some evidence that the form of the chemical carcinogen that ultimately reacts with cellular macromolecules must contain a reactive electrophilic center, that is, an electron-deficient atom that can attack the numerous electron-rich centers in polynucleotides and proteins. As examples, significant electrophilic centers include free radicals, carbonium ions, epoxides, the nitrogen in esters of hydroxylamines and hydroxamic acids, and some metal cations. It is believed that carcinogens, which in themselves are not electrophiles, are metabolized to electrophilic derivatives that then become the "ultimate" carcinogens.

In this context, oxygen free radicals have been linked to many diseases other than cancer. There is much evidence that such free radicals may be developed in any kind of inflamed tissues and in chronically irritated organs the free radicals produced may convert exogenous chemicals to active carcinogens.

Workplace Carcinogens

During the early 1990s, an extensive study of occupational medicine was undertaken by the Yale-New Haven Occupational Medicine Program, Yale University School of Medicine, and the Occupational Medicine Program, University of Washington School of Medicine. M.R. Cullen, M.G. Cherniack, and L. Rosenstock, members of the Yale-Washington team, reported, "The success of epidemiologists in the 1960s and 1970s in establishing the excess cancer risk for workers exposed to several widespread workplace agents, most notably asbestos, benzene, and benzidine dyes, raised the possibility that cancer overall might largely be attributable to exposure in the workplace. Ecologic (sic) data showed some congruity between regions with high rates of cancer and high levels of industrial activity, and an unpublished government document purporting to show that 20 to 38 percent of all cancers were attributable to workplace exposure received circulation and attention. The past decade (1980s) has witnessed a considerable sobering and refinement of the prevailing views. Although over 300 compounds have been shown to have carcinogenic potential on the basis of their effects in laboratory animals, no new class of compounds has been added to the list of previously established human carcinogens." See Tables 1 and 2.

Carcinogen Mechanisms

The biochemical pathways in the cell are closely interconnected and are in a state of dynamic equilibrium (homeostasis). This equilibrium is maintained by feedback relationships existing between a great number of pathways. Chemical communication between subcellular organelles, such as the nucleus (within which the chromosomes contain the genetic blueprints for cell reproduction and the synthetic processes of cell life), the mitochondria (the powerhouse of the cell, which assures the synthesis of the universal cellular fuel, ATP, through the metabolism of carbohydrates and fatty acids), and the endoplasmic reticulum (synthesizing the proteins of the cell and assuring the metabolic breakdown — detoxification — of a multitude of endogenous and foreign compounds), depends on the constant interchange of a large variety of metabolic products and inorganic ions between them. There are probably a very great number of loci (receptor sites) upon which these regulatory chemical "stimuli" act. The receptor sites are of an enzymatic and nucleic acid nature. Other control points of protein character regulate the morphology of the intracellular lipoprotein membranes, which serve as "floor space" to the organized arrangements of multi-enzyme systems. The specificity of compounds of chemical control toward given receptor sites is due to a three-dimensional geometric "fit" following the lock and key analogy. Such is the general scheme of functional interrelationships in monocellular organisms which, hence, in a favorable medium multiply unchecked to the limit of the availability of nutrients.

In multicellular organisms, the subordination of the individual cells to the whole is assured by the existence of additional receptor sites which enable the cells to be response to chemical "stimuli" emitted by neighboring cells in the tissue and to hormonal regulation by the endocrine system in higher organisms. Hence, depending on the requirements of the moment, cells may remain stationary or may undergo cell division because of the need for repair of tissue injury, they may secrete different products, or they may perform some other specialized function depending on the nature of the particular tissue.

Carcinogenic substances are nonspecific cell poisons that cause the alterations and hence functional deletion of a large number of metabolic control sites. Present evidence suggests that these alterations are produced by the accumulation of the carcinogen in subcellular organelles, by covalent binding of the carcinogen to cellular macromolecules (proteins and nucleic acids) through metabolism, and by denaturation (i.e., destruction of the three-dimensional geometry) of the control sites through secondary valence

TABLE 1. DEFINITELY ESTABLISHED WORKPLACE CARCINOGENS[a]

Operations/processes carcinogen	Primary body organ where encountered	Affected
Para-aminodiphenyl	Chemical processing	Urinary bladder
Asbestos	Construction, asbestos mining and milling, production of friction products (brake Linings, etc.), and cement	Pleura and bronchus (lungs) and peritoneum
Arsenic	Copper mining and smelting	Skin, bronchus, liver
Alkylating agents (mechlorethamine hydrochloride) and bis [chloromethyl] ethe	Chemical processing	Bronchus
Benzene	Chemical and rubber processing, petroleum refining	Bone marrow
Benzidine, beta naphthylamine and derived dyes	Dye and textile production	Urinary bladder
Chromium and chromates	Tanning, pigment making	Nasal sinus, bronchus
Ionizing radiation	Nuclear industry, health care settings bone marrow	Skin, thyroid, bronchus,
Radon	Uranium and hematite mining	Bronchus
Radium	Watch painting	Bone
Nickel	Nickel plating	Nasal sinus, bronchus
Polynuclear aromatic hydrocarbons (from coke, coal tar, shale, mineral oils and creosote)	Steelmaking, roofing, chimney cleaning	Skin, scrotum, bronchus
Vinyl chloride monomer	Chemical processing	Liver
Wood dust	Cabinetmaking, carpentry	Nasal sinus

[a] Adapted from Yale-Washington Occupational Medicine Program

TABLE 2. SUSPECTED (WIDELY USED) CARCINOGENS[a]

Operations/Processes Agent	Primary Body Organ Where Encountered	Affected
Beryllium	Beryllium processing, aircraft manufacturing, electronics, secondary smelting	Bronchus
Cadmium	Smelting, battery making, welding	Bronchus
Ethylene oxide	Hospitals, hospital supply manufacturing	Bone marrow
Formaldehyde	Plastics, textile and chemical processing; health care	Nasal sinus, bronchus
Synthetic mineral fibers (fiberglass)	Fiber manufacturing and installation	Bronchus
Polychlorinated biphenyls (PCBs)	Electrical equipment manufacturing/maintenance	Liver
Organochlorine pesticides (e.g., chlordane, dieldrin)	Pesticide manufacture and agricultural applications	Bone marrow
Silica	Casting, mining, refracting	Bronchus

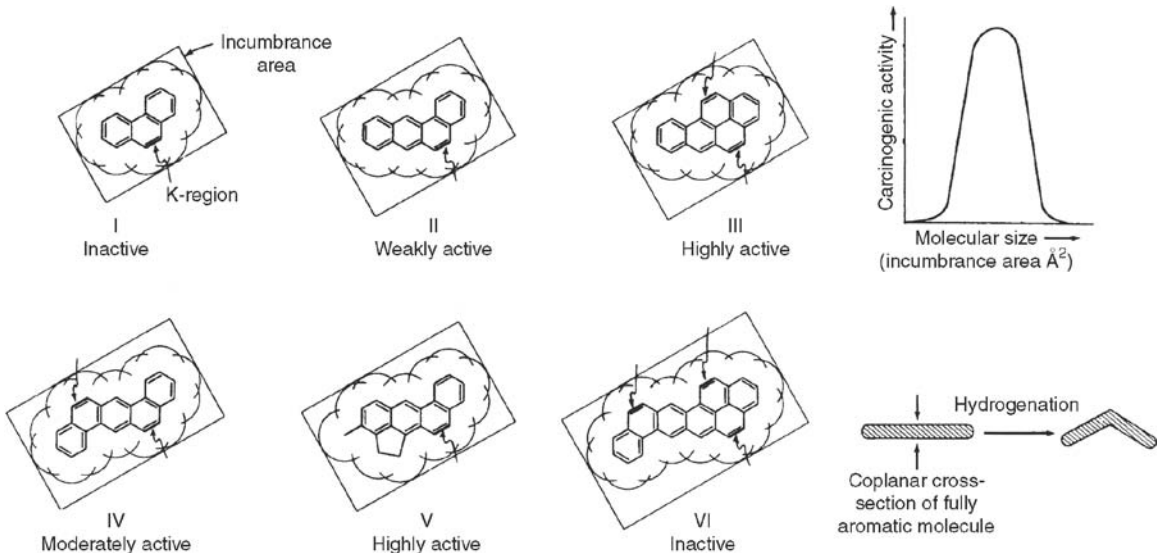

Fig. 1. Polycyclic aromatic hydrocarbons.

interactions (hydrogen bonds, hydrophobic bonding, etc.) with the carcinogen. Early stages of tumor induction generally coincide with extensive cell death (necrosis) in the target tissues because a number of the biochemical lesions cause the irreversible blocking of metabolic pathways essential for cell life. However, because of the random distribution of the biochemical lesions in the cell population, in a small number of cells vital pathways are only slightly damaged and the lesions involve those sites and pathways which are not essential for cell life proper, but are necessary for organismic control. Thus, due to the action of the carcinogen, these cells escape physiological control and revert to a simpler, less specialized cell type (i.e., dedifferentiate). Such cells respond to continuous nutrition with continuous growth, which is an essential characteristic of malignant tumor cells.

The high incidence of skin cancer in coal tar workers was recognized as early as 1880. The carcinogenic activity of coal tar was demonstrated in 1915, when Yamagiwa and Ichikawa obtained epitheliomas (malignant tumor originating from epithelial cells) by its prolonged application to the ears of rabbits. Identification of the active material (in 1933) as the polycyclic aromatic hydrocarbon 3,4-benzopyrene (III, Fig. 1) is due to Cook, Kennaway, Hieger and their co-workers. This discovery was followed up by the synthesis and testing of a considerable variety of polycyclic aromatic hydrocarbons. All compounds of this class may be regarded as composed of condensed benzene rings. The arrangement of the hexagonal rings in various patterns results in a variety of compounds having different physical, chemical, and biological properties. However,

not all polycyclic aromatic hydrocarbons possess carcinogenic activity; certain requirements of molecular geometry must be met.

For maximum activity, the molecule must have (Fig. 1): (a) an optimum size; (b) a coplanar molecular configuration, meaning that all hexagonal rings must lie flatly in one plane; in fact, hydrogenation of many of the active hydrocarbons results in buckled molecular conformation and this is concomitant with partial or total loss of activity; and (c) at least one meso-phenanthrenic double bond, also called the K-region (indicated by arrows in Fig. 1) of high π-electron density (i.e., of high chemical reactivity). In addition to III, 1,2,5,6-dibenzanthracene (IV) [CAS: 53-70-3], and 20-methylcholanthrene (V) [CAS: 56-49-5] are commonly used to study the experimental induction of tumors. The activity of most hydrocarbon carcinogens was tested on the skin of mice and the subcutaneous connective tissue of mice and rats. There is a vast body of evidence indicating that 3,4-benzopyrene [CAS: 50-32-8] and other carcinogenic hydrocarbons are formed during pyrogenation or incomplete burning of almost any kind of organic material. For example, carcinogenic hydrocarbons have been identified in overheated fats, broiled and smoked meats, coffee, burnt sugar, rubber, commercial paraffin oils and solids, soot, the tar contained in the exhaust fumes of internal combustion engines, cigarette smoke, etc.

It must be pointed out, however, that direct evidence of human involvement is lacking. For example, despite much publicity, N-nitrosamines have *not* been proven to be causative agents on induction of human cancer. They are, however, patent carcinogens in *experimental animals*.

Attention to the carcinogenic aromatic amines was drawn by the high incidence of urinary bladder tumors in dye works exposed to 2-naphthylamine [CAS: 91-59-8] (VII, Fig. 2), and benzidine (IX). The carcinogenic activity of VII, IX, and 4-aminobiphenyl [CAS: 92-67-1] (X) toward the bladder of the dog and the mouse has been demonstrated. In the rat, however, there is a change in target specificity, and tumors are induced by IX and X in the liver, mammary gland, ear duct, and small intestine. Carcinogenic activity is considerably heightened in 2-acetylaminofluorene [CAS: 53-96-3] (XI) without change of target specificity. Increased activity is due to the fact that XI is more coplanar than X, because of the internuclear methylene ($-CH_2-$) bridge in the former. 2-Acetylaminofluorene was proposed as an insecticide before its carcinogenic activity was accidentally discovered; it is a ubiquitous, potent carcinogen in a variety of species. Changing the internuclear bridge of XI to $-CH{=}CH-$, as in 2-aminophenanthrene (XII), causes a shift in target specificity; thus, in the rat, XII is inactive toward the liver, but in addition to inducing tumors in the mammary gland, ear duct, and small intestine, it produces leukemia. Compound XII represents a structural link between the aromatic amine and polycyclic hydrocarbon carcinogens (compare XII with I); it is also interesting in this respect that 2-amino-anthracene (VIII), which is a higher homologue of VII, is inactive toward the bladder, but is able to induce skin tumors in rats.

4-Dimethylamino-azobenzene [CAS: 60-11-7] (XIII) is the parent compound of the amino-azo dye carcinogens; it is also known in the earlier literature as Butter Yellow, because it was used to color butter and vegetable oils before its carcinogenic activity was discovered. Many derivatives of XIII have been prepared and tested for carcinogenic activity. In the rat, the amino-azo dye carcinogens, administered in the diet, specifically induce hepatomas. Tumor induction by most of the amino-azo dyes is delayed or inhibited by high dietary levels of riboflavin (vitamin B_2) or protein. Replacement of the $-N{=}N-$ azo linkage by $-CH{=}CH-$, as in 4-dimethylaminostilbene [CAS: 1145-73-9] (XIV), results in widening the target tissue spectrum; XIV induces tumors in the liver, mammary gland, and ear duct. Mice are much more resistant than rats to the carcinogenic activity of both amino-azo dyes and aminostilbenes.

Figure 3 illustrates some aliphatic carcinogens. *N*-Methyl-bis-β-chloro ethylamine (XV), a nitrogen mustard, produces local sarcomas, lung, mammary, and hepatic tumors upon injection in mice; because of its tumor-inhibitory properties, XV has also been used in the therapeutic treatment of certain types of human cancers. Bisepoxybutane (XVI), β-propiolactone (XVII), and *N*-lauroylethyleneimine (XVIII) produce local sarcomas in rats upon injection. Ethylcarbamate (XIX), the parent compounds of several hypnotic drugs used in humans, produces malignant lung adenomas in rats, mice, and chickens. Dimethylnitrosamine (XX) is a potent carcinogen toward the liver, lung, and kidney, and ethionine (XXI) toward the liver

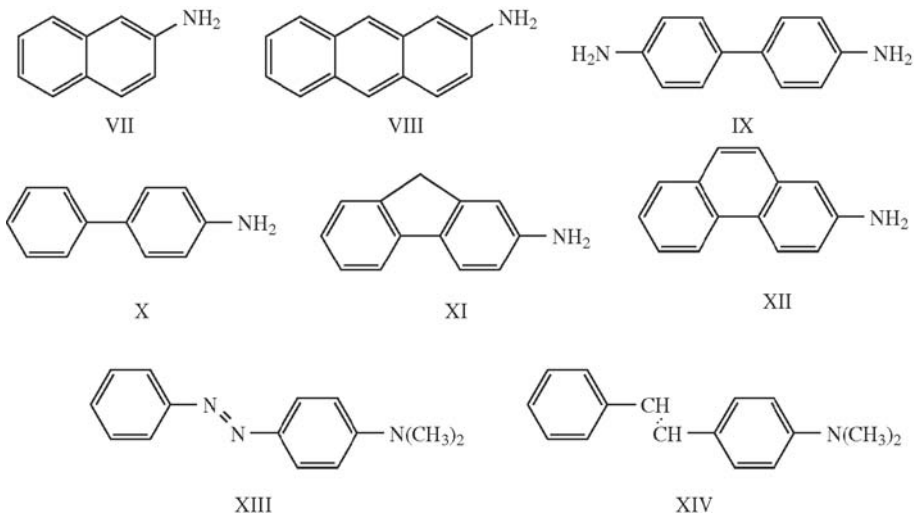

Fig. 2. Carcinogenic aromatic amines.

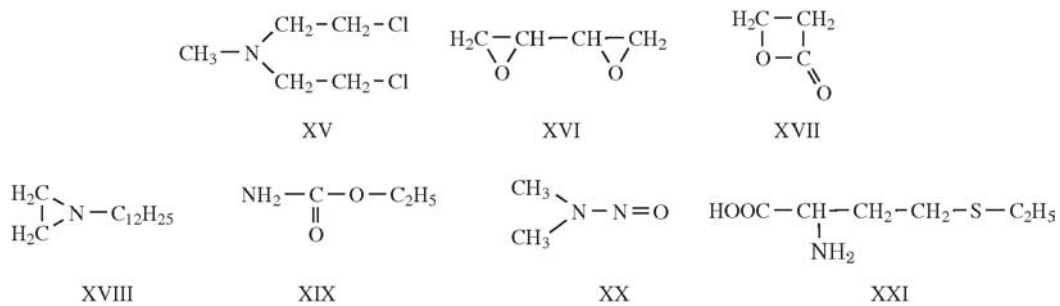

Fig. 3. Aliphatic carcinogens.

of the rat; the former is an intermediate in the manufacture of the rocket-fuel component, dimethylhydrazine $(CH_3)_2N-NH_2$, while the latter is the *S*-ethyl analogue of the natural amino acid methionine.

Testing

Because of their short life span (average 3 years) small rodents (mice, rats, and hamsters) are frequently used for the testing of chemicals for carcinogenic activity; occasionally testing is done with rabbits, dogs, fowls, monkeys, etc. While a great variety of ways of administration has been used, a common method is to introduce substances to be tested in the following ways: (a) skin painting; small volumes of solution of the substance in an inactive solvent (e.g., benzene) are applied to the shaved surface of the skin (generally of mice, in the interscapular region) daily or at longer intervals; (b) subcutaneous injection of the pure substance or its solution (once or at repeated intervals); (c) feeding: the substance is mixed in the diet at given levels, or dissolved in the drinking water. Testing of new substances for possible carcinogenic activity is conducted for a minimum of 1 year to be meaningful. At the end of the testing period, all animals are necropsied, and all tumors and dubious tissues examined histopathologically.

Within the past few years, the costs of carrying out long-term bioassays have increased markedly to the point at which it is too costly for small or medium-size manufacturers to fund a study of the long-term toxicity or carcinogenicity of any chemicals proposed for commercial development. Therefore, many short-term tests are being developed to predict which compounds would more likely be carcinogenic. A prominent one is a test for mutagenicity in various strains of the bacterium *Salmonella typhimurium*. The tests generally involve addition of the compound under test into a culture dish, which is seeded with the bacterium. The medium is deficient or lacking in histidine; therefore, no bacterial growth occurs, unless mutation by the test chemical yields a form of bacteria that does not require histidine. A count of the bacterial colonies can therefore be used as a measure of the mutagenicity of the test compound. The test, although quite rapid, does suffer from certain deficiencies. For one, a fair number of compounds are not mutagenic even though they are strong carcinogens in animals. These are usually compounds that require metabolic activation to demonstrate their carcinogenicity. Several variations on the test conditions have been proposed and, therefore, with these variations and parallel tests in other systems it is possible to establish whether the chemical under test may be a potential hazard.

A carcinogen that is highly active in one species may be totally inactive in another species, and vice versa. The susceptibility of a species to a given carcinogen also depends on the genetic strain, sex, and dietary conditions. Moreover, carcinogenic substances generally show a rather selective specificity toward certain target tissues; e.g., certain compounds produce exclusively hepatomas in the susceptible species. For these reasons, no chemical compound may be stated safely to be devoid of carcinogenic activity toward humans unless it has been found inactive when tested in a variety of mammalian species and by a variety of routes of administration for a length of time corresponding to half the life span of each species.

The foregoing observation emphasizes one of the main problems in cancer research, namely, *extrapolation* of research findings. For a given population to be fully safe, literally tens of thousands of commonly encountered natural materials and synthetic materials, covering the complete spectrum of products with which people are in contact over their lives, would have to be tested and regarded suspect until thoroughly tested on the species of most importance to humans, namely, the testing of reactions among people themselves. But this alone would not suffice because, as stressed throughout biochemical studies of human systems, there is individuality. The problem of developing improved (vastly improved) testing systems and attention to the problem of extrapolation of findings rivals in difficulty the basic problem of identifying the nature of cancer itself.

Many lists have appeared indicating the toxicity and/or carcinogenicity of specific chemicals. It would be invidious to attempt to insert these lists in this article because the number is extensive. Reference can be made to the sources cited at the end of this article.

The interesting observation has been made that, because of the vast amounts of money going into cancer research, the field has become a large business for numerous suppliers. Animal cells now can be procured by the kilogram from suppliers. Because of this availability (mostly two kinds, 3T3 and W138), much information has been accumulated concerning the biology of these cells. But is much of what has been learned in this regard meaningful? Researchers have found that viruses and chemicals can transform 3T3 cells to a neoplastic state and that these cells can produce tumors when inoculated in suitable hosts. It should be noted, however, that the tumors so produced are sarcomas (derived from fibroblasts) which are very rare in human beings. Ninety percent of human tumors are carcinomas. With the exception that epithelial cells and fibroblasts are both animal cells, they have little in common. They stem from two embryonic sources with different functions, and the tumors they produce are different as well.

Greater Knowledge of Carcinogenesis Anticipated

To comprehend the process of carcinogenesis is to understand, at the molecular level, the nature and workings of the cells that constitute life itself. Biochemists and geneticists are making excellent progress toward understanding life at the molecular level and out of this research, possibly by the early 2000s, the identification and role of carcinogens, as described here, will be subject to revision in the light of new knowledge.

CARDAMOM *(Elettaria Cardamomum; Zingiberaceae)*. Cardamom is prepared from the seeds of a leafy-stemmed perennial monocotyledon growing from 5–9 feet (1.5–2.7 meters) in height. The flowers, white with purple-striped perianth parts, are borne on leafless stems, which rise from the thick fleshy rhizomes apart from the leafy stems. The angular seeds are borne in 3-celled fruits. The dried seeds are used in India and elsewhere in tropical Asia as a highly flavored spice.

CARDIAC. Pertaining to the heart. A *cardiologist* is a physician who specializes in the diagnosis and treatment of heart diseases and disorders. See **Heart and Circulatory System (Physiology)**.

CARDIAC CATHETERIZATION. See **Coronary Artery Disease (CAD)**.

CARDIAC TRANSPLANTATION. See **Heart and Circulatory System (Physiology)**.

CARDINAL *(Aves, Passeriformes)*. Also known as the cardinal grosbeak or redbird, the cardinal is found both in North and South America. See

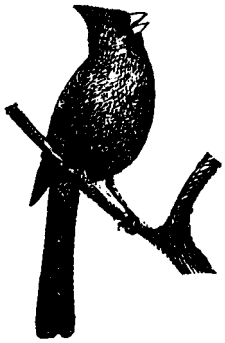

Fig. 1. Cardinal.

Fig. 1. The *Richmondena cardinalis* is found in the United States east of the plain states. It ranges northward as far as southern New York, Ontario, and Minnesota. The male is bright red with a small amount of black on its vermilion-colored head and beak. The female is rather drab in appearance. The bird is about $6\frac{1}{2}$ inches long ($16\frac{1}{2}$ centimeters), with a $3\frac{1}{2}$-inch (9-centimeter) tail, straight back, good posture, and proud, trim, and alert in appearance. It is a solitary nester. The female builds the nest, feeds the young, and incubates the eggs. The male helps with the feeding, sometimes feeding the female while she is on the nest. The birds often breed twice in a season. The egg is pale blue with brown spots and usually is one of four.

The cardinal is distinguished for its clear, loud, and sweet song. It is essentially nonmigratory. Other cardinals include the Florida cardinal (*R.c.floridana*), the Louisiana cardinal (R.c.magnirostris), found in southern Louisiana, and the gray-tailed cardinal (R.c.canicauda), which occurs in central and southern Texas.

CARDINAL NUMBER. It is difficult to give a satisfactory definition of a cardinal number, but this difficulty is not of great importance, since it is clear under what condition two sets contain the same cardinal number of objects, namely that they can be put into one-to-one correspondence with each other. This cardinal number is called the *power* of the set. An infinite set that can be put into one-to-one correspondence with the set of positive integers is said to be countable (or denumerable, or enumerable). A cardinal number that is not finite is called transfinite.

CARDINAL WINDS. See **Winds and Air Movement**.

CARDIOGRAPHY. See **Electrocardiogram**.

CARDIOID. A higher plane curve, which is a special case of the limaçon. Its equations are

$$(x^2 + y^2 - 2ax)^2 = 4a^2(x^2 + y^2)$$

$$r = 2a(\cos\theta \pm 1)$$

$$x = a(2\cos\phi - \cos 2\phi)$$

$$y = a(2\sin\phi - \sin 2\phi)$$

where ϕ is a parameter in the last case.

The cardioid (see Fig. 1) is also an epicycloid in which the radius of the fixed circle equals the radius of the rolling circle. The name comes from its heart-like shape. See Fig. 1. It has been used in the classical problem of trisecting an angle.

See also **Epicycloid**; and **Limacon**.

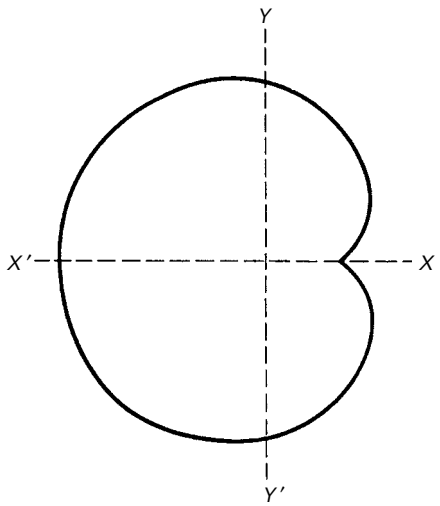

Fig. 1. Cardioid.

CARDIOMYOPATHY. See **Cardiovascular Devices**.

CARDIOMYOPLASTY. See **Cardiovascular Devices**.

CARDIOPULMONARY BYPASS. See **Heart and Circulatory System (Physiology)**.

CARDIOPULMONARY RESUSCITATION. Sometimes referred to as artificial respiration, cardiopulmonary resuscitation (CPR) is now the preferred term. Because the various techniques required to perform CPR are best explained by reference to large diagrams that should be quickly available unless committed to memory, the medium of an encyclopedia is not well suited to provide these details. CPR standards and guidelines were rather extensively revised in 1980. For those readers who do not have up-to-date information immediately available for emergencies, contact with local health departments and American Red Cross offices is suggested.

CARDIOVASCULAR DEVICES. Treatment of cardiovascular diseases is a vast and growing industry. Cardiovascular disease is a progressive condition which can eventually block the flow of blood through the coronary arteries to the heart muscle, thereby causing heart attacks and other life-threatening situations. The same plaque deposits occur in the peripheral arteries, leading to gangrene, amputations, aneurysms, and strokes. Despite enormous progress in cardiovascular medicine since World War II, challenges and unmet needs abound. Mortality rates have declined significantly, millions of people have been helped to lead normal lives, but the prevalence and incidence of cardiovascular diseases remain high. Open-heart surgery, cardiac pacing, heart transplants, implantable valves, and coronary angioplasty and clot busters, have been developed, but none of the great advances in cardiovascular medicine is preventive. There has been no "Salk vaccine" to preclude the buildup of fatty deposits or plaque in the arteries.

Cardiovascular Problems

Despite its durability and resilience, different aspects of the cardiovascular system can malfunction. Some problems are congenital; many are inherited. Diseases can also be caused by infection such as damaged heart valves owing to rheumatic fever. Cardiomyopathy, a diseased heart muscle which may become enlarged, can result from infection or an unknown cause. Other problems may be a function of age. Pacemaker patients often have conduction systems that have simply started to wear out. Lifestyle also plays a role. Although poor diet and smoking cause or contribute to multiple problems such as hypertension and lung disease, when it comes to cardiovascular problems, the main culprit, regardless of its origin, is atherosclerosis. Atherosclerosis is a disease of the arteries resulting from the deposit of fatty plaque on the inner walls.

Plaque. A heart attack, or myocardial infarction, results from insufficient delivery of oxygen to parts of the heart muscle owing to restricted blood flow in the coronary arteries. If heart muscle tissue is deprived of oxygen long enough, it may infarct or die (Fig. 1). The heart attack is often precipitated by a clot, or thrombus, which forms on a severely narrowed portion of a coronary artery. Silent ischemia is somewhat reduced blood supply from narrowing of the arteries. As the name implies, the disease provides no symptomatic warning of an impending problem. When coronary arteries are blocked to the degree that they cannot meet the heart's temporary demand for more oxygenated blood, angina pectoris, or sharp pain, may result. Further progression of the blockage then brings on the myocardial infarction. Atheroma is the medical term used to describe what plaque, the fatty deposits, does to the walls of the arteries. Plaque also

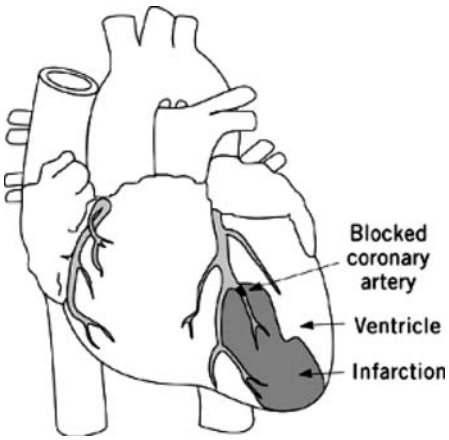

Fig. 1. Myocardial infarction occurs during insufficient delivery of oxygen to a portion of the heart muscle.

causes other problems such as strokes and aneurysms, as well as complications of peripheral vascular disease. See also **Arteries and Veins (Vascular System)**; and **Ischemic Heart Disease**.

Lethal Arrhythmias. Arrhythmias are a second significant source of cardiovascular problems. An arrhythmia is an abnormal or irregular heart rhythm. Bradyarrhythmias result in heart rates that are too slow; tachyarrhythmias cause abnormally fast rates. A bradyarrhythmia can be debilitating, causing a person to be short of breath, unable to climb stairs, black out, or even to go into cardiac arrest. Tachyarrhythmias can be unsettling and painful at best, life-threatening at worst.

Arrhythmias are caused by disturbances of the normal electrical conduction patterns synchronizing and controlling heartbeats. The wiring leading to the ventricles might, in effect, break or become frayed, causing a slowdown in the signals getting through, or perhaps result in intermittent electrical impulses. If damage to heart muscle tissue occurs, for example, from a myocardial infarction, this could create new electrical pathways. These in turn set up a separate focus of electrical activity (like another natural pacemaker) generating extra beats which can be highly disruptive. If a tachyrhythmia (tachycardia) occurs in the ventricles, the pumping chambers of the heart, the problem can be severely uncomfortable or even cause death if it deteriorates into ventricular fibrillation. Fibrillation is uncontrolled electrical activity. In this chaotic situation, cells become uncoordinated so that the heart muscle only quivers or twitches and no longer contracts rhythmically. Approximately three-fourths of the more than 500,000 deaths per year in the United States from coronary heart disease are sudden deaths.

There is a close correlation between myocardial infarctions and tachyarrhythmias, illustrated by the presence of complex ventricular arrhythmias among heart attack victims which are estimated to affect one-third of the survivors each year. Frequently, the immediate cause of sudden death is ventricular fibrillation, an extreme arrhythmia that is difficult to detect or treat. In the majority of cases, victims have no prior indication of coronary heart disease. See also **Arrhythmias (Cardiac)**.

Valvular Disease. Valve problems severely limit the efficiency of the heart's pumping action bringing forth definitive symptoms. There are two types of conditions, both of which may be present in the same valve. The first is narrowing, or stenosis, of the valve. The second condition is inability of the valve to close completely. Narrowing of the mitral valve, for example, can result in less blood flowing into the left ventricle and subsequently less blood being pumped into the body. If the same valve does not close completely, blood may also back up or regurgitate into the left atrium when the ventricle contracts, preventing even more blood from properly flowing. The backward pressure which results can cause a reduction in the efficiency of the lungs.

Cardiomyopathy. Cardiomyopathy, or diseased heart muscle, may reach a point at which the heart can no longer function. It arises from a combination of factors, including hypertension, arrhythmias, and valve disease. Other problems, such as congestive heart failure, cause the interrelated heart–lung system to break down. Because the heart can no longer adequately pump, fluid builds up in the lungs and other areas. See also **Heart and Circulatory System (Physiology)**.

Atherosclerosis. The first solution to the problem of atherosclerosis was the coronary artery bypass graft (CABG) procedure, first performed in 1964. In a coronary bypass procedure, a graft is taken from the patient's own saphenous vein. The graft is attached to the aorta (Fig. 2) where the coronary arteries originate and the opposite end is connected to the artery below the blocked segment. Blood can then bypass the obstructed area and reach the surrounding tissue below. Extensions of this useful surgery are CABG procedures which utilize mammary arteries of the patient instead of saphenous veins.

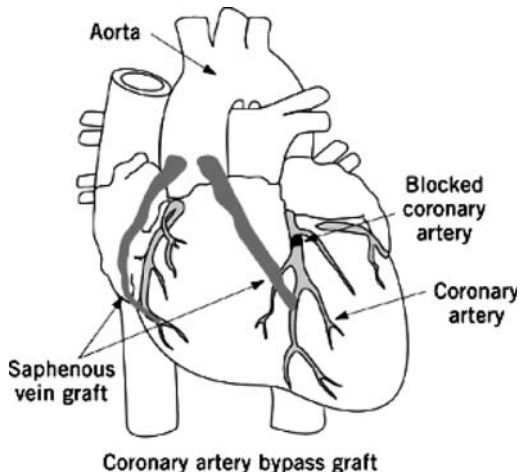

Fig. 2. In coronary bypass, an autologous saphenous vein is used to provide critical blood to the heart muscle, bypassing a blockage in the coronary artery.

The second step toward solving cardiovascular disease from atherosclerosis, i.e., angioplasty, was preceded by the diagnostic tool of angiocardiography by nearly 20 years. Angiocardiography, or angiography, permits x-ray diagnosis using a fluoroscope. A radiopaque contrast medium is introduced into the arteries through a catheter, and angiography allows accurate location of the plaque blockage. See also **Radiopaques**. Percutaneous transluminal coronary angioplasty (PTCA), a nonsurgical procedure, emerged in the 1980s as a viable method for opening up blocked arteries. A PTCA catheter has a balloon at its tip which is inflated after it is positioned across the blocked segment of the artery. Plaque is then compressed against the arterial walls, permitting blood flow to be restored. The same solutions of bypass surgery and angioplasty have been applied to atherosclerosis in the peripheral arteries.

Arrhythmias. The first solution to cardiovascular problems arising from arrhythmias came about as a result of a complication caused by open-heart surgery. During procedures to correct congenital defects in children's hearts, the electrical conduction system often became impaired, and until it healed, the heart could not contract sufficiently without outside electrical stimulation. A system that plugged into a wall outlet was considered adequate until an electrical storm knocked out power, leading to the development of the first battery-powered external pacemaker. See also **Arrhythmias (Cardiac)**.

The first implantable pacemaker, introduced in 1960, provided a permanent solution to a chronic bradyarrhythmia condition. This invention had a profound impact on the future of medical devices. The pacemaker was the first implantable device which became intrinsic to the body, enabling the patient to lead a normal life.

Early pacemakers paced the heart continuously at a fixed rate, were larger than a hockey puck, and had to be replaced frequently owing to power source technology limitations. Advances in electronics, materials, and knowledge have yielded pacemakers about the size of a U.S. 50-cent piece that last five years or more. More importantly, pacemakers restore the heart to functioning in a completely natural way. The pacemaker senses the electrical activity of the heart and kicks in only when something is wrong. If the impulses initiated by the SA node cannot get all the way through to the lower part of the ventricles, the pacemaker takes over completing the electrical process at the same rate indicated by the heart's natural pacemaker. If the SA node is dysfunctional and cannot put out an appropriate signal, sensors in rate-responsive pacemakers can correlate

other data such as sound waves from body activity, body temperature, or the respiratory rate to compute the proper heart rate. See also **Sensors**.

The first automatic implantable cardioverter defibrillator (AICD) was implanted in 1980. As for pacemakers, early generations of AICDs were bulky and cumbersome, did not last very long, and required open-heart surgery. However, these kept people alive by automatically shocking the heart out of its chaotic electric state whenever it went into ventricular fibrillation. Future devices are being designed to provide the full spectrum of arrhythmia control, including pacing, cardioversion, and defibrillation. Techniques are also being developed to map, ie, locate, the source of certain tachyarrhythmias (an ectopic focus or scar tissue) and remove it without open-heart surgery. See also **Fibrillation**.

External defibrillation was first performed in 1952 and continues as a routine procedure in hospitals and ambulances. The problem of external defibrillation has not been a technological one, but rather a legal one. Only in the 1990s have laws been passed to permit people other than doctors and paramedics to operate semiautomatic defibrillators to provide help when it is needed. New and better defibrillation devices continue to come to market and are easier and safer to use. See also **Electric Shock**.

Valve Problems. The primary solution to valve problems has been implantable replacement valves. The introduction of these devices necessitates open-heart surgery. There are two types of valves available: tissue (porcine and bovine) and mechanical. The disadvantage of tissue valves is that these have a limited life of about seven years before they calcify, stiffen, and have to be replaced. The mechanical valves can last a lifetime, but require anticoagulant therapy. In some patients, anticoagulants may not be feasible or may be contraindicated. Of the valves which require replacement, 99% are mitral and aortic valves. The valves on the left side of the heart are under much greater pressure because the left ventricle is pumping blood out to the entire body, instead of only to the lungs. Occasionally, two valves are replaced in the same procedure.

Cardiomyopathy. The best available solution to cardiomyopathy may be one that is less sophisticated than transplant surgery or the artificial heart. The cardiomyoplasty-assist system combines earlier electrical stimulation technology with a new surgical technique of utilizing muscle from another part of the body to assist the heart.

Efforts to develop an artificial heart have resulted in a number of advancements in the assist area. The centrifugal pump for open-heart surgery, the product of such an effort, has frequently been used to support patients after heart surgery (post-cardiotomy), or as a bridge to life prior to transplant. Other efforts have led to the development of ventricular assist devices to support the heart for several months and intra-aortic balloon pumps (IABPs) which are widely used to unload and stabilize the heart.

Interventional Procedures

The emergence of angioplasty created a specialty called interventional cardiology. Interventional cardiologists not only implant pacemakers and clear arteries using balloon catheters, but they also use balloons to stretch valves (valvuloplasty). In addition, they work with various approaches and technologies to attack plaque, including laser energy, mechanical cutters and shavers, stents to shore up arterial walls and deliver drugs, and ultrasound to break up plaque or to visualize the inside of the artery. See also **Angioplasty**.

Typically, procedures have become less invasive as technology evolves. Early pacemaker procedures involved open-heart surgery to attach pacemaker leads (wires) to the outside of the heart. Later, leads could be inserted in veins and pushed through to the interior of the heart, no longer necessitating opening a patient's chest. Using fluoroscopy, the physician can visualize the process, so that the only surgery needed is to create a pocket under the skin for the implantable generator to which the leads are connected.

Clinical evaluation is underway to test transvenous electrodes. Transvenous leads permit pacemakers to be implanted under local anesthesia while the patient is awake, greatly reducing recovery time and risk. As of 1996, the generation of implantable defibrillators requires a thoracotomy, a surgical opening of the chest, in order to attach electrodes to the outside of the heart. Transvenous electrodes would allow cardiologists to perform pacemaker procedures without a hospital or the use of general anesthesia.

Coronary bypass surgery and angioplasty are vastly different procedures, but both procedures seek to revascularize and restore adequate blood flow to coronary arteries. Balloon angioplasty, which looks much like a pacemaker lead except that it has a tiny balloon at the end instead of an electrode, involves positioning a catheter inside a coronary artery under fluoroscopy. The balloon is inflated to compress the offending plaque. Angioplasty is far less invasive than bypass surgery and patients are awake during the procedure. For many patients, angioplasty may not be indicated or appropriate.

Interventional cardiology is but one specialty that has arisen in cardiovascular medicine. Another is interventional radiology for similar procedures in the peripheral arteries, in addition to conventional bypass graft surgery. Competition has been intense among surgeons, cardiologists, and radiologists. Because coronary artery disease is progressive, many patients who are candidates for peripheral and/or coronary angioplasty may be future candidates for bypass surgery.

Cardiologists may be described in terms of three overlapping specialties: interventional, who perform most angioplasty; invasive, who implant about 70% of the pacemakers in the United States; and diagnostic. A subspecialty of diagnostic cardiology, electrophysiology, has grown in importance because it is critical to the treatment of tachrhythmia patients, especially those who are prone to ventricular fibrillation. The further development of implantable devices in this last area depends on close cooperation between companies and electrophysiologists.

Cardiovascular devices are being employed by a wider diversity of specialists and are thus finding applications in other medical areas. This has been particularly true for devices developed to support open-heart surgery. Oxygenators and centrifugal pumps, which take over the functions of the lungs and heart, are used in applications such as support of angioplasty and placing a trauma or heart attack victim on portable bypass in the emergency room. Some devices are finding utility by improving surgical techniques. For example, cardiac surgeons are working with balloon catheters and laser angioplasty systems as an augmentation to regular bypass surgery.

Other cardiovascular devices developed initially for use in open-heart surgery are used extensively in other parts of the hospital and, in many cases, outside the hospital. Patients have been maintained for prolonged periods of time on portable cardiopulmonary support systems while being transported to another hospital or waiting for a donor heart. Blood pumps and oxygenators may take over the functions of the heart and lungs in the catheterization lab during angioplasty, in extracorporeal membrane oxygenation (ECMO) to support a premature baby with severe respiratory problems, or in the emergency room to assist a heart attack victim. It is possible that future patients could be put on portable bypass at the site of the heart attack or accident. The market for cardiac assist devices and oxygenators plus related products such as specialized cannulae and blood monitoring devices is expected to expand rapidly into these areas.

Biomaterials for Cardiovascular Devices

Perhaps the most advanced field of biomaterials is that for cardiovascular devices. For several decades bodily parts have been replaced or repaired by direct substitution using natural tissue or selected synthetic materials. The development of implantable-grade synthetic polymers, such as silicones and polyurethanes, has made possible the development of advanced cardiac assist devices. See also **Silicon**; and **Urethane Polymers**.

Implantable devices to pace, cardiovert, and defibrillate the heart without the need for open-heart surgery should become widely accepted. Dramatic developments and growth are also taking place in other areas such as the use of laser systems intended to ablate significant amounts of plaque. Laser ablation systems hold considerable promise if restenosis (reblocking of the arteries) rates are reduced. Mechanical or atherectomy devices to cut, shave, or pulverize plaque have been tested extensively in coronary arteries. Some of these have also been approved for peripheral use. The future of angioplasty, beyond the tremendous success of conventional balloon catheters, depends on approaches that can reduce restenosis rates. For example, if application of a drug to the lesion site turns out to be the solution to restenosis, balloon catheters would be used for both dilating the vessel and delivering the drug. An understanding of what happens to the arterial walls, at the cellular level, when these walls are subjected to the various types of angioplasty may need to come first.

A primary aspect of cardiovascular devices through the twenty-first century is expected to involve the incorporation of diagnostic and visualization capabilities. A separate ultrasound system has been approved for this purpose. Laser angioplasty systems under development include visualization capabilities to distinguish plaque from the arterial wall. Future pacemakers, which already utilize sensors to determine an appropriate

heart rate, are expected to incorporate various other sensors for diagnostic purposes. The biggest challenge in averting sudden death is not so much to perfect a life-sustaining device, but to gain the ability to identify the susceptible patient. Appropriate screening and diagnoses for patients having silent ischemia must be developed. If the presence and extent of coronary artery disease can be identified early, intervention could save thousands of people from an untimely death and help others to live a fuller life. Sensors and specific diagnostic devices are expected to play a large role at about the same time as effective implantable defibrillators. See also **Optical Sensors**.

One of the more intriguing cardiovascular developments is cardiomyoplasty where implantable technologies are blended with another part of the body to take over for a diseased heart. One company, Medtronic, http://www.medtronic.com/, in close collaboration with surgeons, has developed a cardiomyoplasty system to accompany a technique of wrapping back muscle around a diseased heart which can no longer adequately pump. A combination pacemaker and neurological device senses the electrical activity of the heart and correspondingly trains and stimulates the dorsal muscle to cause the defective heart to contract and pump blood. Cardiomyoplasty could greatly reduce the overwhelming need for heart transplants. It might also eliminate the need for immunosuppressive drugs. Development of appropriate materials and manufacturing methods are needed to maintain patency without damaging blood in grafts below 4 mm (0.16 in) in diameter.

Pacemakers. The implantable cardiac pacemaker (Fig. 3) has been a phenomenal technological and marketing success. In the early 1980s, however, many critics were predicting the demise of these devices and the industry was the subject of congressional investigations over sales practices, alleged overuse, and excessive prices. Critics advocated low priced generic pacemakers, and pacemaker unit volume and prices declined about 10% on average. However, costs have been reduced by curtailing the length of time patients need to stay in the hospital following the implantation procedure and by selection of the correct pacemaker for each patient. Significantly lower cost is attached to a single-chamber device having limited longevity than to the far more expensive dual-chamber device which may be indicated for a young and active patient.

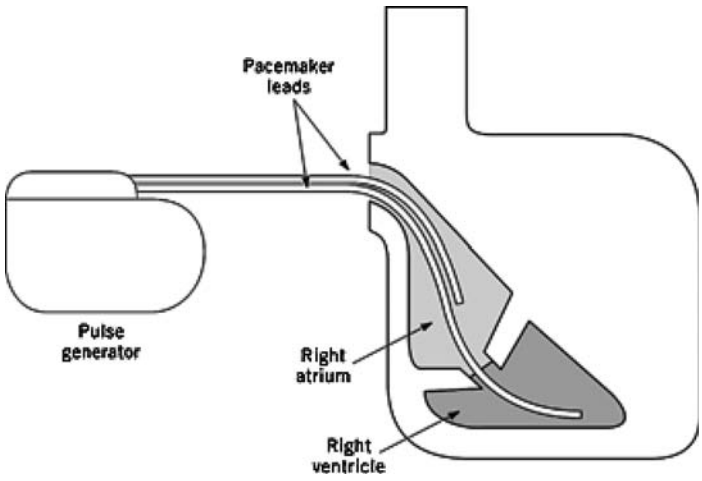

Fig. 3. A pacemaker provides electrical impulses to the heart in an effort to correct potentially fatal arrhythmias.

As of the mid-1990s, the market for bradyarrhythmia devices was fully penetrated in Western countries. Some growth is expected to result from an aging population but, by and large, the market is mature. The market for tachyrhythmia devices, in contrast, is only beginning.

Implantable tachyrhythmia devices, available for some years, address far less dangerous atrial tachyarrhythmias and fibrillation. The technical barriers to counteracting ventricular tachyarrhythmias and fibrillation using massive shocks have been formidable and are compounded by the possibility of causing the very problem the shock is designed to overcome. Newer tachyrhythmia devices are being readied that can safely regulate arrhythmias across the full spectrum.

Surgical Devices. Surgical devices comprise the equipment and disposables to support surgery and to position implantable valves and a variety of vascular grafts. Central to open-heart surgery is the heart–lung machine and a supporting cast of disposable products. Two devices, the oxygenator and the centrifugal pump, amount to significant market segments in their own right. Other disposables include cardiotomy reservoirs, filters, tubing packs, and cardioplegia products to cool the heart. The oxygenator market has been driven more recently by the conversion from bubbler to membrane devices which account for about 80% of the oxygenators used in the United States.

Centrifugal pumps are increasingly being used as a safer and more effective alternative to the traditional roller pump in open-heart surgery and liver transplants. About 45% of open-heart procedures use a centrifugal pump. In the latter 1980s, that number was less than 10%. Implantable valves, particularly mechanical valves which continue to encroach on tissue valves, are unique. Methods such as valvuloplasty, mitral valve repair, or use of ultrasound are unlikely to reduce the number of valve replacements into the twenty-first century. Valve selection remains in the hands of the surgeon because of the critical nature of the procedure. If anything goes wrong, the result can be catastrophic to the patient.

Vascular grafts are tubular devices implanted throughout the body to replace blood vessels which have become obstructed by plaque, atherosclerosis, or otherwise weakened by an aneurysm. Grafts are used most often in peripheral bypass surgery to restore arterial blood flow in the legs. Grafts are also frequently employed in the upper part of the body to reconstruct damaged portions of the aorta and carotid arteries. In addition, grafts are used to access the vascular system, such as in hemodialysis to avoid damage of vessels from repeated needle punctures. Most grafts are synthetic and made from materials such as Dacron or Teflon. Less than 5% of grafts utilized are made from biological materials.

Cardiac-Assist Devices. The principal cardiac-assist device, the intra-aortic balloon pump (IABP), is used primarily to support patients before or after open-heart surgery, or patients who go into cardiogenic shock. As of the mid-1990s, the IABP was being used more often to stabilize heart attack victims, especially in community hospitals which do not provide open-heart surgery. The procedure consists of a balloon catheter inserted into the aorta which expands and contracts to assist blood flow into the circulatory system and to reduce the heart's workload by about 20%. The disposable balloon is powered by an external pump console.

Other devices, which can completely take over the heart's pumping function, are the ventricular assist devices (VADs), supporting one or both ventricles. Some patients require this total support for a period of time following surgery (post-cardiotomy); others require the support while being transported from one hospital to another, or while waiting for a donor heart (bridge-to-transplant). Several external and implantable devices are being evaluated for short-term and long-term applications. Considerable interest has emerged in devices providing cardiopulmonary support (CPS), ie, taking over the functions of both the heart and lungs without having to open up the chest. There are several applications for other portable bypass systems or mini-heart–lung machines. Thus far, CPS has been used most frequently in support of anigoplasty prophylactically in difficult cases which could not be otherwise undertaken. The greatest potential is in the emergency room to rest the heart and lungs of heart attack and trauma victims.

Other specialized applications of cardiac arrest devices include extracorporeal membrane oxygenation (ECMO) which occurs when the lungs of a premature infant cannot function properly. The market segments for cardiopulmonary support devices are potentially significant.

Artificial Hearts. Congestive heart failure (CHF) is a common cause of disability and death. It is estimated that three to four million Americans suffer from this condition. Medical therapy in the form of inotropic agents, diuretics, and vasofilators is commonly used to treat this disorder. See also **Diuretic Agents**. Cardiac transplantation has become the treatment of choice for medically intractable CHF. Although the results of heart transplantation are impressive, the number of patients who might benefit far exceeds the number of potential donors. Long-term circulatory support systems may become an alternative to transplantation. See also **Congestive Heart Failure (CHF)**.

In 1980, the National Heart, Lung and Blood Institute of NIH, http://www.nhlbi.nih.gov/, established goals and criteria for developing heart devices and support techniques in an effort to improve the treatment of heart disease. This research culminated in the development of both temporary and permanent left ventricular-assist devices that are tether-free, reliable over two years, and electrically powered. The assist devices support the failing heart and systemic circulation to decrease cardiac work, increase

blood flow to vital organs, and increase oxygen supply to the myocardium. The newer ventricular assists are required to have no external venting, have a five-year operation with 90% reliability, pump blood at a rate of 3–7 L/min into the aorta at a mean arterial pressure of 90 mm Hg (12 kPa) when assisting the human left ventricle, and have a specific gravity of 1.0 for the implantable ventricular assist device.

In contrast, the total artificial heart (TAH) is designed to overtake the function of the diseased natural heart. While the patient is on heart–lung bypass, the natural ventricles are surgically removed. Polyurethane cuffs are then sutured to the remaining atria and to two other blood vessels that connect with the heart.

One successful total artificial heart is ABIOMED's electric TAH. This artificial heart consists of two seamless blood pumps which assume the roles of the natural heart's two ventricles. The pumps and valves are fabricated from a polyurethane, Angioflex. Small enough to fit the majority of the adult population, the heart's principal components are implanted in the cavity left by the removal of the diseased natural heart. A modest sized battery pack carried by the patient supplies power to the drive system. Miniaturized electronics control the artificial heart which runs as smoothly and quietly as the natural heart. Once implanted, the total artificial heart performs the critical function of pumping blood to the entire body.

Heart Valves. Since the early 1960s nearly 50 different heart valves have been developed. The most commonly used valves include mechanical prostheses and tissue valves. Caged-ball, caged disk, and tilting-disk heart valves are the types most widely used.

Blood Salvage. In a growing awareness that a patient's own blood is the best to use when blood is needed, newer techniques are reducing the volume of donor blood used in many cardiovascular and orthopedic surgeries. Surgical centers have a device, called the Cell Saver (Haemonetics), which allows blood lost during surgery to be reused within a matter of minutes, instead of being discarded. This device collects blood from the wound, runs it through a filter that catches pieces of tissue and bone, and then mixes the blood with a salt solution and an anticoagulant. The device then cleanses the blood of harmful bacteria. Subsequently the blood is reinfused back to the same patient through catheters inserted in a vein in the arm or neck, eliminating the worry of cross-contamination from the HIV or hepatitis viruses. See also **Blood**; and **Blood Coagulation and Anticoagulant Drugs**.

Use of intraoperative autotransfusion (IAT) eliminates disease transmission, compatibility testing, and immunosuppression that may result from the use of homologous blood products, reduces net blood loss of the patient, and conserves the blood supply. During vascular surgery, the principal indications for the use of the Cell Saver are ruptured spleen, ruptured liver, aneurysms, and vascular trauma. During orthopedic surgery the principal indications are total hip arthroplasty, spinal fusions, total knee, and any procedure that has wound drains.

Blood Access Devices. An investigational device called the Osteoport system allows repeated access to the vascular system via an intraosseous infusion directly into the bone marrow. The port is implanted subcutaneously and secured into a bone, such as the iliac crest. Medications are administered as in any conventional port, but are taken up by the venous sinusoids in the marrow cavity, and from there enter the peripheral circulation.

Blood Oxygenators. The basic construction of an oxygenator involves any one of several types of units employing a bubble-type, membrane film-type, or hollow-fiber-type design. The most important advance in oxygenator development was the introduction of the membrane-type oxygenator. These employ conditions very close to the normal physiological conditions in which gas contacts occur indirectly via a gas-permeable membrane. Blood trauma is minimized by the use of specialized biomaterials such as PTFE, PVC, and cellophane, although lately silicone rubber and cellulose acetate have predominated. A silicone–polycarbonate copolymer, ethylcellulose perfluorobutyrate, and poly(alkyl sulfone) were introduced in the mid-1980s, and tend to dominate this field.

Polyurethanes as Biomaterials

Much of the progress in cardiovascular devices can be attributed to advances in preparing biostable polyurethanes. See also **Urethane Polymers**. Biostable polycarbonate-based polyurethane materials such as Corethane and ChronoFlex offer far-reaching capabilities to cardiovascular products. These and other polyurethane materials offer significant advantages for important long-term products, such as implantable ports, hemodialysis, and peripheral catheters; pacemaker interfaces and leads; and vascular grafts.

Implantable Ports. The safest method of accessing the vascular system is by means of a vascular access device (VAD) or port. Older VAD designs protruded through the skin. The totally implanted ports are designed for convenience, near absence of infection, and ease of implantation. Ports allow drugs and fluids to be delivered directly into the bloodstream without repeated insertion of needles into a vein. The primary recipients of totally implanted ports are patients receiving chemotherapy, bolus infusions of vesicants, parenteral nutrition, antibiotics, analgesics, and acquired immune disease syndrome (AIDS) medications.

Vascular access ports typically consist of a self-sealing silicone septum within a rigid housing which is attached to a radiopaque catheter. See also **Radiopaques**. The catheter must be fabricated from a low modulus elastomeric polymer capable of interfacing with both soft tissue and the cardiovascular environment. A low modulus polyurethane-based elastomer is preferred to ensure minimal trauma to the fragile vein.

Placement of vascular access ports is similar to that of a long-term indwelling arterial catheter. A small incision is made over the selected vein and a second incision is made lower in the anterior chest to create a pocket to house the port. The catheter is tunneled subcutaneously from its entry point into the vein with the tip inside the right atrium. The final position of the catheter is verified by fluoroscopy, secured with sutures, and the subcutaneous pocket is closed. The port septum is easily palpable transcutaneously, and the system may be used immediately. A surgeon typically inserts the vascular access port in an outpatient setting.

To use the port, the overlying skin is prepared using conventional techniques. A local anesthetic is sometimes used to decrease pain of needle insertion, though this is usually not necessary using techniques which utilize small-bore needles. A special point needle is used to puncture the implanted ports as the point of these needles is deflected so it tears the septum rather than coring it, allowing multiple entries. The septum reseals when the needle is removed.

The primary advantages of implantable ports are no maintenance between uses other than periodic flushing with heparinized saline every 28 days to ensure patency, lower incidence of clotting and thrombosis, no dressing changes, insignificant infection incidence, unobtrusive cosmetic appearance, and no restriction on physical activity.

Pacemaker Interfaces and Leads. Problems of existing pacemaker interfaces and pacemaker lead materials made from silicones and standard polyurethanes are environmental stress cracking, rigidity, insulation properties, and size.

Technical advances in programmable pacemakers that assist both the tachycardia and bradycardia have led to the requirement of implanting a two-lead system. Owing to the ridigity and size of silicones, the only material that fulfills this possibility without significantly impeding blood flow to the heart is polyurethane. The primary needs in this medical area are reduction in making frequent changes and in failure rate, and the ability to have multiple conductors to handle advanced pacemaker technology.

Vascular Grafts. Although the use of vascular grafts in cardiovascular bypass surgery is widely accepted and routine, numerous problems exist in these surgeries for the materials available. Biocompatibility is often a problem for vascular grafts which also tend to leak and lead to scarring of the anastomosis. The materials are not useful for small-bore () grafts. The primary needs that materials can be developed to address are matching compliance to native vessels, having a lesser diameter for small-bore grafts which would serve as a replacement for the saphenous vein in coronary bypass, thinner walls, biostability, controlled porosity, and greater hemocompatibility for reduced thrombosis.

The advent of newer polyurethane materials is expected to lead to a new generation of cardiovascular devices. The characteristics of polyurethanes, combined with newer manufacturing techniques, should translate into direct medical benefits for the physician, the hospital, and the patient. This field offers exciting growth opportunities.

CARIBBEAN CURRENT. An ocean current flowing westward through the Caribbean Sea. It is formed by the commingling of part of the waters of the north equatorial current with those of the Guiana current. It flows through the Caribbean Sea as a strong current and continues with increased speed through the Yucatan Channel; there it bends sharply to the right and flows eastward with great speed out through the Straits of Florida to form the Florida current.

CARIBOU. See **Deer**.

CARIES, CARIOLOGY, AND DENTISTRY. *Caries* is the decay of a bone or tooth; a progressive decalcification and proteolysis of the enamel and dentin. *Cariology* is the study of tooth decay. *Dentistry* is the practice of preventing, diagnosis, and treating diseases, injuries, and malformations of the teeth, jaws, and mouth. Like physicians, dentists must be registered by regulatory bodies after education and training in approved schools of dentistry. *Dentition* is the form and arrangement of the teeth in vertebrates. See **Dentition**.

This article is directed principally to caries because, aside from teeth and bones that have been deformed naturally (possibly as the result genetic defects), tooth decay and related conditions are the principal causes of dental problems. In a recent study conducted by the U.S. Navy, for example, it was found that of over 200,000 sailors surveyed, only 360 were found to be caries-free. Statistical studied have shown that there are wide geographical differences in the incidence of tooth decay. Decay rates are high in the New England states, Illinois, Minnesota, Ohio, Oregon, Pennsylvania, Washington, and Wisconsin. The incidence is more moderate in Idaho, Louisiana, Montana, North and South Dakota, and Utah. Incidence is considered low in most other states, with the exception of Arkansas, Colorado, Oklahoma, and Texas, where the rates, on a geographically comparative basis, are considered quite low. In past attempts to correlate incidence with cause, a principal conclusion is that regions with predominantly acid soils are caries prone, whereas those areas with alkaline soils are caries low. The fluoridation of drinking water, as practiced in a high percentage of public water systems, has a tendency to even out to some extent the geographical incidence of caries. See discussion of "Fluoridation" in the article on **Fluorine**.

The Caries Process. In the process of tooth decay formation, bacteria adheres to the tooth surface, especially in pits and other harboring areas. In this process, *plaque* is formed. Plaque is made up of microorganisms that are able to attach to the surfaces of teeth because the bacteria secrete a sticky slime called *zooglea* (living glue). Plaque is also known as the microcosm. The microcosm keeps out substances that might harm the bacteria. Water, mouthwash, and saliva have little ability to penetrate the sticky mass, but sugar and fermentable carbohydrates penetrate easily. These foods are sources of energy for the caries bacteria.

These bacteria with their enzymes are capable of acting on fermentable foods to form acids. When sugar or carbohydrates contact the plaque, acids are produced within a few minutes. The concentration continues for several minutes and by the end of a half-hour, the concentration may be sufficient to dissolve enamel.

When acid concentration is sufficient to react with the inorganic salts of the tooth, there is partial decalcification of tooth substance. This produces a porous, opaque, white spot within the enamel substance. The process of acid formation and decalcification continues until all fermentable food is used and the acids are neutralized by saliva and minerals of the tooth substance. Decalcification stops when the acids are neutralized until more fermentable substance is brought into the plaque, upon which the cycle is repeated. Organic material of the tooth is destroyed by *proteolytic* bacteria normally present in the plaque.

Any condition that leads to the formation of a bacterial film upon the tooth's surface will predispose to dental caries if acid-producing bacteria are present. Most people who appear to be resistant to dental caries can be shown to have very low intake of carbohydrates. Often these apparently resistant individuals become susceptible when they eat carbohydrates frequently. Eating in between meals (snacking) of carbohydrates is particularly favorable to microbial growth. Those microbes dependent upon carbohydrates then begin to grow and crowd out nonacid-producing bacteria (*acidogenic*). Any condition that diminishes salivary flow, thereby contributing to poor natural cleansing of the teeth and a diminished quantity of saliva in the mouth, will elevate the incidence of carious lesions. This has been observed frequently by the rapid production of decay in patients who have received radium or deep x-ray therapy for mouth cancer.

The first sign of dental decay is a white spot in the enamel. As demineralization continues, a hole (*cavity*) is produced. When a cavity forms, the area becomes more difficult to clean and the microbes flourish.

Restoration through the use of fillings is the most successful means of stopping a carious lesion. Amalgams, cast gold inlays, and gold foil have served for years as effective agents for repair. When the diseased portion of the tooth is completely removed and the remaining tooth substance cleaned and prepared to receive a filling, the caries will usually be arrested. If a cavity is not filled when it is small, decay progresses through the enamel and dentin of the tooth until the dental pulp is reached. Then, the patient experiences excruciating pain, for which there is no permanent relief until the pulp dies, or a root canal procedure is used, or the tooth is extracted.

The connection between tooth decay and bacteria has been known since the 1920s. Mainly as the result of studies with laboratory animals, researchers ultimately identified the bacterium *Streptococcus mutans* as the principal agent of tooth decay. *S. mutans*, as compared with other oral cavity bacteria, is outstanding in its ability to produce an acidic environment. Researchers also found that plaque has an electrical charge distribution that appears to contribute to the damage that is promoted by bacteria. The electrical field permits sucrose from foods to diffuse into the plaque and thus nourish the dense pockets of bacteria, but at the same time preventing outward diffusion of the large quantities of acid produced. Thus, in essence, a sponge of acid nestles directly against the tooth surface.

Researchers also have attempted to replace harmful mouth bacteria with more benign strains, an approach that has been used in other areas of medicine. Another pathway of research has been to attack the glucosyl-transferase enzymes, which are responsible for converting sugar from foods to the sticky material by which bacteria adhere to teeth and thus form plaque. Much of this research has been of a proprietary nature and dental health care products have improved. The nature of saliva has been carefully studied, and it has been established that saliva can slow or hasten the tooth decay process. For example, persons with xerostomia (dry mouth) have an increased incidence of tooth decay. A small molecule made up of just four amino acids and known as *sialin* was isolated in the 1970s, and this knowledge has contributed to the improvement of mouthwashes and toothpastes. The substitution of nonnutritive sweeteners in the diet also has been quite beneficial in reducing tooth decay resulting from excessive consumption of sugars.

Trace elements in the diet also have been studied. Investigations to date have shown that fluorine and phosphorus are strongly *cariostatic*; molybdenum, vanadium, strontium, boron, and lithium are mildly cariostatic; and selenium, magnesium, cadmium, copper, lead, silicon, and manganese are *cariogenic*.

Recent Concerns in Dentistry. In 1990, the Centers for Disease Control (U.S.) issued a report on the possible transmission of the human immunodeficiency virus (HIV) from a dentist to a patient. This report has alerted the profession to the institution new preventive measures that will protect both patient and dentist.

Nitrous oxide (so-called laughing gas) has been used as an anesthetic in hospital and dental facilities for many years. As reported by P.A. Baird (*N. Eng. J. Med.*, **1026**, October 1, 1992): "In the past two decades, epidemiological studies have shown that serious health consequences may be associated with prolonged exposure to low levels of nitrous oxide. Although most studies have examined cognitive, neurological, hepatic, and hematopoietic side effects, there has also been some evidence suggesting an increase in spontaneous abortion and birth defects in the offspring of exposed women." These risks continue to be evaluated.

CARINA. A southern constellation which once, with Puppis and Vela, was part of a superconstellation known as Argo Navis. The bright star Canopus is contained in Carina.

CARNALLITE. This mineral is a product of evaporation of saline deposits rich in potash content, as a hydrated chloride of potassium and magnesium, $KMgCl_3 \cdot 6H_2O$. Hardness, 2.5; specific gravity, 1.602. It crystallizes in the orthorhombic system usually as massive, granular aggregates. Luster greasy, with indistinct cleavage and conchoidal fracture. Color grades from colorless to white, into reddish from included hematite scales. Transparent to translucent with bitter taste, deliquesces readily in moist environment.

Found associated with sylvite, halite and polyhalite at Stassfurt, Germany; Abyssinia; the former U.S.S.R.; and in southeastern New Mexico and adjacent areas in Texas. It is an important source of potash for use in fertilizers. See also **Potassium**.

CARNELIAN. The mineral carnelian is a red or reddish-brown chalcedony; the word is derived from the Latin word meaning flesh, in reference to the flesh color sometimes exhibited. See also **Chalcedony**.

CARNIVORA *(Mammalia)*. Flesh-eating mammals, mostly predacious in habits, although some are omnivorous and some eat carrion. They have four or five toes on each foot, are armed with claws, the canine teeth are prominent, and the premolar and molar teeth are formed for cutting. The major species, families, etc. are listed in the accompanying table. In terms of numbers of living types, the *Carnivora* represent the fourth largest order of *Mammalia*, exceeded by *Rodentia*, *Chiroptera*, and *Artiodactyla*. Members of *Carnivora*, with exception of Australia and the oceanic islands, are widely distributed throughout the world. Specific references in Table 1 indicate the titles of entries in this *Encyclopedia* where detailed information on specific varieties can be found.

CARNOT CYCLE. An ideal cycle of four reversible changes in the physical condition of a substance, useful in thermodynamic theory. Starting with specified values of the variable temperature, specific volume, and pressure, the substance undergoes, in succession, an isothermal (constant temperature) expansion, an adiabatic expansion (see also **Adiabatic Process**), and an isothermal compression to such a point that a further adiabatic compression will return the substance to its original condition. These changes are represented on the volume-pressure diagram respectively by *ab*, *bc*, *cd*, and *da* in Fig. 1. Or the cycle may be reversed: *a d c b a*.

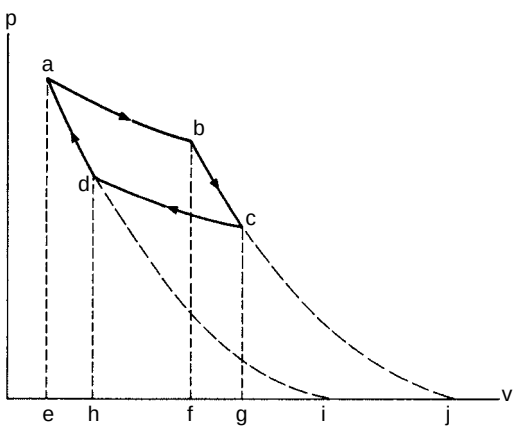

Fig. 1. Carnot cycle on *vp* diagram: *ab* and *cd*, isothermals: *bc* and *da*, adiabatics which, for some theoretical purposes, are produced to infinity.

In the forward (clockwise) case, heat is taken in from a hot source and work is done by the hot substance during the high-temperature expansion *ab*; also additional work is done at the expense of the thermal energy of the substance during the further expansion *bc*. Then a less amount of work is done on the cooled substance, and a less amount of heat discharged to the cool surroundings, during the low-temperature compression *cd*; and finally, by the further application of work during the compression *da*, the substance is raised to its original high temperature. The net result of all this is that a quantity of heat has been taken from a hot source and a portion of it imparted to something colder (a "sink"), while the balance is transformed into mechanical work represented by the area *abcd*. Thus, the forward Carnot cycle can be used for the production of power. If the cycle takes place in the counterclockwise direction, heat is transferred from the colder to the warmer surroundings at the expense of the net amount of energy which must be supplied during the process (also represented by area *abcd*). It can thus serve as a refrigerating cycle.

The temperature-entropy diagram for the Carnot cycle, corresponding to the pressure-volume diagram is shown in Fig. 2.

It should be noted that the efficiency of the forward cycle is highest when T_1 is as high as possible. Since, in practice, T_0 will always be fixed by the temperature of the surrounding atmosphere, a high efficiency corresponds to a large difference $T_1 - T_0$. In contrast, a high coefficient of performance,

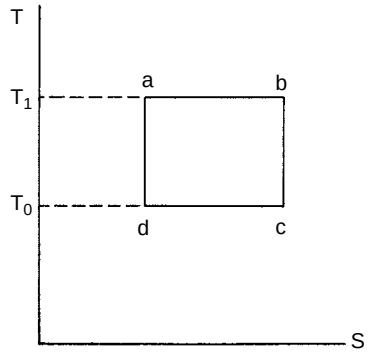

Fig. 2. Carnot cycle temperature-entropy diagram.

or a high effectiveness of a heat pump corresponds to a small difference $T_1 - T_0$.

It would appear that decreasing T_0 for a power cycle below that of the surrounding atmosphere is advantageous in that the efficiency η is increased. However, it must be realized that this can only be achieved at the expense of work in operating a refrigerator, and no advantage is gained. See also **Absolute Zero**; and **Solar Energy**.

CARNOT ENGINE. An idealized reversible heat engine working in a Carnot cycle. The basic model for this engine was developed by Nicolas Léonard Sadi Carnot in 1824. It is the most efficient engine that can operate between two specified temperatures; its efficiency is equivalent to the thermodynamic efficiency.

Every thermodynamic system exists in a particular state. A thermodynamic cycle occurs when a system is taken through a series of different states, and finally returned to its initial state. In the process of going through this cycle, the system may perform work on its surroundings, thereby acting as a heat engine.

A heat engine acts by transferring energy from a warm region to a cool region of space and, in the process, converting some of that energy to mechanical work. The cycle may also be reversed. The system may be worked upon by an external force, and in the process, it can transfer thermal energy from a cooler system to a warmer one, thereby acting as a refrigerator rather than a heat engine.

Web Reference

Carnot Sadi biography: http://www-groups.dcs.st-and.ac.uk/~history/Biographies/Carnot_Sadi.html.

CARNOTITE. This mineral is a vanadate of potassium and uranium with small amounts of radium. Its formula may be written $K_2\ (UO_2)_2\ (VO_4)_2 \cdot 3H_2O$. The amount of water, however, seems to be variable. It occurs as a lemon-yellow earthy powder disseminated through cross-bedded sandstones with rich concentrations around petrified and carbonized trees. Soft; sp gr 4.7. It was mined in Colorado and Utah as a source of radium. Other localities are in Arizona, Pennsylvania, and Zaire.

CARNOT THEOREMS. 1. No heat engine operating between two given temperatures can be more efficient than a perfectly reversible engine operating between the same temperatures.

2. The efficiency of any reversible heat engine working between two temperatures is independent of the nature of the engine and the working substances and depends only on the temperatures.

See also **Carnot Cycle**.

CAROTENOID PIGMENTS. See **Pigmentation (Plants)**.

CAROTENOIDS. Lipid-soluble, yellow-to-orange-red pigments universally present in the photosynthetic tissues of higher plants, algae, and the photosynthetic bacteria. They are spasmodically distributed in flowers, fruit, and roots of higher plants, in fungi, and in bacteria. They are synthesized *de novo* in plants. Carotenoids are also widely, but spasmodically distributed in animals, especially marine invertebrates, where they tend to

accumulate in gonads, skin, and feathers. All carotenoids found in animals are ultimately derived from plants or protistan carotenoids, although because of metabolic alteration of the ingested pigments, some carotenoids found in animals are not found in plants and protista.

Carotenoids are tetraterpenoids, consisting of eight isoprenoid  residues, and can be regarded as being synthesized by the tail-to-tail dimerization of two 20-carbon units, themselves each produced by the head-to-tail condensation of four isoprenoid units. Hydrocarbon carotenoids are termed *carotenes* and oxygenated carotenoids are known as *xanthophylls*. The best-known carotene is β-carotene.

α-Carotene is widely distributed in trace amounts, together with β-carotene in leaves; γ-carotene is found in many fungi, and lycopene is the main pigment of many fruits, such as the tomato.

Beta-Carotene and Carcinogenesis. As the result of analyzing numerous dietary questionnaires, dating back to the early 1980s, and numerous case-control studies, some evidence has been constructed showing an inverse relationship between the risk of cancer and the consumption of fruits and vegetables that have a high beta-carotene content. Sponsored by a grant from the U.S. Public Health Service, researchers from several university medical schools [*N. Eng. J. Med.*, **789** (Sept. 20, 1990)] conducted a large group study (1985–1990). The study involved assigning 1805 patients, who had a recent nonmelanoma skin cancer, to receive either 50 mg of beta-carotene or placebo per day, and conducting annual skin examinations to determine the occurrence of new nonmelanoma skin cancer. In prior studies the most consistent laboratory evidence for an anticancer effect of beta-carotene was accumulated from experiments with skin cancers in animals. Conclusions: "In persons with a previous nonmelanoma skin cancer, treatment with carotene does not reduce the occurrence of new skin cancers over a five-year period of treatment and observation."

In the 1990s, additional studies were underway. A major factor yet to be determined is whether substances other than beta-carotene, derived from fruits and vegetables in the diet, may contribute to a lowering of cancer risk.

CAROTHERS, WALLACE H. (1896–1937). Born in Iowa, Carothers obtained his doctorate in chemistry at the University of Illinois. He joined the research staff of Du Pont in 1928, where he undertook the development of polychloroprene (later called neoprene) that had been initiated by Nieuland's research on acetylene polymers. Carother's crowning achievement was the synthesis of nylon, the reaction product of hexamethylenetetramine and adipic acid. Carother's work in the polymerization mechanisms of fiber like synthetics of cyclic organic structures was brilliant and productive, and he is regarded as one of the most original and creative American chemists of the early 20th century.

CARPAL TUNNEL SYNDROME. Carpal tunnel syndrome is a disorder of the hand (caused by swollen tendons in the wrist) resulting from repetitious, forceful motion of the hands and wrists.

Carpal tunnel syndrome (CTS) occurs when the median nerve, which runs from the forearm into the hand, becomes pressed or squeezed at the wrist. The median nerve controls sensations to the palm side of the thumb and fingers (although not the little finger), as well as impulses to some small muscles in the hand that allow the fingers and thumb to move. This nerve passes through a relatively firm tunnel made up of the wrist bones and the tough transverse carpal ligament. Several tendons also pass through the carpal tunnel. Anything that increases the pressure inside the tunnel can cause nerve compression, as may be present in rheumatoid arthritis, gout, conditions that may cause inflammation, and swelling of the tendons. Repetitive motion involving the hands also can cause tendinitis. This, in turn, causes compression of the median nerve. Women are three times more likely than men to develop CTS, perhaps because the carpal tunnel itself may be smaller in women than in men. The dominant hand is usually affected first and produces the most severe pain. Persons with diabetes or other metabolic disorders that directly affect the body's nerves and make them more susceptible to compression are also at high risk. Carpal tunnel syndrome usually occurs only in adults.

The risk of developing carpal tunnel syndrome is not confined to people in a single industry or job, but is especially common in those performing assembly line work — manufacturing, sewing, finishing, cleaning, and meat, poultry, or fish packing. In fact, carpal tunnel syndrome is three times more common among assemblers than among data-entry personnel. A 2001 study by the Mayo Clinic found heavy computer use (up to 7 hours a day) did not increase a person's risk of developing carpal tunnel syndrome.

An estimated three of every 10,000 workers lost time from work because of CTS. Half of these workers missed more than 10 days of work. The average lifetime cost of carpal tunnel syndrome, including medical bills and lost time from work, is estimated to be about $30,000 for each injured worker.

Symptoms usually start gradually, with frequent burning, tingling, or itching numbness in the palm of the hand and the fingers, especially the thumb and the index and middle fingers. Some carpal tunnel sufferers say their fingers feel useless and swollen, even though little or no swelling is apparent. The symptoms often first appear in one or both hands during the night, since many people sleep with flexed wrists. A person with carpal tunnel syndrome may wake up feeling the need to "shake out" the hand or wrist. As symptoms worsen, people might feel tingling during the day. Decreased grip strength may make it difficult to form a fist, grasp small objects, or perform other manual tasks. In chronic and/or untreated cases, the muscles at the base of the thumb may waste away. Some people are unable to tell between hot and cold by touch.

CTS is often the result of a combination of factors that increase pressure on the median nerve and tendons in the carpal tunnel, rather than a problem with the nerve itself. Most likely the disorder is due to a congenital predisposition — the carpal tunnel is simply smaller in some people than in others. Other contributing factors include trauma or injury to the wrist that cause swelling, such as sprain or fracture; overactivity of the pituitary gland; hypothyroidism; rheumatoid arthritis; mechanical problems in the wrist joint; work stress; repeated use of vibrating hand tools; fluid retention during pregnancy or menopause; or the development of a cyst or tumor in the canal. In some cases no cause can be identified.

There is little clinical data to prove whether repetitive and forceful movements of the hand and wrist during work or leisure activities can cause carpal tunnel syndrome. Repeated motions performed in the course of normal work or other daily activities can result in repetitive motion disorders such as bursitis and tendonitis. Writer's cramp — a condition in which a lack of fine motor skill coordination and ache and pressure in the fingers, wrist, or forearm is brought on by repetitive activity — is not a symptom of carpal tunnel syndrome.

Diagnosis of CTS

Early diagnosis and treatment are important to avoid permanent damage to the median nerve. A physical examination of the hands, arms, shoulders, and neck can help determine if the patient's complaints are related to daily activities or to an underlying disorder, and can rule out other painful conditions that mimic carpal tunnel syndrome. The wrist is examined for tenderness, swelling, warmth, and discoloration. Each finger should be tested for sensation, and the muscles at the base of the hand should be examined for strength and signs of atrophy. Routine laboratory tests and X-rays can reveal diabetes, arthritis, and fractures.

Physicians can use specific tests to try to produce the symptoms of carpal tunnel syndrome. In the Tinel test, the doctor taps on or presses on the median nerve in the patient's wrist. The test is positive when tingling in the fingers or a resultant shock-like sensation occurs. The Phalen, or wrist-flexion, test involves having the patient hold his or her forearms upright by pointing the fingers down and pressing the backs of the hands together. The presence of carpal tunnel syndrome is suggested if one or

more symptoms, such as tingling or increasing numbness, is felt in the fingers within 1 minute. Doctors may also ask patients to try to make a movement that brings on symptoms.

Often it is necessary to confirm the diagnosis by use of electrodiagnostic tests. In a nerve conduction study, electrodes are placed on the hand and wrist. Small electric shocks are applied and the speed with which nerves transmit impulses is measured. In electromyography, a fine needle is inserted into a muscle; electrical activity viewed on a screen can determine the severity of damage to the median nerve. Ultrasound imaging can show impaired movement of the median nerve. Magnetic resonance imaging (MRI) can show the anatomy of the wrist, but to date has not been especially useful in diagnosing carpal tunnel syndrome.

Treatment of CTS

Treatments for carpal tunnel syndrome should begin as early as possible, under a doctor's direction. Underlying causes such as diabetes or arthritis should be treated first. Initial treatment generally involves resting the affected hand and wrist for at least 2 weeks, avoiding activities that may worsen symptoms, and immobilizing the wrist in a splint to avoid further damage from twisting or bending. If there is inflammation, applying cool packs can help reduce swelling.

Non-surgical Treatments

Drugs. In special circumstances, various drugs can ease the pain and swelling associated with carpal tunnel syndrome. Nonsteroidal anti-inflammatory drugs, such as aspirin, ibuprofen, and other nonprescription pain relievers, may ease symptoms that have been present for a short time or have been caused by strenuous activity. Orally administered diuretics ("water pills") can decrease swelling. Corticosteroids (such as prednisone) or the drug lidocaine can be injected directly into the wrist or taken by mouth (in the case of prednisone) to relieve pressure on the median nerve and provide immediate, temporary relief to persons with mild or intermittent symptoms. (Caution: persons with diabetes and those who may be predisposed to diabetes should note that prolonged use of corticosteroids can make it difficult to regulate insulin levels. Corticosterioids should not be taken without a doctor's prescription.) Additionally, some studies show that vitamin B^6 (pyridoxine) supplements may ease the symptoms of carpal tunnel syndrome.

Exercise. Stretching and strengthening exercises can be helpful in people whose symptoms have abated. These exercises may be supervised by a physical therapist, who is trained to use exercises to treat physical impairments, or an occupational therapist, who is trained in evaluating people with physical impairments and helping them build skills to improve their health and well-being.

Alternative Therapies. Acupuncture and chiropractic care have benefited some patients but their effectiveness remains unproved. An exception is yoga, which has been shown to reduce pain and improve grip strength among patients with carpal tunnel syndrome.

Surgical Treatment. Carpal tunnel release is one of the most common surgical procedures in the United States. Generally recommended if symptoms last for 6 months, surgery involves severing the band of tissue around the wrist to reduce pressure on the median nerve. Surgery is done under local anesthesia and does not require an overnight hospital stay. Many patients require surgery on both hands. The following are types of carpal tunnel release surgery:

Open Release Surgery. This is the traditional procedure used to correct carpal tunnel syndrome, consists of making an incision up to 2 inches (5 centimeters) in the wrist and then cutting the carpal ligament to enlarge the carpal tunnel. The procedure is generally done under local anesthesia on an outpatient basis, unless there are unusual medical considerations.

Endoscopic Surgery. Endoscopic surgery may allow faster functional recovery and less postoperative discomfort than traditional open release surgery. The surgeon makes two incisions (about 1/2 inch (1.25 cm) each) in the wrist and palm, inserts a camera attached to a tube, observes the tissue on a screen, and cuts the carpal ligament (the tissue that holds joints together). This two-portal endoscopic surgery, generally performed under local anesthesia, is effective and minimizes scarring and scar tenderness, if any. One-portal endoscopic surgery for carpal tunnel syndrome is also available.

Although symptoms may be relieved immediately after surgery, full recovery from carpal tunnel surgery can take months. Some patients may have infection, nerve damage, stiffness, and pain at the scar. Occasionally the wrist loses strength because the carpal ligament is cut. Patients should undergo physical therapy after surgery to restore wrist strength. Some patients may need to adjust job duties or even change jobs after recovery from surgery.

Recurrence of carpal tunnel syndrome following treatment is rare. The majority of patients recover completely.

CARPELS. Carpels are the female reproductive organs within a flower that enclose the ovules, protecting them and screening out inappropriate pollen. They arose, probably from leaf-like organs, long after the origin of ovules. Genes controlling key steps in carpel and ovule development are being discovered.

In seed plants, which evolved around 360 million years ago, male and female gametes arise within specialized structures formed by the mature diploid plant. The female structure is the ovule, the organ that bears the egg. A specific cell within the ovule undergoes meiosis early in ovule development. One of the resulting haploid products then undergoes cell divisions to form the gametophyte. In turn, one of these cells becomes the egg. In the more primitive seed plants, including gymnosperms, the ovule may be embedded in a leaf-like megasporophyll, but the egg is exposed at the surface so that pollen, the male gametophyte, can gain ready access to it. Following fertilization, the ovule serves to house the developing diploid embryo and encases it in a seed coat for dispersal. See also **Plant Reproduction**; and **Seed**.

Around 130 million years ago, a group of seed plants arose in which the formerly naked ovules became enclosed in a specialized structure, the carpel. Carpels are usually made up of three components — the ovary (the chamber in which ovules arise), the stigma (specialized surface tissue for the reception of pollen) and a style (providing a transmitting tract for growth of the pollen tube between the stigma and the ovary) (Figure 1). All the carpels in one flower, whether single or multiple, free or fused, are collectively called the *gynoecium*. After fertilization, the ovary component of carpels usually undergoes further growth and modification to generate the fruit that encloses the developing seeds. The presence of carpels defines the angiosperms, or flowering plants, a group that has been spectacularly successful with approximately 250 000 species now living. Not only does the carpel protect the ovules during their development, it also provides a barrier through which only appropriate pollen tubes can grow to achieve fertilization, features likely to have contributed to this explosive success. See also **Angiosperms**; and **Fruit**.

Genes and Carpel/Ovule Development

Carpel Genes. The structure of the mature carpel is the result of the finely tuned action of many genes.

Genes that regulate the identity of each floral organ type, including the carpel, are now well known. They function alone or in combination to switch the developmental program of newly arising organ primordia into the pathway appropriate to their position within the flower. In the model laboratory species *Arabidopsis thaliana*, carpel identity function is controlled by the gene *AGAMOUS*. The gene encodes a transcription factor

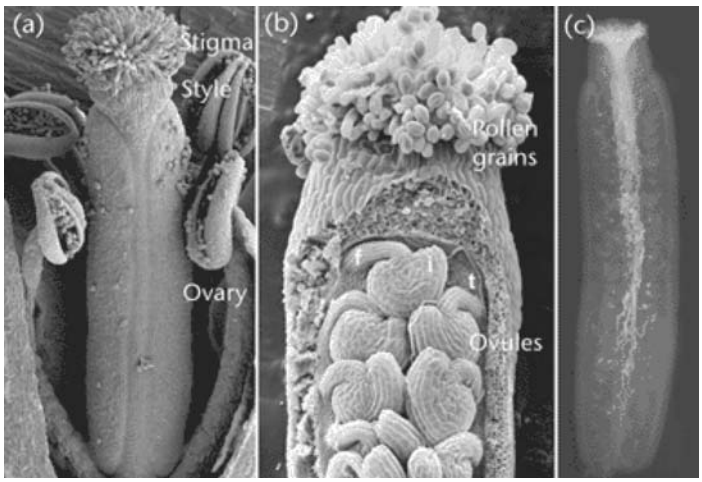

Fig. 1. Structure of carpels of the model laboratory species *Arabidopsis thaliana* (a) Scanning electron micrograph of a mature flower with several sepals, petals and stamens removed to reveal the central female reproductive organ (medial view). This is made up of two congenitally fused carpels (left and right) that are together called the gynoecium. The three components of the gynoecium are an upper stigma with papillae on which pollen grains germinate, a short style with internal transmitting tract tissues through which the pollen tubes grow and a large, two chambered ovary. Each chamber represents one carpel, and the two chambers are separated by a septum, which also carries transmitting tract tissues. (b) Side (lateral) view of a gynoecium of *Arabidopsis* with part of the ovary wall dissected away. This reveals the internal ovules within one of the two chambers (corresponding to one of the two carpels). Each ovule has a short stalk (funiculus, f), an internal nucellus that carries the embryo sac (including the female gamete) and two sheaths of tissue (integuments, i) surrounding the entrance to the ovule (micropyle). In this species, the integuments are turned upwards (anatropous). Pollen grains have germinated on the stigma, and pollen tubes (t) have grown down the style and septum, and several can be seen in the chamber (top right). (c) Cleared gynoecium of *Arabidopsis* in which the pollen tubes have been selectively stained with the fluorochrome aniline blue. Their path of travel from the stigma, down the transmitting tract, and to micropyles of individual ovules, can be observed. (a) and (c) Reproduced from Alvarez and Smyth [2002] with permission of The University of Chicago Press and (b), courtesy of John Alvarez. *Note: this image originally appeared in the Encyclopedia of Life Sciences, John Wiley & Sons, Inc., Hoboken, NJ.*

of the MADS family and its primary function is to regulate the expression of other, mostly unidentified, genes. The genetic mechanism by which carpel identity is established is highly conserved in flowering plants, as orthologues of *AGAMOUS* with similar roles have been reported in many other species.

However, AGAMOUS function is not alone in initiating the *Arabidopsis* carpel development program. When the functions of the closest MADS relatives of the *AGAMOUS* gene were examined, it was found that duplicated *SHATTERPROOF* genes were also involved in defining carpel identity (Table 1). Constitutive expression of these genes could fully restore the carpel developmental program when AGAMOUS function was lost. On the other hand, when SHATTERPROOF function was lost, carpels develop normally because AGAMOUS function is still present. The mutant phenotype of the *SHATTERPROOF* genes revealed itself later during fruit development when the loss of their role in defining the dehiscence zone became apparent.

When individual components of the *Arabidopsis* gynoecium were investigated using genetic dissection methods, it was revealed that AGAMOUS function specifies only the identity of the wall of the ovary (the valve) and outgrowth of the style. Two other transcription factor genes, *CRABS CLAW* and *SPATULA*, have been described whose regulatory functions are required to bring about the full carpel development program [Alvarez and Smyth, 1999]. CRABS CLAW function is required to ensure lateral and vertical growth of the carpels, and SPATULA function is needed for appropriate development of tissues arising from the edges of the carpels, especially the transmitting tract. Among other regionally acting genes uncovered so far, *STYLISH1* and *2* apparently act redundantly to promote growth of the style and stigmatic regions [Kuusk et al.: 2002], and *KNUCKLES*, encoding a zinc-finger transcription factor, acts to support development of the basal region of the ovary [Payne, et al., 2004].

Many other carpel genes are known, although they mostly have pleiotropic mutant effects in other parts of the developing plant. This suggests that they do not play a specific role in defining carpel-specific processes. Even so, one interesting pleiotropic gene that seems to control aspects of both proximal–distal and abaxial–adaxial polarity within the developing *Arabidopsis* gynoecium is *ETTIN* [Nemhauser, et al.: 2000]. This gene is related to those that bind to elements in the promoters of auxin-activated genes, and it may thus provide a link between the action of this hormone and carpel growth processes. See also **Plant Growth Modification and Regulation**.

Ovule Genes. A series of genes controlling the development of ovules has also been discovered. Ovule identity seems to be under simple genetic control. In *Petunia hybrida*, the *FLORAL BINDING PROTEIN 11* gene is expressed specifically in ovules but, when it is expressed ectopically in all tissues, ectopic ovules arise on the surface of sepals and petals. This indicates that the MADS protein encoded by this gene may normally specify ovule identity within newly developing primordia within the gynoecium [Colombo, et al.: 1995]. In *Arabidopsis*, the orthologue of this gene is *SEEDSTICK*, and this, too, establishes ovule identity (Table 1). Interestingly, all close MADS relatives of SEEDSTICK, including AGAMOUS, apparently determine ovule identity, although their other functions (i.e. target genes) are mostly not shared (Table 1).

TABLE 1. THE ROLES OF FOUR CLOSELY RELATED MADS TRANSCRIPTION FACTOR GENES IN CONTROLLING CARPEL, OVULE AND FRUIT DEVELOPMENT ARABIDOPSIS

Gene	Carpel identity	Stamen identity	Flower determinacy	Ovule identity	Fruit dehiscence	Seed abscission
AGAMOUS	+	+	+	+	−	−
SHATTERPROOF1 & 2	+	−	−	+	+	−
SEEDSTICK	−	−	−	+	−	+

Source: see Pinyopich, et al.: [2003].

Other, later-acting genes are also known that are involved in growth of the ovule primordium, development of the ovule coat (integuments), growth of the stalk (funiculus) and development of the female gametophyte within the nucellus [Skinner, et al.: 2004] (Figure 1). It is interesting that several of these genes may have been involved in modifications to ovule development that occurred during angiosperm evolution. The ovules of gymnosperms and other extinct seed plants typically have only one coat or integument (unitegmic) and the body of the ovule sits erect on the stalk (orthotropous). On the other hand, most angiosperm ovules have double coats (bitegmic), and the body of the ovule is turned back along the stalk (anatropous). Mutants with loss of function phenotypes that are now unitegmic, or orthotropous, may have occurred in genes involved in defining the more advanced forms.

Evolution of Carpels

There has been much speculation about how the megasporophyll formed an enclosed chamber during angiosperm evolution. Comparative developmental studies of the single free carpels within basal families suggest that they are derived from leaf-like organs that bear ovules along each edge [Endress and Igersheim, 2000]. If these folded inwards (towards the stem) so that the edges either touched or lay flat alongside each other, structures resembling an ovary would result. Further, the development of hairs and/or secretions at the point of touching would facilitate the development of a transmitting tract that facilitates the growth of pollen tubes to the internal ovules. It is now a series of short steps to generate the typical structure of the enclosed carpel. The infolded edges could fuse postgenitally. Alternatively, a similar outcome is achieved if the edges are fused congenitally from the base. Either way, a cup-shaped structure (ascidium) is produced. The upper region could become elongated into a style, and the hairs and secretions might become localized towards the apex and evolve into stigmatic tissue. The canal within the style (part of the transmitting tract) may also be filled by similar hairs or secretions, or it may be fully sealed by congenital fusion of ingrowing cells.

Such a speculative scheme (among others) accounts for the evolution of single, free carpels. Aggregation into fused multicarpellate gynoecia, such as those that occur in about 80% of all flowering plants, and embedding of the ovary within the floral receptacle to form the inferior ovary seen in many higher angiosperms are apparently additional refinements based on the single carpel unit.

Recently, molecular phylogenetic studies have revealed that the most basal extant angiosperm is the relict woody shrub *Amborella trichopoda* [Qiu, et al.: 1999]. This is the only member of the family Amborellaceae, and is confined to the island of New Caledonia in the South Pacific. Carpels in this species are urn-shaped and capped with a broad, stigmatic surface (Fig. 2). They have an unfused transmitting tract canal that is filled with secretion, as is the chamber that contains the one pendulous, straight (orthotropous) ovule. Each flower has several unfused carpels arranged in a spiral. Thus, the structure of carpels in this primitive species, and indeed in the next most basal families including water lilies and a small group including star anise and the Australian tropical climber *Austrobaileya*, is consistent by it representing an early stage of the carpel evolution pathway outlined above.

Fig. 2. Carpel structure in the most primitive angiosperm, *Amborella trichopoda*. Flowers of this New Caledonian woody shrub have several free urn-shaped carpels, each with a single ovule. In this diagram of a longitudinal section of one carpel, the large cap of stigmatic cells, the narrow canal through which pollen tubes grow (the transmitting tract) and the single, penduluous (orthotropous) ovule within the ovary are visible. Both the canal and the chamber around the ovule are filled with secretion. The floral axis is on the left. For further details see Endress and Igersheim [2000].

Pollination

Carpels play an important role in ensuring that only pollen of the appropriate type fertilizes the egg [Weterings and Russell, 2004]. Pollen grains first make contact with the carpel through the stigma (Fig. 1**b**). Here they hydrate and germinate. A tube emerges from a pore in their wall and penetrates the stigma, growing between stigmatic cells or within the middle lamella of one such cell, or even within the cell itself. The pollen tube then moves into the transmitting tract that underlies the stigma, following this defined path within the style and ovary. In many cases, the transmitting tract is solid and made up from cells that have secreted an extracellular matrix of carbohydrates, glycoproteins and other proteins that provide nutrition for the elongating pollen tube. In other cases, the tract is a hollow tube but the cells lining it provide secretions thought to offer the same specialized support. As the pollen tube continues to grow, it eventually reaches the vicinity of the ovule. Here, a remarkable series of events occurs as it leaves the transmitting tract and grows specifically towards the ovule's opening (micropyle). It contacts the two specialized cells, often protruding into the micropyle (the synergids), penetrates one of them and releases its two haploid sperm cells. Typically, one of these then fuses with the neighboring egg, and another with two polar nuclei of the central cell to generate the nutritive endosperm. See also **Sepals**.

Pollen Recognition. Just how carpel tissues are able to recognize specific pollen grains has been investigated and some answers are available. In a range of different families, genetically controlled systems of self incompatibility have evolved. In species with "wet" stigmas in the nightshade family (Solanaceae), for example, pollen that shares its haploid (gametophytic) genotype with the stylar cells through which it is growing is recognized, and its growth is chemically disrupted. On the other hand, in some species with "dry" stigmas in the mustard family (Brassicaceae), it is only those pollen grains whose outer coat does not share its paternal (sporophytic) genotype with the stigma cells on which it falls that will hydrate and germinate.

The molecular nature of the self versus nonself recognition process has now been established in the Solanaceae and the Brassicaceae. In each case it is a "lock and key" event. In the former, gametophytic system, the style produces degradative S-RNAase molecules [Kao and Tsukamoto, 2004]. The pollen tube expresses a specific F-box protein that presumably recognizes and targets for removal of all S-RNAase molecules "except" for the one encoded by the same S "allele." In this way, the style inactivates the pollen of the same genotype by means of those S-RNAase molecules that have not been eliminated. In the latter, sporophytic system, the stigma carries specific receptor protein kinases that are triggered by ligands generated in the anther and which coat all pollen grains from each plant [Nasrallah, 2002]. In this case, however, the active recognition is between molecules generated by the "same" S "allele." The recognition leads to a blocking of pollen tube penetration of the style. The consequence is that any pollen grain of that species that is not recognized as "self" can grow.

Pollen Tube Guidance. One process that still requires explanation is how the path of pollen tube growth is directed within the gynoecium [Weterings and Russell, 2004]. Chemical signaling processes are presumably involved. One long distance signaling molecule may be gamma aminobutyric acid (GABA). In mutants of *Arabidopsis*, guidance to the ovule is lost when two genes are in mutant form, and one of these genes, *POP2*, controls GABA levels. Pollen of *pop2* mutant plants is hypersensitive to GABA and may lose the ability to grow up a GABA concentration gradient towards the ovule [Palanivelu, et al., 2003]. The existence of a signaling system has also been revealed in experiments using *Torenia fournei* where the egg apparatus (synergids and egg cell) naturally protrudes from the micropyle [Higashiyama, et al., 2001]. Isolated ovules can attract pollen tubes only if at least one of the synergids remains active (individual egg apparatus cells can be inactivated by laser ablation). Also, pollen tubes are attracted only if they have already grown through a style, i.e. they are "potentiated." The chemical basis of these events is not yet known. In maize, however, there is now good evidence that a specific short distance signal that attracts pollen tubes to the female gametophytic tissue is a small peptide [Márton, et al., 2005]. The *Egg Apparatus1* gene, encoding a 94 amino acid peptide, is active only in the two synergids and egg cell. Importantly, while down regulation of the gene in maternal tissue using RNA interference did not disrupt the movement of pollen tubes into the micropyle, they no longer sought out the synergids. The *Egg Apparatus1* gene was not found in fully sequenced genomes outside of the grasses, further suggesting that the peptide may play a role in restricting inter-species fertilization.

CARPENTER-BEE *(Insecta, Hymenoptera).* A bee that excavates its nest in wood. The small carpenter-bee, *Ceratina dupla*, of North America merely digs out the pith or soft wood of a plant, such as sumac, while the large carpenter-bees, *Xylocopa*, of which there are several species, bore into solid wood, even attacking unpainted wood in construction. The larger bees are not unlike bumblebees in appearance.

CARPENTER-MOTH *(Insecta, Lepidoptera).* Moths whose larvae bore in the trunks of trees, entering the solid wood. A few species, including the locust borer, are of large size, and because of their narrow wings and long bodies may be mistaken for sphinx moths. These insects make up the small family *Cossidae*.

CARP *(Osteichthyes).* Carp are members, along with minnows, of the family *Cyprinidae* (group *Cypriniformes*). The common carp is an introduced species, indigenous to eastern Asia, but now thoroughly acclimated in the rivers and lakes of North America and Europe. It is coarse and bony, but widely used as food. The goldfish or golden carp is a related species native to China and Japan. Many strange varieties have been developed in captivity and the species is thriving in some lakes and streams in the eastern United States.

Sports fishermen often consider the carp in extremely negative terms because in some areas the carp has literally taken over habitats, thus excluding more desirable edible and sporting species, usually present prior to the introduction of the carp. On the other hand, the carp is easily cultivated and thus in some areas of the world, the fish is a blessing as a food source. It is notable that a planted and well-fertilized pond will produce more than a half-ton of fish per acre (560 kilograms per hectare) within a reasonable time. In comparison, less than 200 pounds (91 kilograms) of black bass can be produced under the same circumstances within the equivalent period of time. Originally, *Cyprinus carpio* (the common carp) came from the Black and Caspian Seas and environs. It is now found in most of the temperate waters worldwide. The carp is characterized by its four barbels, a pair at each side of the mouth. These features are lacking in the similar goldfish. The number of scales also varies between carp and goldfishes. The Japanese golden carp is dramatic to view and is considered a show fish. Most common goldfish varieties have stemmed from the so-called wild goldfish (*Carassius auratus*), also sometimes referred to as the Missouri minnow, funa (in Japan), or johnny carp. This fish is brownish and quite plain in appearance, but with the physical features of a carp.

Numerous varieties of domestic goldfish have been developed over the years, notably by the Japanese. Some of these include: the normal V-tail (the type most commonly sold in pet stores); the veiltail with its three-lobed tail; the blackmoor, which features a coloration reminiscent of black velvet, bulbous "pop eyes," and a veil tail, the celestial telescope goldfish which has bulbous eyes having the appearance of looking upward as the fish swims forward; and lionheads, lacking the dorsal fin, with thick tumor-like structures over the head. A Singapore carp is illustrated in Fig. 1.

Fig. 1. Singapore carp. (*A.M. Winchester*.)

The raising of carp for commercial purposes is discussed in some detail in entry on **Aquaculture**. See also **Fishes**.

CARRAGEENAN. See **Food Additives**.

CARRIER. 1. A neutral material such as diatomaceous earth used to support a catalyst in a large-scale reaction system.

2. A gas used in chromatography to convey the volatilized mixture to be analyzed over the bed of packing that separates the components.

3. An atomic tracer carrier; a stable isotope or a natural element to which radioactive atoms of the same element has been added for purposes of chemical or biological research.

CARRIER AMPLIFIER. A dc amplifier wherein the signal first is modulated, then demodulated during amplification. Electronic switches or electromechanical devices are used in most cases to effect the modulation. Thus, the "chopping" action accomplishes the equivalent of a square-wave modulation of the signal.

The carrier technique is employed for two main purposes: (1) to reduce to a minimum the effects of zero-offset drift, which is a critical performance parameter in any dc amplifier, and (2) to provide isolation between the input and the output of the amplifier.

With reference to the accompanying diagram (Fig. 1), a conceptual design is shown. The input signal first is modulated to produce an ac signal, after which the signal is amplified by an ac amplifier. Then, the output of the latter is demodulated to provide a dc output signal. Zero-offset drift in the amplification section of the amplifier does not affect the value of the output signal because only the ac component is amplified. However, offsets in the modulator can cause the equivalent of an offset in the output signal should they increase or decrease the magnitude of *both* the positive and negative peaks of the modulated signal. In most cases, if the input signal is greater than 1 V, such offsets do not create a serious problem. In the case of low-level amplifiers, however, they can cause significant errors. Because

the output demodulator usually operates at a high level, demodulator offset is not considered an important limitation on overall amplifier performance. The use of carrier amplifiers designed mainly for the reduction of zero-offset drift is diminishing mainly due to the improvement of techniques and components for accomplishing low-drift direct-coupled amplifiers.

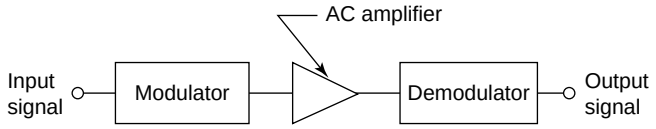

Fig. 1. Carrier amplifier.

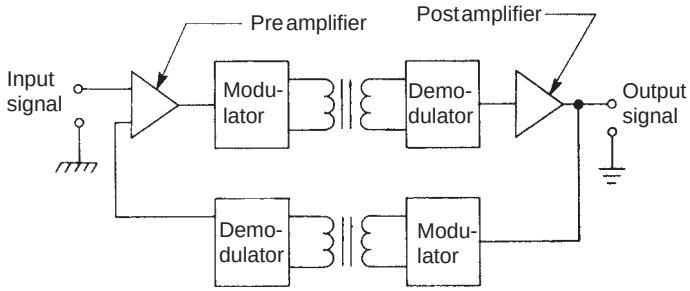

Fig. 2. Floating carrier amplifier.

In the instance of using a carrier amplifier to provide isolation between the input and output of the amplifier, the amplifier commonly is termed a "floating amplifier." See also **Floating Amplifier**. An amplifier of this design, incorporating an overall feedback path, is shown in Fig. 2. The basic carrier concept is used—the input signal is modulated and demodulated by a chopper circuit. In this example, since the main purpose is isolation rather than reduction of drift, an ac amplifier is not used. By means of the four-terminal isolation characteristic of the transformer, the input signal can be referenced to a ground point that is independent of the output-signal reference point. Floating-carrier amplifier designs of this type are used in digital-data acquisition subsystems and instrumentation subsystems to accomplish amplification of signals under conditions where high common-mode voltages may be present. The common-mode voltage is essentially limited by the breakdown voltage of the coupling transformer. Thus, amplifiers of this design can function with up to several hundred volts of common mode, as contrasted with the usual 10 to 20 V limit inherent to most direct-coupled amplifiers as the result of the breakdown limitations of most semiconductor devices.

THOMAS J. HARRISON, IBM Corporation, Boca Raton, FL

CARRIER-AMPLITUDE REGULATION. The change in amplitude of the carrier wave in an amplitude-modulated transmitter when modulation is applied under conditions of symmetrical modulation.

CARRIER (Communications). A wave suitable for being modulated to transmit intelligence. The modulation represents the information; the original wave is used as a "carrier" of the modulation. See also **Modulation**.

CARRIER CURRENT. Carrier current is used in connection with both power and communication circuits but, basically, the principle is the same for both systems. The term refers to the use of a relatively high-frequency ac superimposed on the ordinary circuit frequencies in order to increase the usefulness of a given transmission line. Thus in the case of power systems, carrier currents of several kHz frequency are coupled to the 60-Hz transmission lines. These carrier currents may be modulated to provide telephone communication between points on the power system or they may be used to actuate relays on the system. This latter use is known as carrier relaying. Carrier currents have greatly extended the usefulness of existing line facilities of the telephone and telegraph companies. Several carrier frequencies may be coupled to the lines already having regular voice or telegraph signals on them. Each of these carrier frequencies may be modulated with a separate voice or telegraph channel and thus a given line may carry the regular signals plus several new carrier channels, each of which is equivalent to another circuit at regular frequencies. At the receiving end, the various channels are separated by filters and the signals demodulated and then fed to conventional phone or telegraph circuits. The number of carrier channels applicable to a given line depends upon the characteristics of the line, varying from one or two for some lines to several hundred for the coaxial cable.

See also **Filter (Communications System)**.

CARRIER (Food Additive). A substance well named because its primary function is that of conveying and distributing other substances throughout a food substance. The role parallels that of a carrier in paint, wherein vehicle (carrier) holds and distributes pigment throughout the entire paint product. Silica gel and magnesium carbonate serve as carriers in food substances. For example, the high porosity of silica gel enables it to adsorb internally up to three times its own weight of many liquids. This property is used to convert various liquid ingredients, such as flavors, vinegar, oils, vitamins, and other nutritional additives, into easy-to-handle powders. These powders, in turn, can be measured easily and blended effectively with other constituents to provide a uniform food substance. Advantage is taken of the properties of carriers in the convenience food field, where flavors remain entrapped inside silica particles until the food product is mixed with water, at which time the flavors are released just prior to consumption, giving the product an aura of richness and freshness.

CARRIER FREQUENCY. Also called center frequency or resting frequency, that frequency generated by an unmodulated radio, radar, or carrier communication transmitter; or the average frequency of the emitted wave when modulated by a symmetrical signal.

CARRIER SUPPRESSION. (1) Suppression of the carrier when there is no modulation signal to be transmitted. (2) Suppression of the carrier frequency after conventional modulation at the transmitter, but with reinsertion of the carrier at the receiving end prior to demodulation.

CARRIER-TO-NOISE RATIO. The ratio of the value of the carrier to that of the noise after selection and before any nonlinear process such as amplitude limiting and detection.

CARRION BEETLE *(Insecta, Coleoptera).* Moderate to large beetles found above decaying flesh and to some extent about other decaying matter. Applied to members of the family *Silphidae*, although many other beetles breed in decaying matter and are found in it, both as adults and as larvae.

CARTENOIDS. See **Dyes: Natural**.

CARTESIAN COORDINATES. A coordinate system in which the locations of points in space are expressed by reference to three planes, called coordinate planes, no two of which are parallel. The three planes intersect in three straight lines, called coordinate axes. The coordinate planes and coordinate axes intersect in a common point, called the origin. From any point P in space three straight lines may be drawn, each of which is parallel to one of the three coordinate axes; each of these lines will then intersect one (and only one) of the three coordinate planes. If A, B, C denote these points of intersection, the Cartesian coordinates P are the distances PA, PB, and PC. If the coordinate axes are mutually perpendicular, the coordinate system is rectangular; otherwise, oblique. In meteorology, the most common orientation of the x, y, z rectangular Cartesian coordinates is such that the x axis is directed toward the east, tangent to the earth's surface; the y axis toward the north, tangent to the earth's surface; and the z axis toward the local zenith, perpendicular to the earth's surface.

CARTESIAN TENSOR. A quantity specified by components that transform according to prescribed rules under rotations of (Cartesian) coordinate axes. A Cartesian tensor of rank zero is a scalar and is invariant under rotations. A Cartesian tensor of rank one is a vector, the components of which transform under rotations according to a single 3×3 rotation matrix. Cartesian tensors of rank two have nine components that transform according to a product of two 3×3 rotation matrices. Tensors of higher rank may be defined in similar fashion. As examples related to meteorology, mass is a scalar, velocity is a vector, and the stress tensor is a Cartesian tensor of rank two. [Because of the restriction to transformation under rotation, a Cartesian tensor need not be a (general) tensor. The latter

has components that transform in a prescribed way under arbitrary changes of coordinates.]

CARTILAGE. A supporting tissue associated with the skeleton of vertebrates. Cartilage, like the other connective and supporting tissues, contains a relatively large amount of intercellular substance in which the cells are scattered. This substance is a complex mixture of organic materials, bluish in color and translucent. It contains organic fibrils and around the cavities in which the cartilage cells lie it differs chemically as shown by its reaction to stains. The cells are rounded and may lie singly or in groups in the capsules.

Three kinds of cartilages are recognized: hyaline, elastic, and fibrocartilage. The first contains few fibrils. It is flexible, slightly elastic, and provides a support of moderate rigidity. It covers the ends of bones in movable joints as the articular cartilages, forms the rings of the trachea, and occurs in other parts of the body where such qualities are required. Elastic cartilage is similar to hyaline but has many elastic fibers in the intercellular matrix. It occurs in the pinna of the ear, where its qualities provide support and elasticity, the latter very necessary in a delicately formed projecting structure of this kind which might otherwise be easily broken. Fibrocartilage contains many inelastic white fibers, which give it extreme toughness. It is associated with some joints and forms the intervertebral disks of the backbone. These disks provide very firm connections between the separate vertebrae and at the same time cushion the series.

The term cartilage is also applied to separate skeletal units formed of this material. Each cartilage is surrounded by a tough connective tissue sheath called the perichondrium.

Cartilage is a primitive skeletal material of the vertebrates. It precedes bone in embryonic development and persists in the adult skeleton in the sharks and related fishes. It is not transformed into bone but is replaced by bone in the formation of some of the parts of the skeleton. It may become rigid through the deposition of calcareous material in its matrix, particularly in old age. This calcified cartilage, while rigid like bone, does not have the minute structure of that tissue. See also **Arthritis**; and **Bone**.

Cartilage is also the term used for the internal structure of the ligament that connects the valves of the shell in some of the bivalve mollusks.

CARVER, GEORGE WASHINGTON (1864–1943). Carver was born into slavery in Diamond Grove, Missouri. Along with his mother, Mary, he was stolen from Moses Carver's farm by Confederate bushwhackers. Because he was sickly, he was taken from his mother and abandoned along the side of a road and left to die. Moses and Susan Carver found him and raised him as their own child. Because George was a slave and did not have a last name, he later took the name "Carver" and used it as his own.

As a young child Carver, appreciated nature and spent a great deal of time working in the family garden. He was given the nickname "the plant doctor" because he seemed to have an ability to help plants thrive. At the age of 12, Carver began attending a school for black children. Later, he attended a mostly white high school. He kept his interests in plants and earned his Bachelor's degree and a Masters of Agriculture degree from Iowa State College. Although he was offered many prestigious teaching jobs, Carver fulfilled his dreams as a research scientist at Tuskegee Normal and Industrial Institute in Alabama, an institute for higher education for poor blacks.

Carver ushered in a new era in agriculture with his teachings of crop rotation. Based on his knowledge of agriculture, he taught Southern farmers to plant sweet potatoes, peanuts, and soybeans to help restore the nutrients to the soil which were depleted by cotton and tobacco crops. In order to use the surplus of peanuts and sweet potatoes, Carver worked on experiments to determine new uses for them. Sometimes referred to as the "Peanut Man," Carver developed peanut butter, peanut oil, and more than 300 synthetic materials that could be made from the peanut plant including: milk and cheese substitutes, soap and dyes He found 108 uses for the sweet potato and 75 uses for the pecan. His work in developing industrial applications for agricultural products created 118 products including a rubber substitute and over 500 dyes and pigments. He also invented a process for producing paints and stains from soybeans.

In 1923, Carver received the Spingarn Medal which is awarded annually to a black person who has made the greatest contribution to the advancement of his race. Carver was honored by U.S. President Franklin Delano Roosevelt in July 14, 1943 for his accomplishments as a researcher, instructor, and chemical investigator, with a national monument near Carver's childhood home near Diamond Grove, Missouri.

CAS. See **Chemical Abstract Service Registry Number**.

CASCADE. (1) Any connected arrangement of separative elements whose result is to multiply the effect, such as isotope separation, created by the individual elements. A bubble plate-tower is a cascade whose elements are the individual plates; a plant consisting of many towers in series and parallel is similarly a cascade whose elements may be considered to be either the towers or the individual plates. Similarly, an amplifier, in which each stage except the first has as its input the output of the preceding stage, is called a cascade amplifier. A stage of a grounded-cathode vacuum-tube amplifier is defined as the section from a point just before the grid of one tube to that just before the grid of the next. Similarly, for grounded-emitter transistor amplifiers, it is defined as the section from a point just before the base of one transistor to that just before the base of the next. (2) Coined term used to describe a large number of compounds derived from a common source, e.g., the arachidonic acid cascade.

CASCADE COOLING. See **Crygenics**; and **Natural Gas**.

CASCADE SHOWER. A type of cosmic ray shower brought about when a high-energy electron, in passing through matter, produces one or more photons of energies of an order of magnitude of its own. These photons are converted into electron pairs by the process of pair production. Then the secondary electrons produce the same effects as the primary, so that the process continues, and the number of particles increases. This cascade shower of negatrons and positrons continues to build up until the energy level of product particles falls to a point where photon emission and pair production can no longer occur. See also **Cosmic Rays**.

CASCARA. A drug, used as a laxative and cathartic, obtained from the bark of a shrub, *Rhamnus purchiana*, a member of the family *Rhamnaceae* (buckthorn family). The plant is found in western North America.

CASE HARDENING. Hardening of the surface layer or case of a ferrous alloy while leaving the core or center in a softer, tougher condition. There are two basic methods of case hardening. In the first, gaseous elements such as carbon or nitrogen are introduced into the surface layer, thereby forming a hardening or hardenable alloy at the surface. Examples are carburizing, nitriding, and carbonitriding. Alternatively, the surface may be given a hardening heat treatment that does not affect the core. This may be accomplished by flame hardening or induction heating, whereby the surface is rapidly heated into the austenite range and the specimen quenched before the center has obtained a temperature high enough to allow it to be hardened.

CASEIN. Casein [CAS: 9005-46-3] is the phosphoprotein of fresh milk; the rennin-coagulated product is sometimes called paracasein. British nomenclature terms the casein of fresh milk caseinogen and the coagulated product casein. As it exists in milk it is probably a salt of calcium.

Casein is not coagulated by heat. It is precipitated by acids and by rennin, a proteolytic enzyme obtained from the stomach of calves. Casein is a conjugated protein belonging to the group of phosphoproteins. The enzyme trypsin can hydrolyze off a phosphorus-containing peptone.

The commercial product also known as casein is used in adhesives, binders, protective coatings, and other products.

The purified material is a water-insoluble white powder. While it is also insoluble in neutral salt solutions, it is readily dispersible in dilute alkalies and in salt solutions such as those of sodium oxalate and sodium acetate.

CASHEW AND SUMAC TREES. The family Anacardiaceae (cashew family) is full of interesting variety, thus making generalizations difficult. Several of the species are known for their poisonous, irritating nature, such as poison ivy and poison oak. On the other hand, other species produce edible fruits and nuts, such as the mango, and cashew, and pistachio nuts.

Poison ivy (Rhus radicans) is a shrub or climbing woody vine, frequently found in wooded areas and along roadsides. The plant can extend itself to considerable heights by climbing tree trunks, masonry walls, and wooden screens and fences. The shrub is characterized by three pale green, ovate leaflets that are smooth on top, with slight fine hairs underneath on young leaves. The plant tolerates wet or dry conditions and is hardy, but generally prefers partial shade. All parts of the plant are irritating to humans. Poison oak (Rhus toxicodendron) also is of the cashew family and all parts of the plant are also poisonous irritants. This is an erect shrub ranging up

to 20 inches (50.8 centimeters) in height, occurs in many locations, but more frequently in the southern states. The shrub is named for its oak-like leaves, which are toothless, ovate, compound, and occur in groups of three. They are of a pale green color and even a lighter green underneath. The plant frequents uncrowded woody areas and on wasteland. Its preferred regions include the coastal plains south of Maryland and New Jersey to Florida and westward into Texas. Another poisonous species is *Rhus vernix*, poison sumac, all parts of which are irritants. The shrub ranges from 5 to 10 feet (1.5 to 3 meters) in height, although it may be in the form of a small tree as high as 20 feet (6 meters). The trunk is short, with forking occurring close to the ground. The leaves are compound, smooth, toothless, sharply pointed, and light green. The plant prefers moist, swampy locations and ranges widely from southern Maine south and west to Florida and Texas.

The cashew nut is the fruit of a Brazilian tree of moderate size (Anacardium occidentale). The kidney-shaped nut grows at the end of a curiously enlarged fleshy peduncle, which is juicy and bright yellow or red. The fleshy portion is eaten in tropical South America. The nut itself contains a biting, caustic oil, which is driven off by roasting. The single kernel of this fruit is the familiar cashew nut, widely distributed as a confection. The oil has been used in termite insecticides. Oil from cashew shells also has been used in compounding of rubber and plastics. The nuts range considerably in size (from 200 to 450 per pound; 441 to 992 per kilogram) and thus require grading before marketing.

The pistachio tree (*Pistacia vera*) is a small tree with deciduous pinnate leaves and is native to southwestern Asia, from which region it has spread in cultivation to the Mediterranean countries. Greece, for example, is an important producer of pistachio nuts. The apetalous flowers are unisexual and borne in panicles and the plants are dioecious. The fruit is a drupe, containing an elongated seed with a greenish kernel, having a very characteristic flavor. The kernels are used in confections, ice cream, and also eaten alone, usually after salting. Related to the true pistachio is Pistacia lentiscus, a shrub or small tree of the Mediterranean region with evergreen, pinnate compound leaves. From it is obtained a resin, mastic, which is often chewed by the natives of Turkey. It is used in medicine as a mild stimulant, as well as in varnishes. Another species is Pistacia terebinthus, a native of eastern Mediterranean countries, which yields China turpentine.

The mango tree (*Manaifera indica*), also of the cashew family, is a long-lived tree, which often develops a massive trunk and widely spreading branches. The lanceolate leaves of the mango are evergreen and about 4 inches (10 centimeters) in length. The flowers are numerous, small, pink, and borne in racemes. The ovoid fruits, 1 to 5 inches (2.5 to 12.7 centimeters) in diameter, are one-seeded berries having a thick, rough, greenish rind and a pleasantly aromatic, orange-colored flesh that is esteemed by many people. This fruit may be eaten fresh, or in salads. Reproduction is either by seedlings, which do not always come true, or by grafting. The tree is extensively cultivated in tropical regions, and was introduced a number of years ago to Florida and southern California. Probably it was first introduced into tropical America (Jamaica) in 1782. For successful growth, hot moist weather is necessary, followed by a short dry period for successful ripening of the fruit. Although the fruit is usually the important consideration of this tree, it also can make an excellent shade tree. The wood is soft, easily worked and, when available, can be used for constructing boats, canoes, and light buildings.

The South American paper tree (*Schinus molle*), another member of the cashew family, has been introduced into the Mediterranean region and in the warmer areas of North America. This tree, of a somewhat drooping contour, with small red berries, often gnarled trunk and branches, can make an interesting garden tree. However, generous space must be allowed because the tree can attain a height of nearly 40 feet (12 meters) within a 20-year period. This tree is not to be confused with the genera of plants (Piper and Capsicum), the sources of commercial paper.

Smoke trees are of the genus Cotinus. C. coggyria is frequently found in the gardens of Europe for its purple decor. An American counterpart, the C. obovatus, is a highly colorful plant and is often used in gardens and landscaping.

Tung oil, a powerful drying oil, is obtained from the seeds of Aleurites fordii and closely related species, also in the family Anacardiaceae. This is a tree of China. The sap of Rhus verniciflua yields a furniture lacquer.

Some species of sumac find acceptance in gardens, notably the varieties shown in the Table 1. Although the various sumacs, such as the staghorn

TABLE 1. RECORD SUMAC TREES IN THE UNITED STATES[1]

	Circumference[2]		Height		Spread		
Specimen	Inches	Centimeters	Feet	Meters	Feet	Meters	Location

and dwarf sumacs, are generally considered as shrubs, the dimensions shown in the table indicate the large proportions they can assume when situated in very favorable conditions.

CASSEGRAIN TELESCOPE. A reflecting telescope in which a small hyperboloidal mirror reflects the convergent beam from the paraboloidal primary mirror through a hole in the primary mirror to an eyepiece in back of the primary mirror. Also called *Cassegrainian* telescope, *Cassegrain*. See also **Newtonian Telescope**; and **Telescope (Astronomical-Optical)**.

CASSINI, GIAN DOMENICO (1625–1712). Cassini was an Italian scientist who made contributions in astronomy, earth science, and physics. Early in life he spent hours observing the stars with telescopes. His career began as a professor of mathematics at the University of Bologna. While at this university, he studied Jupiter and its bright satellites. He is known for his set of tables that could predict the eclipses of satellites as they pass through Jupiter's shadow. His tables helped to determine longitude at sea and aided system.

When King Louis XIV of France built his observatory, he chose Cassini as the first director of the Paris Observatory. Here, Cassini discovered four new satellites of Saturn. In 1675, he observed that Saturn's ring was divided into at least two concentric rings. This division is known as the Cassini division.

See also **Cassini-Huygens Mission to Saturn and Titan**; **Jupiter**; **Oval of Cassini**; and **Saturn**.

J.M.I.

CASSINI-HUYGENS MISSION TO SATURN AND TITAN. With its stunning rings and dozens of moons, Saturn is an intriguing planet for many reasons. The giant planet has a huge magnetosphere and a stormy atmosphere with winds clocked at about 1,800 kilometers per hour (1,118 mph) near the equator. These super-fast winds, combined with heat rising from within the planet's interior, cause the yellow and gold bands visible in its atmosphere.

Like Jupiter, Uranus and Neptune, Saturn is a gas giant. It is made mostly of hydrogen and helium.

Saturn's beautiful rings are what set it apart from the other planets in our solar system. It is the most extensive and complex ring system in our solar system, extending hundreds of thousands of miles from the planet. Made up of billions of particles of ice and rock — ranging in size from grains of sugar to houses — the rings orbit Saturn at varying speeds.

There are hundreds of individual rings, believed to be made of pieces of shattered moons, comets and asteroids. Each of the billions of rings particles orbits the planet on its own path.

For centuries, Saturn and its rings puzzled observers. Italian astronomer Galileo Galilei, the first to use a telescope to explore space, couldn't understand why Saturn looked so different in the night sky at different times. We now know this is caused by a shifting in our view of the ring plane. The rings are virtually invisible when they are edge-on to Earth. The rings seem to reappear months later as our angle of view changes.

Despite tremendous advances in observations in the 400 years since Galileo began studying Saturn's rings, many questions remain about the composition and structure of the rings.

Saturn's 34 known moons are equally mysterious, especially Titan. Bigger than the planets Mercury and Pluto, Titan is of particular interest to scientists because it is one of the few moons in our solar system with its own atmosphere. The moon is cloaked in a thick, smog-like haze that scientists believe may be very similar to Earth's before life began more than 3.8 billion years ago. Further study of this moon promises to reveal much about planetary formation and, perhaps, about the early days of Earth as well.

In addition to Titan, Saturn has many smaller icy satellites. Some, like Pan, Atlas, Prometheus, and Pandora, are "shepherd moons" that herd Saturn's orbiting particles into distinct ring. Some moons produce twisting and wave patterns in the rings.

One moon, Enceladus, is one of the shiniest objects in the solar system. It is about as wide as Arizona and covered with water ice that reflects sunlight like freshly fallen snow. And strange Iapetus has one side black as asphalt and the other as bright as snow. All of Saturn's moons are unique and intriguing science targets.

Four NASA spacecraft have been sent to explore Saturn. *Pioneer 11* was first to fly past Saturn in 1979. *Voyager 1* flew past a year later, followed by its twin, *Voyager 2*, in 1981. See also **Voyager Missions to Jupiter and Saturn**.

The *Cassini* spacecraft is the first to explore the Saturn system of rings and moons from orbit. *Cassini-Huygens* entered orbit on Jun. 30, 2004 and immediately began sending back intriguing images and data. The European Space Agency's *Huygens* Probe dove into Titan's thick atmosphere in January 2005. The sophisticated instruments on both spacecraft are providing scientists with vital data and the best views ever of this mysterious, vast region of our solar system.

The *Cassini-Huygens* mission to Saturn is the most ambitious effort in planetary space exploration ever mounted. A joint endeavor of NASA, the European Space Agency (ESA) and the Italian space agency, Agenzia Spaziale Italiana (ASI), *Cassini* is sending a sophisticated robotic spacecraft to orbit the ringed planet and study the Saturnian system in detail over a four-year period. Onboard *Cassini* is a scientific probe called *Huygens* that was released from the main spacecraft to parachute through the atmosphere to the surface of Saturn's largest and most interesting moon, Titan.

Cassini-Huygens was launched October 15, 1997, at 4:43 a.m. Eastern Daylight Time (0843 Universal Time) from Cape Canaveral Air Force Station in Florida aboard a Titan IVB/Centaur launch system — the most powerful launch vehicle in the U.S. fleet. See Fig. 1. After *Cassini-Huygens* was placed in a parking orbit around Earth, a Centaur upper stage fired to send *Cassini-Huygens* on the interplanetary trajectory that delivered the spacecraft to Saturn. *Cassini-Huygens* reached Saturn on June 30, 2004 after an interplanetary cruise spanning nearly seven years. Along the way, it has flown past Venus, Earth and Jupiter in "gravity assist" maneuvers to increase the speed of the spacecraft. Saturn is the second largest planet in the solar system. Like the other gaseous outer planets (Jupiter, Uranus and Neptune) it has an atmosphere made up mostly of hydrogen and

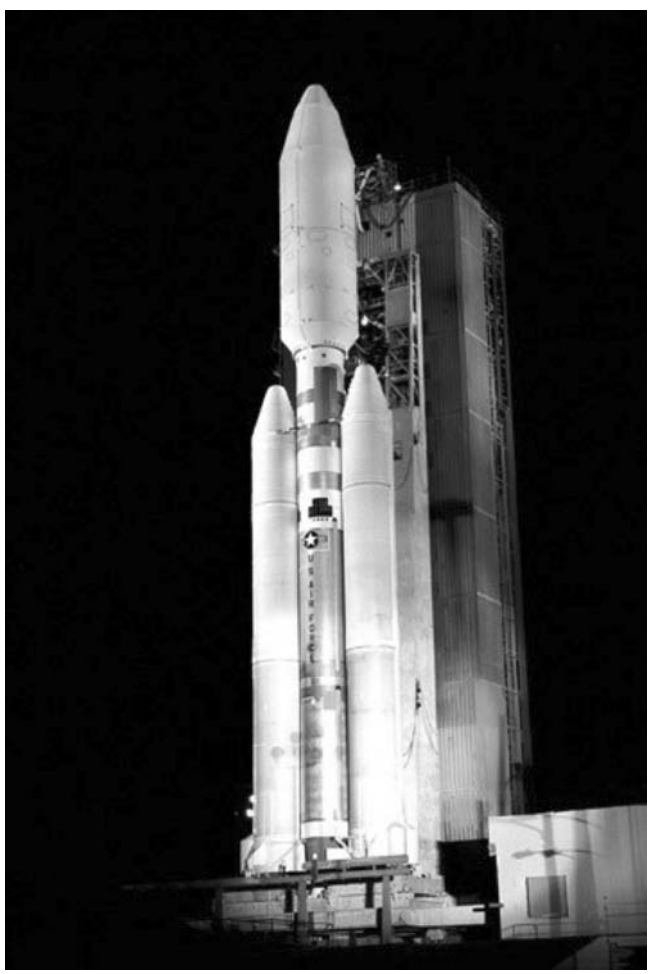

Fig. 1. *Cassini* aboard a Titan IVB/Centaur, the most powerful launch vehicle in the U.S. Fleet. (*JPL/NASA.*)

helium. Saturn's distinctive, bright rings are made up of ice and rock particles ranging in size from grains of sand to boxcars. More moons of greater variety orbit Saturn than any other planet. So far, observations from Earth and by spacecraft have found Saturnian satellites ranging from small asteroid-size bodies to the aptly named Titan, which is larger than the planet Mercury.

Radio Science Subsystem (RSS). If you were to shout at the top of your lungs, how far away could people hear you? How much softer would your voice be if you where behind a curtain, a thick door or a brick wall?

Cassini's Radio Science Subsystem (RSS) is designed to take measurements using radio waves beamed to Earth that explore similar concepts at a distance of more than a billion kilometers (more than 621 million miles).

"Our instrument can measure exactly how well you could hear somebody talking, and the quality of the sound traveling through whatever is between you and the speaker," explains Sami Asmar, RSS task leader. "By studying the changes in your voice as it goes through various materials, we'd learn information on the composition and characteristics of the door or the curtain behind which you'd be talking. For us, the materials are the rings of Saturn or the planet's atmosphere."

The largest instrument on the mission, RSS is split in two parts: one resides on the spacecraft, the other at stations equipped to receive very stable radio signals at each of the three Deep Space Network complexes.

The instrument's split personality allows it to measure the forces acting on the spacecraft by detecting slight changes in the frequency of radio signals sent from the spacecraft to Earth. It also measures how radio signals are affected by whatever material comes between the spacecraft and Earth — allowing scientists to study the composition and properties of Saturn's rings and atmosphere.

The 12 scientific instruments on the *Cassini* orbiter have conducted in-depth studies of the planet, its moons, rings, and magnetic environment. The six instruments on the *Huygens* probe, which were dispatched from *Cassini* during its first orbit of Saturn, have provided our first direct sampling of Titan's atmospheric chemistry and the first photographs of its hidden surface.

Saturn's butterscotch-colored face appears placid at the surface, but it masks a windswept atmosphere where an equatorial jet stream blows at 1,800 kilometers per hour (1,100 miles per hour) and swirling storms roil beneath the cloudtops. Early explorations by NASA's *Pioneer* 11 spacecraft in 1979, and the *Voyager 1* and 2 spacecraft in 1980 and 1981, found Saturn to possess a huge and complex magnetic environment, where trapped protons and electrons interact with each other, the planet, the rings and the surfaces of many of the satellites. The bright rings for which Saturn is best known were found to consist of not just a few monolithic bands but thousands of rings and ringlets broad and thin, with particles sometimes herded into complicated orbits by the gravitational interaction of small moons previously unseen from Earth.

Haze-covered Titan offers a tantalizing mix of an Earth-like, nitrogen-based atmosphere and a surface that many scientists believe probably features chilled lakes of ethane and a surface coated with sticky brown organic condensate that has rained down from the atmosphere. Standing on Titan's surface beneath an orange sky, a visitor from Earth likely would find a cold, exotic world with a pungent odor reminiscent of a petroleum processing facility. Because Titan and Earth share so much in atmospheric composition, Titan is thought to hold clues to how the primitive Earth evolved into a life-bearing planet.

The Saturnian system offers more variety in scientific targets for study than any other planet in our solar system. Over the course of *Cassini's* four-year mission, and through the studies of Titan by the Huygens probe, scientists expect to reveal new discoveries and enrich the understanding of phenomena in fields including biology, atmospheric chemistry and physics, climatology, volcanism, tectonics, the physics of disc systems such as galaxies and solar systems in formation, and more.

The Cassini Spacecraft

The *Cassini* spacecraft, including the orbiter and the *Huygens* probe, is one of the largest, heaviest and most complex interplanetary spacecraft ever built. The orbiter alone weighs 2,125 kilograms (4,685 pounds). When the 320-kilogram (705-pound) *Huygens* probe and a launch vehicle adapter were attached and 3,132 (6,905 pounds) of propellants were loaded, the spacecraft at launch weighed 5,712 kilograms (12,593 pounds). See Fig. 2. Of all interplanetary spacecraft, only the two *Phobos* spacecraft sent to Mars by the former Soviet Union were heavier.

The *Cassini* spacecraft stands more than 6.7 meters (22 feet) high and is more than 4 meters (13.1 feet) wide. The magnetometer instrument is mounted on an 13-meter (42-foot) boom that extends outward from the spacecraft. Three other 10-meter (32-foot) rod-like booms that act as the antennas for the radio plasma wave subsystem extend outward from the spacecraft in a Y shape. The complexity of the spacecraft is necessitated both by its flight path to Saturn and by the ambitious program of scientific observations to be undertaken once the spacecraft reaches its destination. The spacecraft includes 22,000 wire connections and more than 12 kilometers (7.5 miles) of cabling. Because of the very dim sunlight at Saturn's orbit, solar arrays are not feasible and electrical power is supplied by a set of radioisotope thermoelectric generators, which use heat from the natural decay of plutonium-238 to generate electricity to run *Cassini's* systems. These power generators are of the same design as those used on the *Galileo* and *Ulyssess* missions.

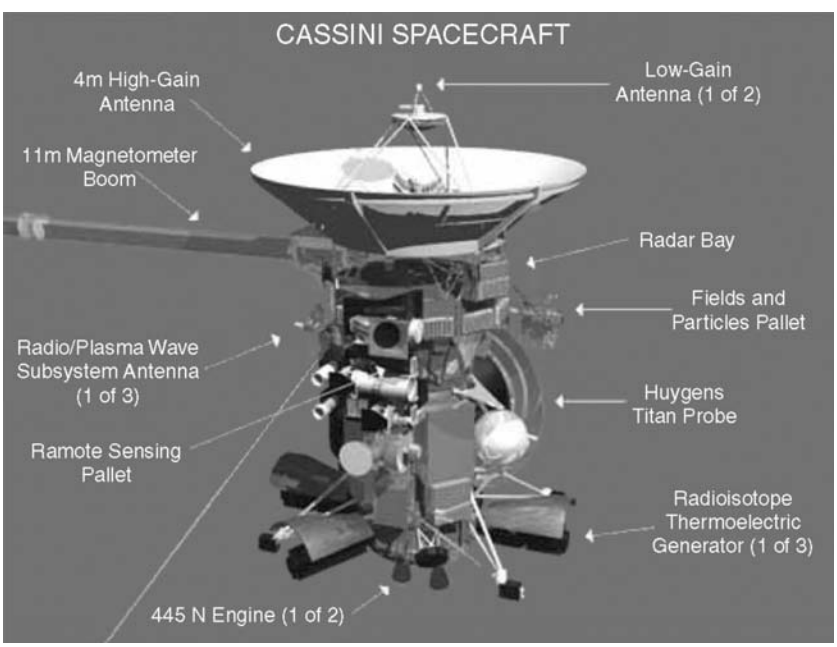

Fig. 2. *Cassini* Spacecraft. (*JPL/NASA.*)

Equipment for a total of 12 science experiments is carried onboard the *Cassini* orbiter. Another six fly on the Huygens probe, which will detach from the orbiter to parachute through Titan's atmosphere to its surface.

The *Cassini* orbiter has advanced and extended the United States technology base with several innovations in engineering and information systems. Whereas previous planetary spacecraft used onboard tape recorders, *Cassini* has pioneered a new solid state data recorder with no moving parts. The solid state recorder eventually will likely replace tape recorders used during space missions. Similarly, the main onboard computer that directs operations of the orbiter uses a novel design drawing on new families of electronic chips. Among them are very high-speed integrated circuit (VHSIC) chips developed under an U.S. government-industry research and development initiative. Also part of the computer are powerful new application-specific integrated circuit (ASIC) parts; each component replaces a hundred or more traditional chips.

Elsewhere on the *Cassini* orbiter, the power system benefits from an innovative solid-state power switch developed for the mission. This switch eliminates rapid fluctuations called transients that usually occur with conventional power switches, with a significantly improved component lifetime. The solid-state power switch holds great promise for use in numerous Earth-based applications as well.

Science Instruments and Experiments

Orbiter

Imaging Science Subsystem (ISS). Officially named Imaging Science Subsystem (or ISS) the instrument consists of a wide-angle camera and a narrow-angle camera. The narrow-angle camera provides high-resolution images of targets of interest, while the wide-angle camera allows more extended spatial coverage at lower resolution.

At the heart of each camera is a charged coupled device (CCD) detector consisting of a 1024 square array of pixels, each 12 microns on a side. The data system allows many options for data collection, including choices for on-chip summing and data compression. The narrow-angle camera packs plenty of power too, and could see a quarter — 2.4 centimeters (0.9 inches) across — from a distance of nearly 4 kilometers (2.5 miles).

To increase the images' scientific value, each camera on *Cassini* has two filter wheels designed to take images at specific wavelengths of light. The narrow-angle camera has 12 filters in each wheel for a total of 24 filters; the wide-angle has 9 in each wheel for a total of 18. Some filters only allow light of a certain color to reach the sensor. Combining three such images can produce a color image. The most scientifically interesting images are calibrated in order to turn the electrical signals that emerge from the CCDs into an absolute measure of brightness. See Figs. 3 and 4.

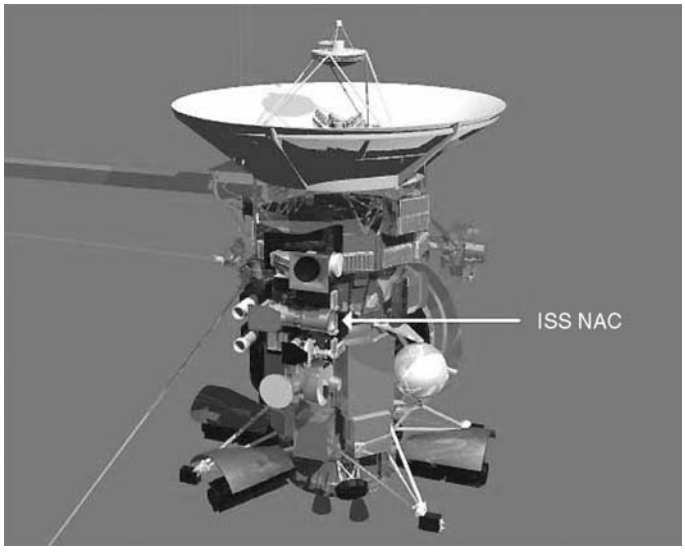

Fig. 3. The location of *Cassini* Narrow Angle Camera. (*JPL/NASA.*)

The two cameras on *Cassini* have already returned a visual feast of images. The instrument sends to Earth an average of 2,700 raw images a month. The cameras can also obtain optical navigation frames — images of Saturn's moons against a star background — that are used to keep the spacecraft on the correct trajectory.

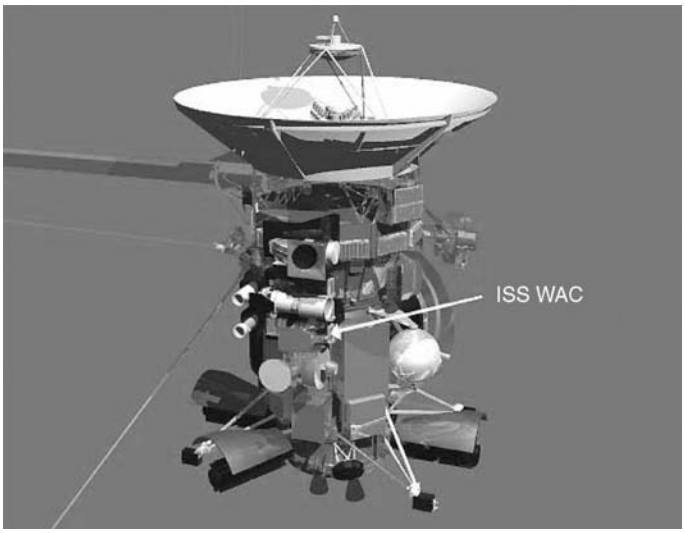

Fig. 4. The location of *Cassini* Wide Angle Camera. (*JPL/NASA.*)

ISS Scientific Objectives:

- To map the 3-dimensional structure and motions within the Saturn/Titan atmospheres.
- To study the composition, distribution, and physical properties of clouds and aerosols.
- To investigate scattering, absorption, and solar heating within the S/T atmospheres.
- To search for evidence of lightning, aurorae, airglow, and planetary oscillations.
- To study the gravitational interactions between the rings and Saturn's satellites.
- To determine the rate and nature of energy and momentum transfer within the rings.
- To determine ring thickness and sizes, composition, and physical nature of ring particles.
- To map the surfaces of the satellites (including Titan) to study their geological histories.
- To determine the nature and composition of the icy satellite surface materials.
- To determine the rotation states of the icy satellites.

Cassini Radar (RADAR). The *Cassini* Radar (RADAR) takes pictures like a camera but it "sees" using microwaves instead of light. It measures how objects reflect microwaves, which tells scientists something about how rough they are, or how they would conduct electricity. All this information helps scientists deduce what a celestial body's landscape looks like and figure out its composition.

Another great feature of radar is that it can pierce through an atmosphere, even one as thick and murky as the one engulfing Titan. By bouncing radio signals off Titan's surface and timing their return, the RADAR is producing maps of Titan's surface and measuring the height of surface objects such as mountains and canyons.

The *Cassini* Radar (RADAR) uses the five-beam Ku-band antenna feed assembly associated with the spacecraft high gain antenna to direct radar transmissions toward targets, and to capture blackbody radiation and reflected radar signals from targets. See Fig. 5.

RADAR Scientific Objectives:

- To determine whether oceans exist on Titan, and, if so, to determine their distribution.
- To investigate the geologic features and topography of the solid surface of Titan.
- To acquire data on non-Titan targets (rings, icy satellites) as conditions permit.

The Radio Science instrument can measure changes in velocity less than a micron per second at enormous distances allowing scientists to gain

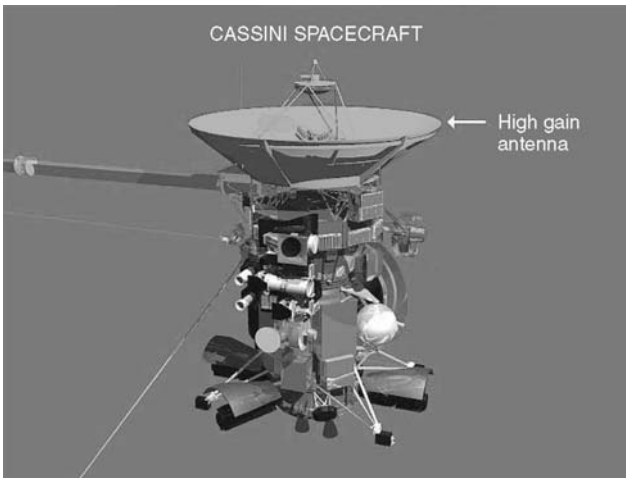

Fig. 5. The location of *Cassini* Radar (RADAR). (*JPL/NASA*.)

information on the interior structure of the planet and its many natural satellites.

The Radio Science Subsystem (RSS) uses the spacecraft X-band communication link as well as S-band downlink and Ka-band uplink and downlink to study compositions, pressures, and temperatures of atmospheres and ionospheres, radial structure and particle size distribution within rings, body and system masses, and gravitational waves. See Fig. 6.

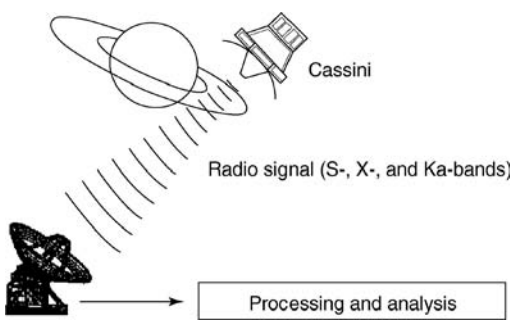

Fig. 6. Radio Science Subsystem (RSS). (*JPL/NASA*.)

RSS Scientific Objectives:

- To search for and characterize gravitational waves coming from beyond the solar system.
- To study the solar corona and general relativity when Cassini passes behind the Sun.
- To improve estimates of the masses and ephemerides of Saturn and its satellites.
- To study the radial structure and particle size distribution within Saturn's rings.
- To determine temperature and composition profiles within Saturn's/Titan's atmospheres.
- To determine temperatures and electron densities within Saturn's/Titan's ionospheres.

Ion and Neutral Mass Spectrometer (INMS). The Ion and Neutral Mass Spectrometer (INMS) is collecting data to determine the composition and structure of positive ions and neutral particles in the upper atmosphere of Titan and the magnetosphere of Saturn. It is also measuring the positive ion and neutral environments of Saturn's rings and icy moons. See Figs. 7 and 8.

The instrument is capable of determining the chemical, elemental and isotopic composition of the gaseous and volatile components of the neutral particles and the low energy ions in Titan's atmosphere and ionosphere, Saturn's magnetosphere, and the ring environment.

INMS Scientific Objectives:

- To measure ion and neutral species composition and structure in the upper atmosphere of Titan.

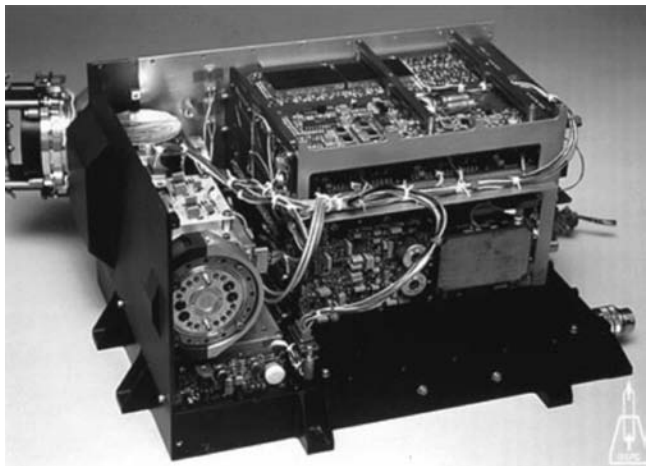

Fig. 7. Ion and Neutral Mass Spectrometer (INMS). (*JPL.NASA*.)

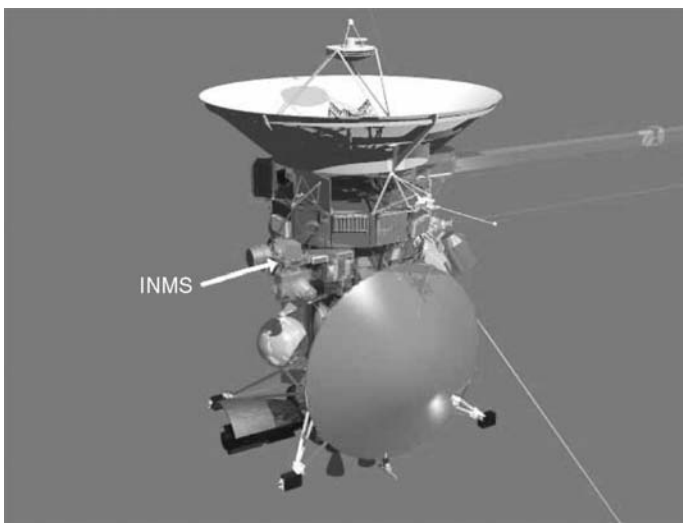

Fig. 8. The location of *Cassini* Ion and Neutral Mass Spectrometer (INMS). (JPL/NASA.)

- To study Titan atmospheric chemistry.
- To investigate the interaction of Titan upper atmosphere with the magnetosphere and solar wind.
- To measure ion and neutral species compositions during ring plane crossings and icy satellite flybys.

Visible and Infrared Mapping Spectrometer (VIMS). There are a lot of things that our eyes cannot see; just ask those who operate a spectrometer — an optical instrument that splits the light received from objects into its component wavelengths. Since each chemical has a unique spectral signature, they can be identified this way.

The Visual and Infrared Mapping Spectrometer (VIMS) onboard the *Cassini* spacecraft is made up of two cameras in one: one is used to measure visible wavelengths, the other infrared. Combined, the two cameras gather a lot of information on the composition of moon surfaces, the rings, and the atmospheres of Saturn and Titan.

"Our instrument measures the characteristic colors of the many materials that make up planetary surfaces and atmospheres: rocks, ices — such as water, ammonia, methane — and organic compounds," says Dr. Bonnie J. Buratti, VIMS Investigation Scientist. "VIMS data makes it possible to know what surfaces and atmospheres are made up of."

The instrument detects signals from a large range of wavelengths — three octaves — and it gathers 99 percent of radiation that is reflected from the Sun to a surface. Soon after *Cassini* reached Saturn, the instrument sent home valuable information.

"Data from VIMS allowed us to discover an ice volcano on Titan and the presence of fresh ice at the 'tiger stripes' on the moon Enceladus," Buratti says. "We are looking forward to the many upcoming flybys of Titan and of the moon Rhea. I am excited about Rhea because I'd like

to see if it's an older version of Enceladus — like Dione — or something completely different."

The Visible and Infrared Mapping Spectrometer (VIMS) is a pair of imaging grating spectrometers designed to measure reflected and emitted radiation from atmospheres, rings, and surfaces over wavelengths from 0.35 to 5.1 micrometers to determine their compositions, temperatures, and structures. See Figs. 9 and 10.

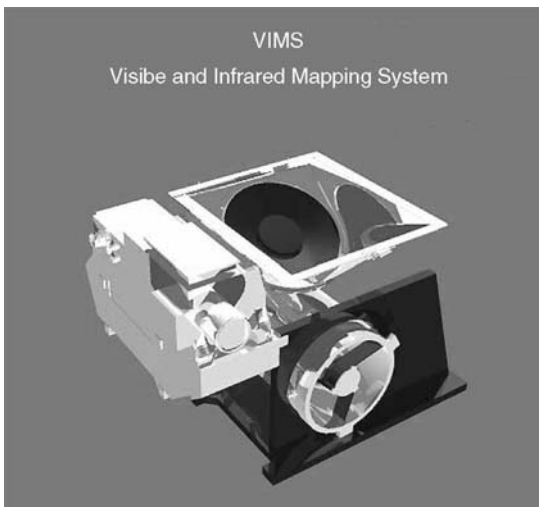

Fig. 9. Visible and Infrared Mapping System (VIMS). (*JPL/NASA.*)

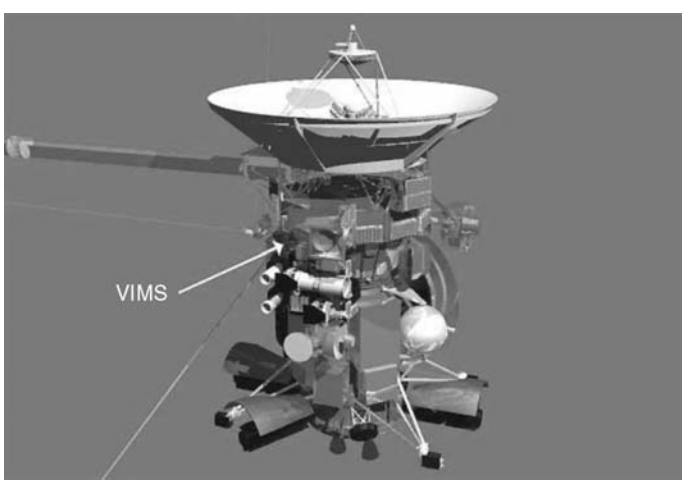

Fig. 10. The location of *Cassini* Visible and Infrared Mapping Spectrometer (VIMS). (*JPL/NASA.*)

With VIMS, scientists are also conducting a long-term study of cloud movement and morphology in the Saturn system to determine the planet's weather patterns. VIMS also observes the sunlight and starlight that pass through the rings to learn more about ring structure.

VIMS Scientific Objectives:

- To map the temporal behavior of winds, eddies, and other features on Saturn/Titan.
- To study the composition and distribution of atmospheric and cloud species on S/T.
- To determine the composition and distribution of the icy satellite surface materials.
- To determine temperatures, internal structure, and rotation of Saturn's deep atmosphere.
- To study the structure and composition of Saturn's rings.
- To search for lightning on Saturn and Titan and for active volcanism on Titan.
- To observe Titan's surface.

Composite Infrared Spectrometer (CIRS). With its capacity to see light that's redder than the red we see, the Composite Infrared Spectrometer (CIRS) searches for heat and is capable of discerning an object's composition.

"Our instrument looks at the world the way a snake's tongue does — always searching for heat, not light," explains Dr. Glenn Orton, a senior research scientist and CIRS co-investigator. "Another way to look at it is that we're looking at what our skin feels as heat, rather than what our eyes see as light."

But CIRS can do a lot more than just seeing beyond what our eyes can see.

"What's cool is that CIRS can tell us how hot something is and what's in it — like finding out that there's a hot bowl of soup over there and that it's chicken noodle, not tomato."

Our noses, of course, are capable of doing the same thing, but only when up close. And, as Orton points out, "We can't get that close to Saturn or Titan."

Orton researches temperatures and compositions of planetary atmospheres using a variety of facilities, some based on Earth — such as Keck Observatory and the Infrared Telescope Facility — and some up in space, such as Hubble and Spitzer.

"We can measure pretty precisely how hot things are in planets and on their surfaces," Orton says. "That's a big deal for weather prediction."

From this information scientists can tell a lot about a planet, starting with how hot it is and also what it is made of. A planet's atmosphere, such as Saturn or the moon Titan, is composed of different gases distributed in layers upon layers of varying temperatures that increase and decrease from the surface up through the edge of space. Data from the instrument helps scientists figure out what an atmosphere is composed of.

"Each gas emits or absorbs heat rays in a characteristic way, some wavelengths more than others," explains Conor Nixon, assistant research scientist on the Cassini CIRS team. "By measuring the infrared spectrum we can tell what gases are in the atmosphere, and how much of each one."

CIRS has produced some exciting results so far.

"The most exciting results must be the discovery of 'hot cracks' on the south pole of the moon Enceladus. The cracks were seen by the Cassini cameras (ISS), but CIRS was able to tell that they are much hotter than the surroundings," Nixon says.

The Composite Infrared Spectrometer (CIRS) consists of dual interferometers that measure infrared emission from atmospheres, rings, and surfaces over wavelengths from 7 to 1000 micrometers (1400 to 10 cm^{-1}) to determine their composition and temperatures. See Figs. 11 and 12.

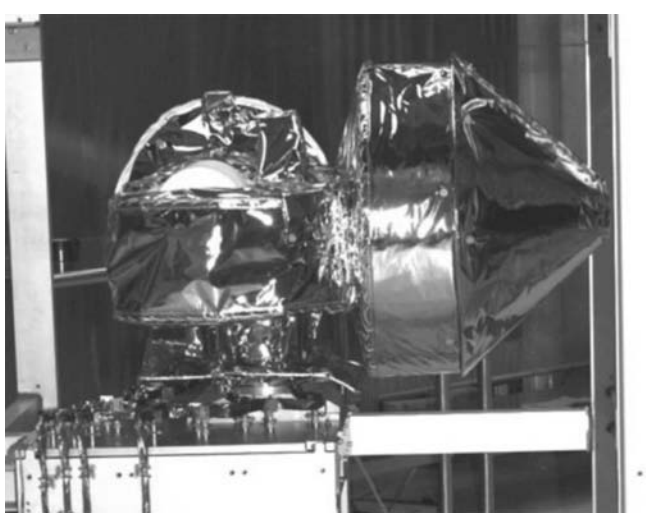

Fig. 11. Composite Infrared Spectrometer (CIRS). (*JPL/NASA.*)

CIRS Scientific Objectives:

- To map the global temperature structure within Titan's and Saturn's atmospheres.
- To map the global gas composition within Titan's and Saturn's atmospheres.

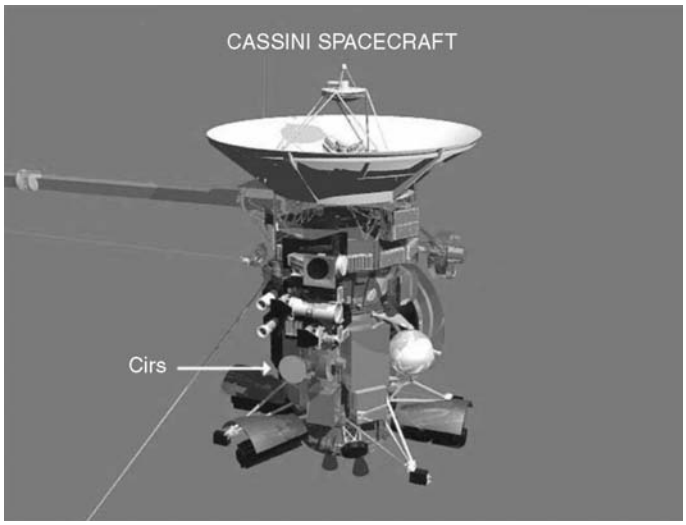

Fig. 12. The location of *Cassini* Composite Infrared Spectrometer (CIRS). (*JPL/NASA.*)

- To map global information on hazes and clouds within Titan's and Saturn's atmospheres.
- To collect information on energetic processes within Titan's and Saturn's atmospheres.
- To search for new molecular species within Titan's and Saturn's atmospheres.
- To map the global surface temperatures at Titan's surface.
- To map the composition and thermal characteristics of Saturn's rings and icy satellites.

Cosmic Dust Analyzer (CDA). Astronomers have long been puzzled by a mysterious faint glow that appears at various times in certain parts of the sky. Eventually, they concluded this was caused by the presence of cosmic dust. Giovanni Cassini was the first astronomer to recognize this dust in interplanetary space, and its presence around the sun, through telescopic observations in the 17th century. Revealing the origins of this cosmic dust, its composition and how it may affect life on Earth has been an ongoing focus of research and exploration ever since.

The *Cassini* spacecraft continues this research with an instrument capable of detecting the impact of tiny particles — 1/1,000 of a millimeter wide. To understand their true size and consistency, this cosmic dust can best be visually compared to icy cigar smoke particles. Under certain conditions, the Cosmic Dust Analyzer (CDA) onboard the spacecraft can even detect smaller dust grains called nano-dust. A nano-dust particle is one-millionth of a millimeter in size. Particles this small have as few as one million atoms, and are even smaller than a single influenza virus. Detection of these particles by the Cosmic Dust Analyzer would be equivalent to the detection of a single raindrop falling into the Gulf of Mexico.

"We are a factor of 1,000 times more sensitive than an optical instrument and able to see 'dust clouds'," says Dr. Ralf Srama, CDA Principal Investigator of the Max Planck Institute for Nuclear Physics, Heidelberg, Germany. "Therefore we would be able to find one smoke sized particle in a football stadium!"

The CDA is capable of detecting the impact of very tiny particles in the Saturnian system. Saturn's broad, diffuse E ring — within which several of Saturn's major moons travel in their orbits — is composed primarily of dust particles that are one-thousandth of a millimeter in size. These particles are tiny, much smaller than the width of a human hair, smaller even than red blood cells, but are easily detectable by the CDA. See Figs. 13 and 14.

Interesting results quickly followed after the instrument was switched "on" early in 1999, five years before the spacecraft reached Saturn.

"First, we detected interplanetary dust particles and measured their composition," Srama says. "Those grains are very rare, and we got just one impact per week."

While in Jupiter's vicinity the instrument detected nano-dust particles traveling through the solar system with speeds of 400 kilometers per second (about 894,800 miles per hour). Continuously released into our solar system by the Jovian system, these particles were "seen" by the instrument as far as 100 million kilometers (62,137,119 miles) away.

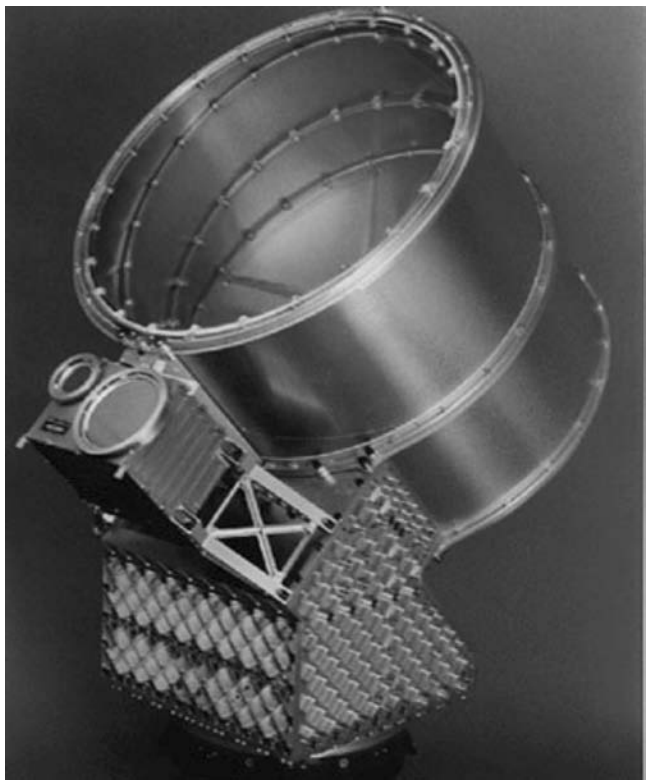

Fig. 13. Cosmic Dust Analyzer (CDA). (*JPL/NASA.*)

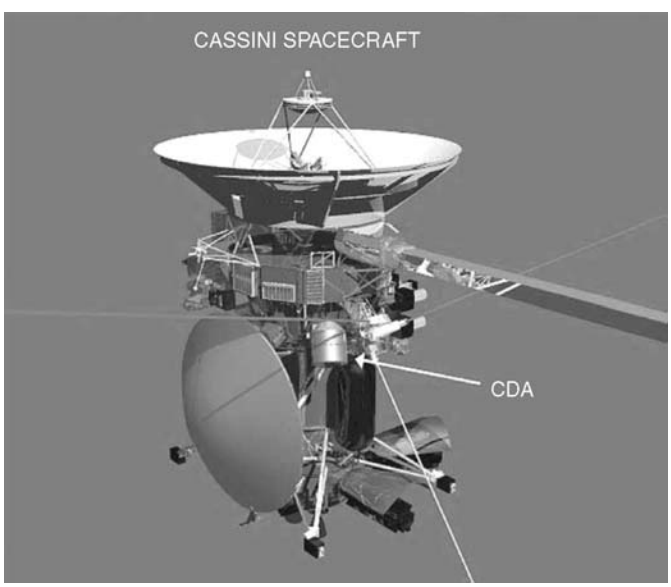

Fig. 14. The location of *Cassini* Cosmic Dust Analyzer (CDA). (*JPL/NASA.*)

It has been predicted that Saturn also releases smaller nano-dust particles traveling at slower speeds. Although more difficult to detect, the cosmic dust analyzer has such outstanding performance and sensitivity that it caught and found these smaller particles at distances of 100 million kilometers (62,137,119 miles) away from Saturn.

"We were even measuring their composition, and we found out that at least some of them are coming from Saturn's main ring (A ring)," Srama says.

CDA Scientific Objectives:

- To extend studies of interplanetary dust (sizes and orbits) to the orbit of Saturn.
- To define dust and meteoroid distribution (sizes, orbits, composition) near the rings.
- To map the size distribution of ring material in and near the known rings.

- To analyze the chemical compositions of ring particles.
- To study processes (erosional and electromagnetic) responsible for E ring structure.
- To search for ring particles beyond the known E ring.
- To study the effect of Titan on the Saturn dust complex.
- To study the chemical composition of icy satellites from studies of ejecta particles.
- To determine the role of icy satellites as a source for ring particles.
- To determine the role that dust plays as a magnetospheric charged particle source/sink.

Radio and Plasma Wave Spectrometer (RPWS). The Radio and Plasma Wave Science (RPWS) instrument receives and measures the radio signals coming from Saturn, including the radio waves given off by the interaction of the solar wind with Saturn and Titan.

The instrument studies the configuration of Saturn's magnetic field and its relationship to Saturn Kilometric Radiation (SKR), and also monitors and maps Saturn's ionosphere and plasma, and lightning from Saturn's atmosphere.

RPWS is also adept at determining the dust and meteoroid distributions throughout the Saturn system and between the icy satellites, the rings, and Titan.

The instrument measures electrical and magnetic fields in the plasma of the interplanetary medium and Saturn's magnetosphere, as well as electron density and temperature.

Plasma is essentially a soup of free electrons and positively charged ions, the latter being atoms that have lost one or more electrons. Plasma makes up most of the universe and is created by the heating of gases by stars and other bodies in space. Plasma is distributed by the solar wind; it is also "contained" by magnetic fields — that is, the magnetospheres — of bodies such as Saturn and Titan.

The major components of the instrument are an electric field sensor, a magnetic search coil assembly and a Langmuir probe. The electric field sensor is made up of three deployable antenna elements mounted on the upper equipment module of the Cassini orbiter. Each element is a collapsible beryllium-copper tube that was rolled up during launch and subsequently unrolled to its approximately 10-meter (33-foot) length by a motor drive. The magnetic search coils are mounted on a small platform attached to a support for Cassini's high-gain antenna. The Langmuir probe, which measures electron density and temperature, is a metallic sphere about 50 millimeters (2 inches) in diameter. The probe is attached to the same platform by an approximately 1-meter (3-foot) deployable boom. See Figs. 15 and 16.

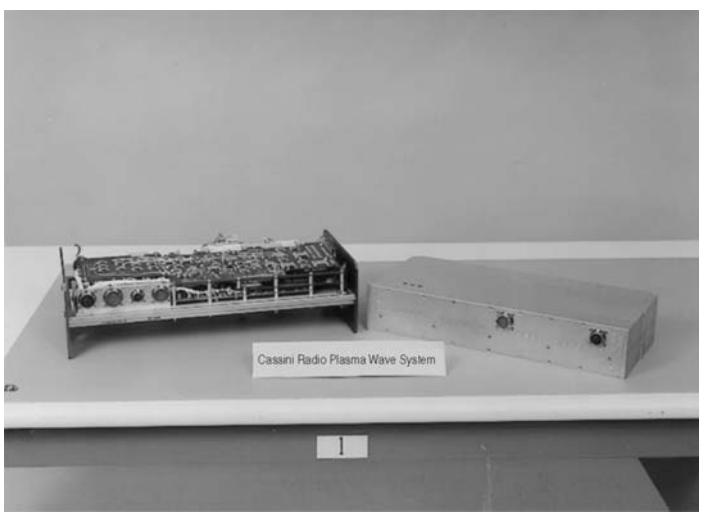

Fig. 15. *Cassini* Radio Plasma Wave System (RPWS). (*JPL/NASA.*)

RPWS Scientific Objectives:

- To study the configuration of Saturn's magnetic field and its relationship to Saturn Kilometric Radiation (SKR).
- To monitor and map the sources of SKR.
- To study daily variations in Saturn's ionosphere and search for outflowing plasma in the magnetic cusp region.

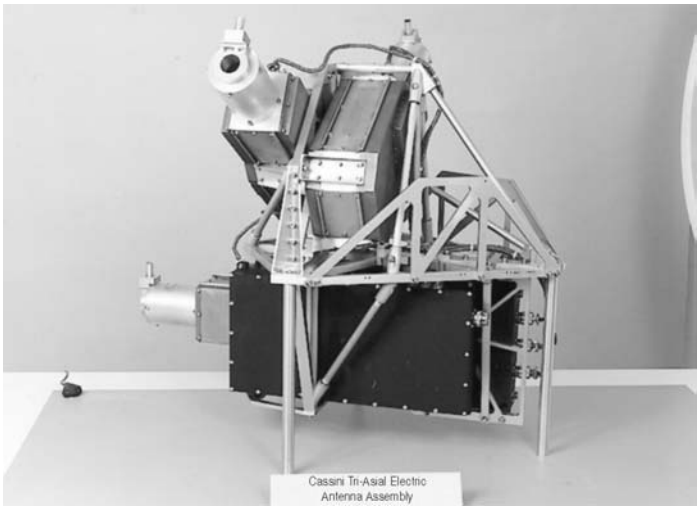

Fig. 16. *Cassini* Tri-Axial Electric Antenna Assembly. (*JPL/NASA.*)

- To study radio signals from lightning in Saturn's atmosphere.
- To investigate Saturn Electric Discharges (SED).
- To determine the current systems in Saturn's magnetosphere and study the composition, sources, and sinks of magnetospheric plasma.
- To investigate the dynamics of the magnetosphere with the solar wind, satellites, and rings.
- To study the rings as a source of magnetospheric plasma.
- To look for plasma waves associated with ring spoke phenomena.
- To determine the dust and meteroid distributions throughout the Saturnian system and interplanetary space.
- To study waves and turbulence generated by the interaction of charged dust grains with the magnetospheric plasma.
- To investigate the interactions of the icy satellites and the ring systems.
- To measure electron density and temperature in the vicinity of Titan.
- To study the ionization of Titan's upper atmosphere and ionosphere and the interactions of the atmosphere and exosphere with the surrounding plasma.
- To investigate the production, transport, and loss of plasma from Titan's upper atmosphere and ionosphere.
- To search for radio signals from lightning in Titan's atmosphere, a possible source for atmospheric chemistry.
- To study the interaction of Titan with the solar wind and magnetospheric plasma.
- To study Titan's vast hydrogen torus as a source of magnetospheric plasma.
- To study Titan's induced magnetosphere.

Cassini Plasma Spectrometer (CAPS). The *Cassini* Plasma Spectrometer (CAPS) measures the energy and electrical charge of particles such as electrons and protons that the instrument encounters. The instrument is used to study the composition, density, flow, velocity, and temperature of ions and electrons in Saturn's magnetosphere. Shaped much like a teardrop, Saturn's magnetosphere is huge. It spreads out almost a million miles, engulfing the orbits of Titan and most of the ringed planet's icy moons, as well as the famous rings.

The instrument consists of three sensors: an electron spectrometer, an ion beam spectrometer, and an ion mass spectrometer. A motor-driven actuator rotates the sensor package to provide 208-degree scanning in the azimuth of the spacecraft. The electron spectrometer makes measurements of the energy of incoming electrons; its energy range is 0.7 to 30,000 electron volts. The ion beam spectrometer determines the energy to charge ratio of an ion; its energy range is 1 electron volt to 50 kilo-electron volts. The ion mass spectrometer's energy range is 1 electron volt to 50 kilo-electron volts. See Figs. 17 and 18.

CAPS Scientific Objectives:

- To measure the composition of ionized molecules originating from Saturn's ionosphere and Titan.
- To investigate the sources and sinks of ionospheric plasma: ion inflow/outflow, particle precipitation.

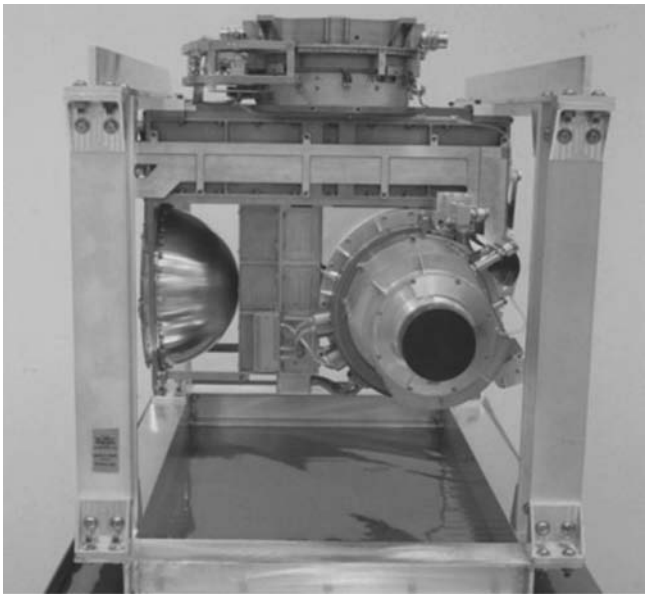

Fig. 17. *Cassini* Plasma Spectrometer (CAPS). (*JPL/NASA*.)

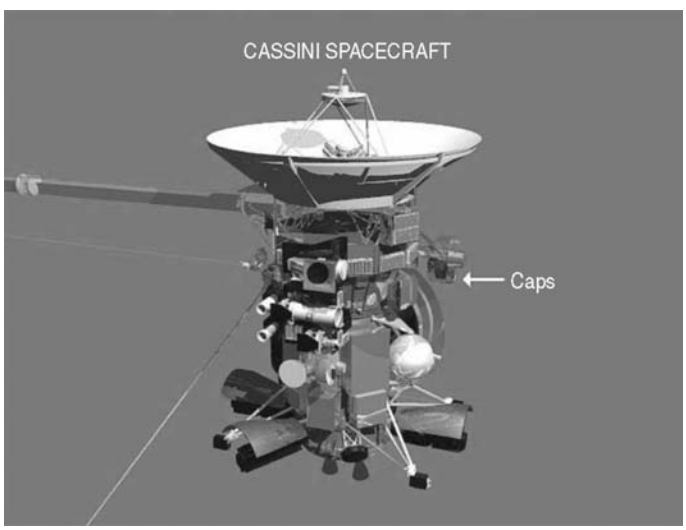

Fig. 18. The location of *Cassini* Plasma Spectrometer (CAPS). (*JPL/NASA*.)

- To study the effect of magnetospheric/ionospheric interaction on ionospheric flows.
- To investigate auroral phenomena and Saturn Kilometric Radiation (SKR) generation.
- To determine the configuration of Saturn's magnetic field.
- To investigate the plasma domains and internal boundaries.
- Investigate the interaction of the Saturn's magnetosphere with the solar wind and solar-wind driven dynamics within the magnetosphere.
- Study the microphysics of the bow shock and magnetosheath.
- Investigate rotationally driven dynamics, plasma input from the satellites and rings, and radial transport and angular momentum of the magnetospheric plasma.
- Investigate magnetotail dynamics and substorm activity.
- Study reconnection signatures in the magnetopause and tail.
- To characterize the plasma input to the magnetosphere from the rings.
- To characterize the role of ring/magnetosphere interaction in ring particle dynamics and erosion.
- To study dust-plasma interactions and evaluate the role of the magnetosphere in species transport between Saturn's atmosphere and rings.
- To investigate auroral phenomena and Saturn Kilometric Radiation (SKR) generation.
- To study the interaction of the magnetosphere with Titan's upper atmosphere and ionosphere.
- To evaluate particle precipitation as a source of Titan's ionosphere.
- To characterize plasma input to magnetosphere from the icy satellites.
- To study the effects of satellite interaction on magnetospheric particle dynamics inside and around the satellite flux tube.

Ultraviolet Imaging Spectrograph (UVIS). Built by the Laboratory for Atmospheric and Space Physics (LASP) http://lasp.colorado.edu/, located in the Research Park of the University of Colorado in Boulder, UVIS is a Remote Sensing Instrument (think sight) that captures images of the ultraviolet light reflected off an object. Designed to measure ultraviolet light over wavelengths from 55.8 to 190 nanometers, this instrument is also a valuable tool to help determine the composition, distribution, aerosol particle content and temperatures of their atmospheres. UVIS includes a two-channel, far- and extreme-ultraviolet imaging spectrograph that studies light over wavelengths from 55.8 to 190 nanometers.

A set of telescopes on *Cassini* is taking scientists to invisible territory. The Ultraviolet Imaging Spectrograph (UVIS) is a box of four telescopes that can see ultraviolet light. Ultraviolet (UV) light, known as the cause of sunburn on Earth, is invisible to the human eye. See Figs. 19 and 20.

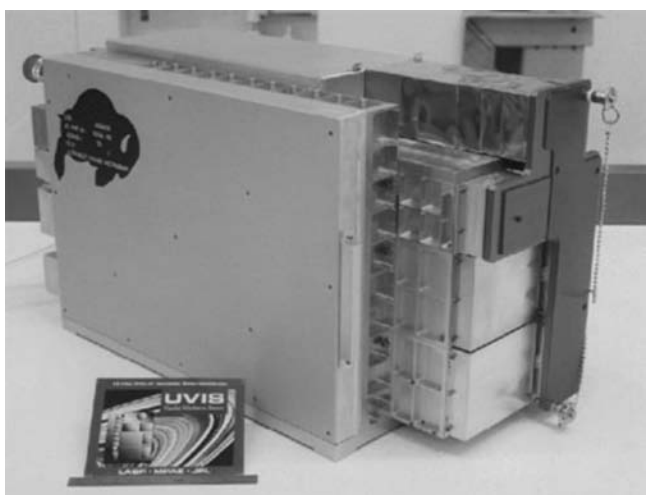

Fig. 19. *Cassini* Ultraviolet Imaging Spectrograph (UVIS). (*JPL/NASA*.)

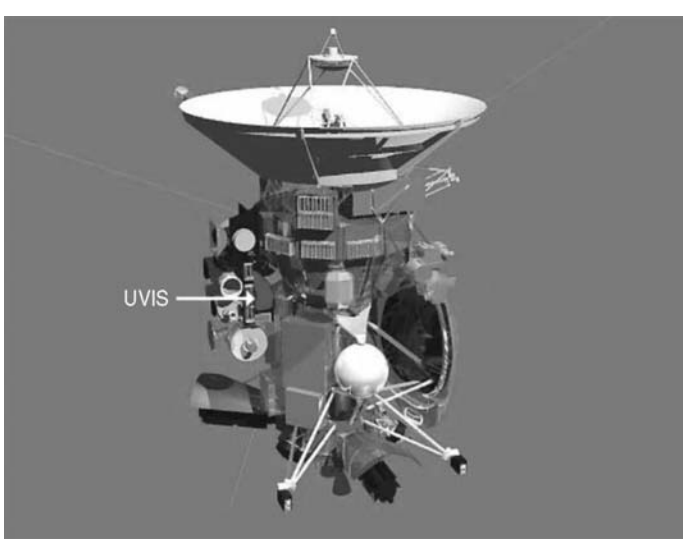

Fig. 20. The location of *Cassini* Ultraviolet Imaging Spectrograph (UVIS). (*JPL/NASA*.)

The instrument measures the views in ultraviolet light, and scientists use these measurements to produce pictures we can see. Since there is no table that maps ultraviolet "colors" to the colors humans see, the team exercises creative freedom when it makes representative images from the collected data.

"It is cool that we can pick our own colors in the pictures we produce," says Dr. Larry W. Esposito, a professor of Astrophysical and Planetary Sciences at the University of Colorado and UVIS Principal Investigator. "No person has ever seen ultraviolet light, although some butterflies can. Our pictures may thus represent a 'butterfly's-eye view' of the Saturn system."

The instrument's unique capabilities expand on the quality of the data collected by Cassini as it orbits the ringed planet.

"The cool thing about UVIS is that we can 'see' things that are invisible to other instruments!" says Dr. Amanda Hendrix, a planetary scientist at JPL and a UVIS team member who analyzes icy satellite data. "For example, UVIS can 'see' gases in the Saturn system that aren't seen by the camera. The instrument can also see the dark night side of the moons of Saturn, which stand out against the sky because they are bright at ultraviolet wavelengths."

Ultraviolet is particularly interesting because it includes the light characteristics of some key chemical elements and compounds. These light patterns are like fingerprints in UVIS observations. They allow scientists to identify conclusively what distant objects are made of.

"Already, UVIS has detected hydrogen, oxygen, methane, water, acetylene and ethane," Esposito says. "Our measurements tell us about the environment of Saturn that surrounds its moons and rings. We have also learned about the composition of Titan's upper atmosphere."

UVIS Scientific Objectives:

- To map the vertical/horizontal composition of Titan's and Saturn's upper atmospheres.
- To determine the atmospheric chemistry occurring in Titan's and Saturn's atmospheres.
- To map the distribution and properties of aerosols in Titan's and Saturn's atmospheres.
- To infer the nature and characteristics of circulation in Titan's and Saturn's atmospheres.
- To map the distribution of neutrals and ions within Saturn's magnetosphere.
- To study the radial structure of Saturn's rings by means of stellar occultations.
- To study surface ices and tenuous atmospheres associated with the icy satellites.

Magnetospheric Imaging Instrument (MIMI). The Magnetospheric Imaging Instrument (MIMI) is designed to: (1) measure the composition, charge state and energy distribution of energetic ions and electrons; (2) detect fast neutral species; and, (3) conduct remote imaging of the Saturn's magnetosphere. The information gathered is used to study the overall configuration and dynamics of the magnetosphere and its interactions with the solar wind, Saturn's atmosphere, rings, and icy moons, and Titan. It is the first instrument ever designed to produce an image of a planetary magnetosphere.

The instrument provides images of the ionized gases, called plasma, surrounding Saturn and determines the charge and composition of ions. Like the Cassini plasma spectrometer, this instrument has three sensors that perform various measurements: the low-energy magnetospheric measurement system, the charge-energy-mass spectrometer, and the ion and neutral camera.

The low-energy magnetospheric measurement system will measure low and high-energy proton, ion and electron angular distributions (the number of particles coming from each direction). The charge-energy-mass spectrometer uses an electrostatic analyzer, a time-of-flight mass spectrometer and microchannel plate detectors to measure the charge and composition of ions. The third sensor, the ion and neutral camera, makes two different type of measurements. It will obtain three-dimensional distributions and velocities and determine the rough composition of magnetospheric and interplanetary ions.

MIMI Scientific Objectives:

- To determine the global configuration and dynamics of hot plasma in the magnetosphere of Saturn.
- To monitor and model magnetospheric substorm-like activity and correlate this activity with Saturn Kilometric Radiation (SKR) observations.
- To study magnetosphere/ionosphere coupling through remote sensing of aurora and measurements of energetic ions and electrons.
- To investigate plasma energization and circulation processes in the magnetotail of Saturn.
- To determine through imaging and composition studies the magnetosphere/satellite interactions at Saturn and understand the formation of clouds of neutral hydrogen, nitrogen, and water products.
- To measure electron losses due to interactions with whistler waves.
- To study the global structure and temporal variability of Titan's atmosphere.
- Monitor the loss rate and composition of particles lost from Titan's atmosphere due to ionization and pickup.
- To study Titan's interaction with the magnetosphere of Saturn and the solar wind.
- To determine the importance of Titan's exosphere as a source for the atomic hydrogen torus in Saturn's outer magnetosphere.
- To investigate the absorption of energetic ions and electrons by Saturn's rings and icy satellites.
- To analyze Dione's exosphere.

Dual Technique Magnetometer (MAG). Orbiting Saturn and its icy moons is like seafaring on a celestial scale — it helps to have a compass that can "see" through celestial bodies. In *Cassini's* case, such a compass is provided by its onboard Dual Technique Magnetometer (MAG). The instrument measures the strength and direction of Saturn's magnetic field near the spacecraft.

"The coolest thing about the magnetometer is that it allows you to 'see' inside planets such as Saturn and moons such as Enceladus," says Marcia Burton, investigation scientist for the Cassini magnetometer and the Cassini Magnetospheric Discipline Scientist. "By measuring the magnetic field very accurately we can determine the size of Saturn's core."

Studying the dynamic interactions between different magnetic fields in the planetary environment allows scientists to better understand the complex Saturnian region.

"Our instrument is like a very sophisticated magnetic compass traveling through space," says Dr. Nick Achilleos, a science planner and operations engineer working on the magnetometer. "Measuring Saturn's internal magnetic field often shows signatures of the boundaries which separate Saturn's magnetosphere from the solar wind — these hold information about how Saturn's magnetosphere is continually changing in size and shape."

Data from MAG could also shed light on various mysteries. For one, Saturn has a magnetic field similar to Earth's, but it has one characteristic that scientist consider to be very strange.

"We all know that when we take a compass reading on Earth, magnetic north is generally not in the same direction as geographic north. Saturn is the only planet on which these directions are exactly the same," Burton says. "This presents a real conundrum to scientists who work in this field. By the time the mission is over, we hope to be able to understand this."

MAG Scientific Objectives:

- To determine the internal magnetic field of Saturn.
- To develop a three-dimensional model of Saturn's magnetosphere.
- To determine the magnetic state of Titan and its atmosphere.
- To derive an empirical model of the Titan electromagnetic environment.
- To investigate the interactions of Titan with the magnetosphere, magnetosheath, and solar wind.
- To survey the ring and dust interactions with the electromagnetic environment.
- To study the interactions of the icy satellites with the magnetosphere of Saturn.
- To investigate the structure of the magnetotail and the dynamic processes therein.

Huygens Probe. The Huygens probe had six complex instruments aboard that ensured that data from Titan was received by the Cassini spacecraft — as well as by Earth — following the probe's descent into Titan's atmosphere. The six instruments were:

Descent Imager and Spectral Radiometer (DISR). This instrument made a range of imaging and spectral observations using several sensors and fields of view. By measuring the upward and downward flow of radiation, the radiation balance (or imbalance) of the thick Titan atmosphere was measured. Solar sensors measured the light intensity around the Sun due to scattering by aerosols in the atmosphere. This permitted the calculation of the size and number density of the suspended particles. Two imagers (one visible, one infrared) observed the surface during the latter stages of the descent and, as the probe slowly rotated, built up a mosaic of pictures around the landing site. There was also a side-view visible imager that

obtained a horizontal view of the horizon and the underside of the cloud deck. For spectral measurements of the surface, a lamp switched on shortly before landing that augmented the weak sunlight.

Huygens Atmospheric Structure Instrument (HASI). This instrument contained a suite of sensors that measured the physical and electrical properties of Titan's atmosphere. Accelerometers measured forces in all three axes as the probe descended through the atmosphere. Since the aerodynamic properties of the probe were already known, it was possible to determine the density of Titan's atmosphere and detect wind gusts. Had the probe landed on a liquid surface, this instrument would have been able to measure the probe motion due to waves. Temperature and pressure sensors also measured the thermal properties of the atmosphere. The Permittivity and Electromagnetic Wave Analyzer component measured the electron and ion (i.e., positively charged particle) conductivities of the atmosphere and searched for electromagnetic wave activity. On the surface of Titan, the conductivity and permittivity (i.e., the ratio of electric flux density produced to the strength of the electric field producing the flux) of the surface material was measured.

Gas Chromatograph and Mass Spectrometer (GCMS). This instrument was a versatile gas chemical analyzer that identified and measured chemicals in Titan's atmosphere. It was equipped with samplers that were filled at high altitude for analysis. The mass spectrometer built a model of the molecular masses of each gas, and a more powerful separation of molecular and isotopic species was accomplished by the gas chromatograph. During descent, the GCMS analyzed pyrolysis products (i.e., samples altered by heating) passed to it from the Aerosol Collector Pyrolyser. Finally, the GCMS measured the composition of Titan's surface in the event of a safe landing. This investigation was made possible by heating the GCMS instrument just prior to impact in order to vaporize the surface material upon contact.

Aerosol Collector Pyrolyzer (ACP). This experiment drew in aerosol particles from the atmosphere through filters, then heated the trapped samples in ovens (the process of pyrolysis) to vaporize volatiles and decompose the complex organic materials. The products were then flushed along a pipe to the GCMS instrument for analysis. Two filters were provided to collect samples at different altitudes.

Surface Science Package (SSP). The Surface-Science Package contained a number of sensors designed to determine the physical properties of Titan's surface at the point of impact. These sensors also determined whether the surface was solid or liquid. An acoustic sounder, activated during the last 100 meters (328 feet) of the descent, continuously determined the distance to the surface, measuring the rate of descent and the surface roughness (e.g., due to waves). During descent, measurements of the speed of sound provided information on atmospheric composition and temperature, and an accelerometer accurately recorded the deceleration profile at impact, providing information on the hardness and structure of the surface. A tilt sensor measured any pendulum motion during the descent and indicated the probe attitude after landing.

Doppler Wind Experiment (DWE). The intent of this experiment was to measure the wind speed during Huygens' descent through Titan's atmosphere by observing changes in the carrier frequency of the probe due to the Doppler effect. This measurement could not be done from space because of a configuration problem with one of Cassini's receivers. However, scientists were able to measure the speed of these winds using a global network of radio telescopes.

The Mission

In maneuvers called gravity-assist swingbys, *Cassini-Huygens* flew twice past Venus, then once each past Earth and Jupiter. The spacecraft's speed relative to the Sun increased as it approached and swung around each planet, giving *Cassini-Huygens* the cumulative boost it needs to reach Saturn. The spacecraft entered Saturn orbit on June 30, 2004, and began its detailed scientific observations of the Saturnian system. *Cassini's* four-year long prime mission ends July 1, 2008.

Cassini-Huygens executed its first Venus flyby April 26, 1998, at an altitude of 287.2 kilometers (178.5 miles). The second Venus flyby took it within 600 kilometers (373 miles) of the planet on June 24, 1999. Two months later, on August 18, 1999, *Cassini-Huygens* swung past Earth at an altitude of 1,171 kilometers (727 miles). It flew by Jupiter at an altitude of 9.7 kilometers (6 million miles) on December 30, 2000. During the six months *Cassini-Huygens* was closest to Jupiter, it collaborated with NASA's *Galileo* spacecraft, which had been orbiting Jupiter since 1995, for the rare opportunity to study the Jovian system from two different nearby perspectives at the same time. The two craft monitored how fluctuations in the solar wind approaching Jupiter affect the planet's magnetosphere, a vast region of ionized gas under the influence of Jupiter's magnetic field. They also examined Jupiter's moons, rings and storm clouds.

After reaching Saturn, *Cassini-Huygens* fired its main engine for 96 minutes to brake the spacecraft's speed and allow it to be captured as a satellite of Saturn. Passing through the dusty, outer-most E-ring, *Cassini* swung in close to the planet (to an altitude only one-sixth the diameter of Saturn itself) to begin the first of 75 orbits during the rest of its four-year mission.

The probe was released from the orbiter on Dec. 24, 2004 PST and was targeted for a 10 degrees South latitude landing site on the "day" side of Titan. The probe entered Titan's atmosphere on Jan. 14, 2005 at a velocity of 6.1 km per second (13,725 mph). The entry phase lasted about 3 minutes, during which the probe's velocity fell to about 400 meters per second (about 895 mph).

Three parachutes were used during the probe's descent. When the onboard accelerometers detected a speed of Mach 1.5 near the end of the deceleration phase, the 2-meter (6.6-foot)-diameter pilot parachute deployed, pulling off the aft cover. This was followed immediately by deployment of the 8.3-meter (27 foot) main parachute. The pilot parachute's ejection device, which induced a load of 13,500 newtons (1.5 tons) on the probe's upper platform for about 5 milliseconds, was a primary "driver" of the probe structural design.

About 30 seconds after deployment of the main chute, the probe's velocity dropped from Mach 1.5 to Mach 0.6. The front heat shield was then released, and the probe descended slowly below the main parachute for about 15 minutes while initial scientific measurements were made. The main parachute then separated from the probe and released a smaller 3-meter (9.8 foot) drogue parachute, which allowed the probe to descend faster, and ensured it would reach the surface before the batteries expired. It arrived at the surface in 2.5 hours, with an impact velocity of about 7 meters per second (15 mph).

The probe's entry into Titan's atmosphere — which is mostly nitrogen with some methane — caused a shock wave to form in front of the 2.7-meter (8.9-foot)-diameter front heat shield. The plasma in the shock, just forward of the shield, reached a temperature of around 12,000 degrees Celsius (21,632 degrees Fahrenheit). Simultaneously, the deceleration force on the probe reached its maximum of around 16 Gs. The high temperature and deceleration pressure were design drivers for most of the probe structure. The outer shell of the probe was able to withstand the extreme cold (-200 degrees Celsius or -392 degrees Fahrenheit) of Titan's atmosphere without buckling.

During its descent, Huygens' camera returned more than 750 images, while the Probe's other five instruments sampled Titan's atmosphere to help determine its composition and structure. See Figs. 21–24. Huygens collected 2 hours, 27 minutes, 13 seconds of descent data, and 1 hour, 12 minutes, 9 seconds of surface data, which turned out to be far more surface data than was ever expected.

Every bit of data from Huygens was successfully relayed to the Cassini Orbiter passing overhead, with the exception of a redundant stream called "Chain A." Chain A's radio frequency was based on Huygens' Ultra Stable Oscillator, designed for the Doppler Wind Experiment. While this signal was not received aboard Cassini, it was received on Earth, thanks to Radio Scientists using Earth-based radio telescopes at Green Bank (http://www.nrao.edu/pr/2004/huygens/) and Parkes (http://www.parkes.atnf.csiro.au/parkes_main.html). They were actually able to capture the tiny signal, now being called "Chain C," directly from Titan! Telemetry data from Huygens was stored onboard Cassini's Solid State recorders (SSR) for playback to Earth. Huygens is managed by the European Space Agency. Complete details on the mission objectives and science can be found on the ESA Huygens Site http://www.esa.int/SPECIALS/Cassini-Huygens/index.html.

During the course of the *Cassini* orbiter's mission, it will execute close flybys of particular bodies of interest, including more than 44 encounters of Titan and seven of selected icy moons of greatest interest. In addition, the orbiter will make at least two dozen more distant flybys of the Saturnian moons. *Cassini's* orbits will also allow it to study Saturn's Polar Regions in addition to the planet's equatorial zone.

Saturn

Saturn is the outermost planet in the solar system readily visible to the naked eye, and was recognized as a slow-moving point of bright yellow light in the sky by ancient cultures around the world. It was not until the invention of the telescope, however, that Saturn's characteristic rings began to come into focus. Italian astronomer Galileo was the first to look at Saturn through a telescope in 1609 and 1610. Saturn, viewed through Galileo's crude instrument was a puzzling sight. Unable to make out the rings, he thought what he saw were two sizable companions close to the planet. Having recently discovered the major moons of Jupiter, it seemed to follow, he supposed, that Saturn could have large moons, too. "... [T]o my very great amazement, Saturn was seen to me to be not a single star, but three together, which almost touch each other," he wrote at the time. He was even more astonished when he again looked at Saturn through his telescope two years later to find that the companion bodies had apparently disappeared. "I do not know what to say in a case so surprising, so unlooked for and so novel," Galileo wrote in 1612. The rings were simply invisible because he was now viewing them edge-on. Two years later, they again reappeared, larger than ever. He concluded that what he saw were some sort of "arms" that grew and disappeared for unknown reasons. He died never knowing that he'd been the first to observe Saturn's rings.

Nearly half a century later, the Dutch scientist Christiaan Huygens solved the puzzle that had vexed Galileo. Thanks to better optics, Huygens was able to pronounce in 1659 that the companions or arms decorating Saturn were in fact a set of rings. The rings were tilted so that, as Saturn orbited the Sun every 29 years, the sheet of rings would occasionally seem to vanish as viewed on-edge from Earth.

While observing Saturn, Huygens also discovered the moon Titan. A few years later, the Italian-French astronomer Jean-Dominique Cassini (also known as Gian Domenico Cassini in his native Italy) added several other key Saturn discoveries. Using new telescopes, Cassini discovered Saturn's four other major moons: Iapetus, Rhea, Tethys and Dione. In 1675, he discovered that Saturn's rings are split largely into two parts by a narrow gap, known since as the "Cassini Division." In the 19th century, James E. Keeler, pursuing theoretical studies by James Clerk Maxwell, showed that the ring system was not a uniform sheet but made up of small particles that orbit Saturn.

The first detection of Saturn's magnetic field came with the flyby of Saturn by NASA's *Pioneer 11* spacecraft in 1979. Then in 1980 and 1981, the NASA *Voyager 1* and *Voyager 2* spacecraft flew through the Saturnian system to reveal storms and subtle latitudinal banding in the planet's atmosphere, several more small moons, and a breathtaking collection of thousands of ringlets. The Voyagers found ring particles ranging in size from nearly invisible dust to icebergs the size of a house. The spacing and width of the ringlets were discovered to be orchestrated in part by gravitational tugs from a retinue of orbiting moons and moonlets, some near ring edges but most far beyond the outermost main rings. Voyager's instruments showed that the rings contain water ice, which may cover rocky particles. See also **Voyager Missions to Jupiter and Saturn**.

Saturn has been a frequent target of the Hubble Space Telescope, which has produced stunning views of long-lived hurricane-like storms in Saturn's atmosphere. The world's major telescopes, including Hubble, were recently trained on Saturn to observe the phenomenon known to astronomers as a Saturn ring plane crossing. The rings were seen edge-on from the Earth's perspective on May 22, 1995, August 10, 1995 and February 11, 1996. Ring plane crossings provide astronomers with unique views of the Saturnian system. With the rings temporarily invisible as viewed from Earth, faint objects near the planet are easier to see. Two new moons observed during these recent opportunities are now believed to be particle swarms within the narrow F-ring. Many of Saturn's 30 known moons were discovered during ring plane crossings. See also **Hubble Space Telescope (HST)**.

Saturn is one of four giant gaseous (and ringed) planets in the solar system, the others being Jupiter, Uranus and Neptune. Second in size only to Jupiter, Saturn is shaped like a ball squeezed from opposite sides; its diameter pole-to-pole is only 108,728 kilometers (67,560 miles), compared to about 120,536 kilometers (about 74,898 miles) for the equatorial diameter. This oblateness is caused in part by Saturn's very rapid rotation rate. Combined with the planet's low density, the fast rotation tends to promote a bulge of material near the equator. Saturn's volume would enclose more than 750 Earths. Even so, its mass is only 95 times that of Earth; with a density less than that of water, it would float in an ocean if there were one big enough to hold it.

Unlike rocky inner planets such as Earth, Saturn and the other gas giants have no surface on which to land. A spacecraft pilot foolhardy enough to descend into its atmosphere would simply find the surrounding gases becoming denser and denser, the temperature progressively hotter; eventually the craft would be crushed and melted. Detailed analysis of Saturn's gravitational field leads astronomers to believe that the deepest interior of Saturn must consist of a molten rock core about the same size as Earth, but much more massive than Earth. This rock core may also be surrounded by a layer of melted ices.

Spectroscopic studies by the Voyager spacecraft found Saturn to be made up of about 94 percent hydrogen and 6 percent helium. Hydrogen and helium are the primary constituents of all the giant gas planets, the Sun and the stars.

A day on Saturn is about 10-2/3 hours, and a Saturnian year is about 29-1/2 Earth years.

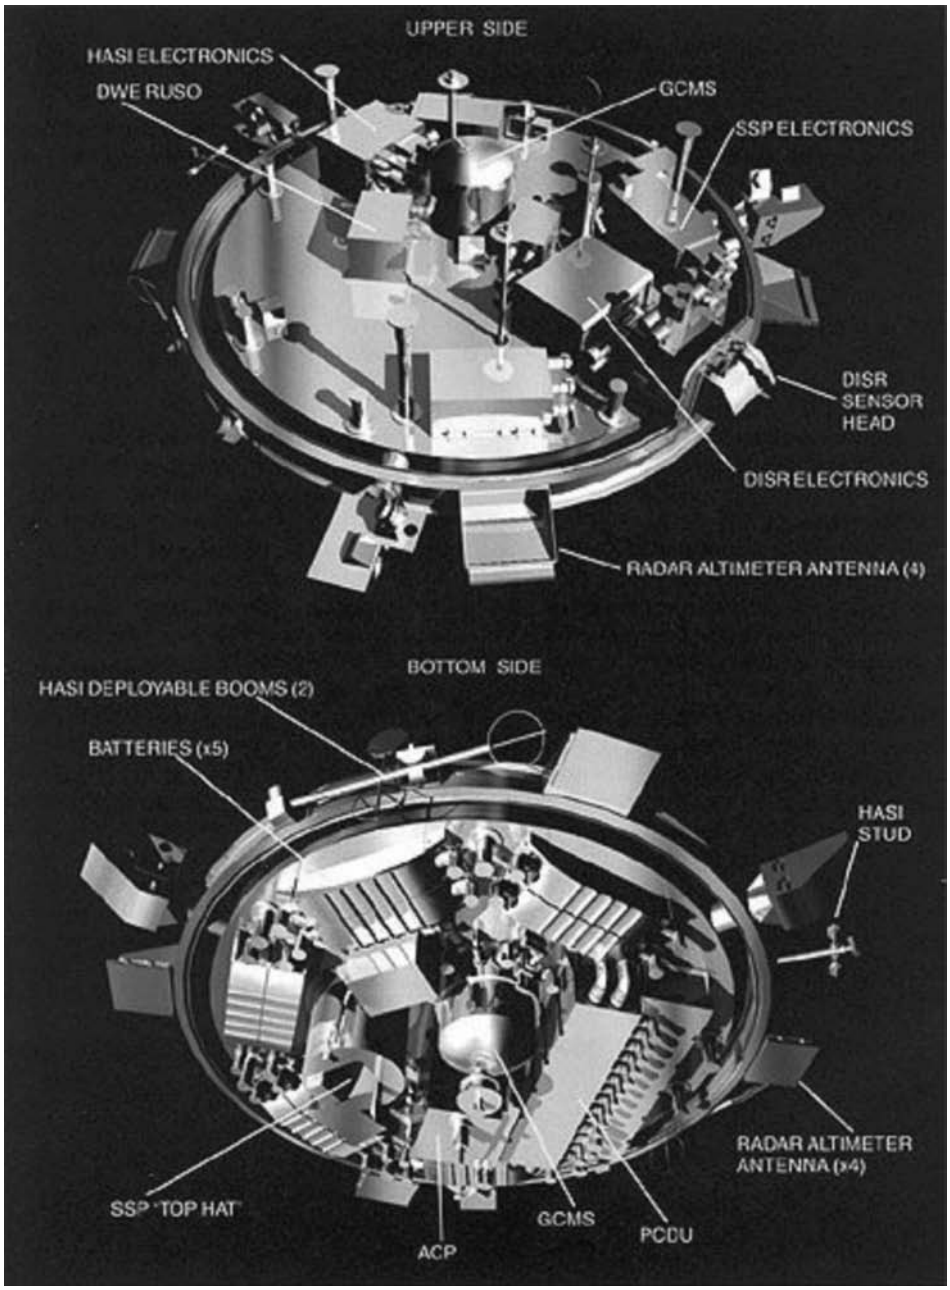

Fig. 23. Huygens Probe top and bottom view. (*JPL/NASA.*)

A fast equatorial flow like a giant jet stream has been clocked on Saturn. This high-velocity wind of 1,800 kilometers per hour (1,100 mile per hour) remains fairly constant over decades. Saturn also has storms like those seen in the atmosphere of Jupiter, but they are much less visible and perhaps less frequent. They may represent Saturnian weather systems that resemble hurricanes on Earth. On Saturn, however, these storms last much longer, perhaps because they do not encounter continents, which reduce their energy sources. On Earth, hurricane-like storms tend to lose their energy as they come into contact with land.

Saturn is colder than Jupiter, but the colors of Saturn's cloud layers are due to the same basic cloud chemistry as on Jupiter. Near the top of the atmosphere, the ammonia becomes cold enough to crystallize into ice particle clouds, much like high cirrus clouds in Earth's skies. These ammonia clouds are the visible part of Saturn. The primary reason why Saturn is more uniformly colored than Jupiter is because this outermost cloud layer is much deeper in the atmosphere than on Jupiter. The haze layers above the clouds therefore hide or mute the colors of the clouds. Latitudinal banding can be seen on Saturn, but it lacks the distinct color contrasts seen between atmospheric bands on Jupiter.

Gravity at the top of Saturn's clouds is similar to the gravity near the surface of the Earth. The temperature near the cloudtops is about -139° Celsius (-218° Fahrenheit). The temperature increases with depth due to increased atmospheric pressure. At the core, Saturn's temperature is predicted to be about $10{,}000^\circ$ Celsius ($18{,}000^\circ$ Fahrenheit).

Saturn is 9-1/2 times farther from the Sun than Earth is, so it receives only about 1 percent as much sunlight per square meter as does Earth. Saturn reflects a somewhat smaller fraction of sunlight received than does Earth (34.4 percent compared to 40 percent for Earth, computed across all wavelengths of light). Thus, Saturn absorbs 65.4 percent of the energy it receives from the Sun. Mysteriously, Saturn emits 87 percent more energy than it absorbs from sunlight. Unlike the rocky Earth and the more massive Jupiter, Saturn should not have any heat left over from its original formation. Therefore there must be a source of heat inside Saturn to produce the excess energy. One theory is that the energy comes from the friction of liquid helium raining through lighter liquid hydrogen in the interior of the planet. *Cassini* scientists will examine Saturn's energy balance for answers to this puzzle.

The Rings. Although the best telescopes on Earth show three nested main rings about Saturn, it is known that the ring system is collection of thousands of ringlets. They are not solid but rather are made up of countless unconnected particles, ranging in size from nearly invisible dust to icebergs

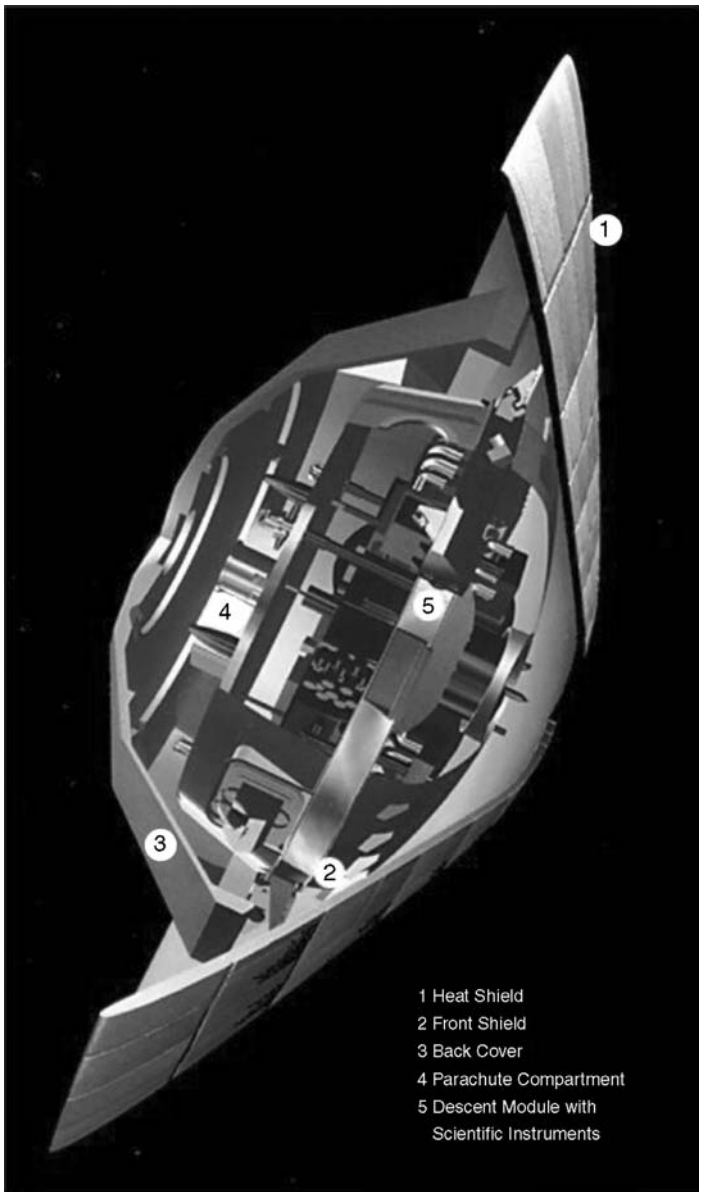

Fig. 24. Cut away view of the Huygens Probe. (*JPL/NASA.*)

the size of a house. The spacing and width of the ringlets are orchestrated by gravitational tugs from a retinue of orbiting moons and moonlets, some near ring edges but most far beyond the outermost main rings. The rings contain water ice, which may cover rocky particles. There are ghostly dark "spokes" in the rings that flicker on and off. Scientists believe they may be electrically charged particles, but we do not really know. Where do the subtle colors in Saturn's rings come from? The *Cassini* mission may well provide the answers.

And what is the origin of the rings themselves? One theory is that they are the shattered debris of moons broken apart by repeated meteorite impacts. Scientists believe that Saturn's ring system may even serve as a partial model for the disk of gas and dust from which all the planets formed about the early Sun. The Cassini mission will undoubtedly provide important clues to help determine the answers.

Mysterious Moons. Saturn has the most extensive system of known moons of any planet in the solar system — ranging in diameter from less than 20 kilometers (12 miles) to 5,150 kilometers (3,200 miles), larger than the planet Mercury. Most are icy worlds heavily studded with craters caused by impacts very long ago.

Thirty moons have been confirmed in orbit at Saturn, including 12 discovered from ground-based telescopes in 2000. *Cassini* may discover others.

The moon Enceladus poses a mystery. Although covered with water ice like Saturn's other moons, it displays an abnormally smooth surface; there are very few impact craters on the portions seen by *Voyager*. Has much of the surface of Enceladus recently melted to erase craters? Scientists now believe that Enceladus is the likely source for particles spewed by ice volcanoes, that create Saturn's outermost E-ring.

Saturn's moon Iapetus is equally enigmatic. On one side, the trailing side in its orbit, Iapetus is one of the brightest objects in the solar system, while its leading side is one of the darkest. Scientists surmise that the bright side is water ice and the dark side is an organic material of some kind. But how the dark material got there is a mystery. Did it rise up from the inside of the moon, or was it deposited from the out-side? The puzzle is compounded by the fact that the dividing line between the two sides is inexplicably sharp.

Titan. Titan is by far the most intriguing natural satellite of Saturn, and one of the most fascinating in the solar system. Titan lies hidden beneath an opaque atmosphere more than 50 percent denser than Earth's. Titan has two major components of Earth's atmosphere, nitrogen and oxygen, but the oxygen is likely frozen as water ice within the body of the moon. If Titan received more sunlight, its atmosphere might more nearly resemble that of a primitive Earth.

What fascinates scientists about Titan's atmosphere is that it is filled with a brownish orange haze made of complex organic molecules, falling from the sky to the surface. Thus in many ways it may be a chemical factory like the primordial Earth. Most scientists agree that conditions on Titan are too cold for life to have evolved, although there are theories concerning the possibility of lifeforms in covered lakes of liquid hydrocarbons warmed by the planet's internal heat. Yet even if Titan proves to be lifeless, as expected, understanding chemical interactions on the distant moon may help us understand better the chemistry of the early Earth and how life came to be.

Saturn has a magnetic field and extensive magnetosphere that shields much of the Saturnian system from the wind of charged particles that flows outward from the Sun. The behavior of charged and other particles trapped in this magnetic bubble around Saturn is of great interest to physicists. *Cassini* will help determine the similarities and differences between the magnetospheres of the planets and possibly moons in the solar system that generates such fields.

The International Team

Hundreds of scientists and engineers from 16 European countries and 33 states of the United States make up the team responsible for designing, building, flying, and collecting data from the *Cassini* orbiter and Huygens probe.

The *Cassini* mission is managed by NASA's Jet Propulsion Laboratory in Pasadena, California, where the orbiter was designed and assembled. JPL is a division of the California Institute of Technology. Development of the Huygens Titan probe was managed by the European Space Technology and Research Center (ESTEC). ESTEC 's prime contractor for the probe is Alcatel in France. Equipment and instruments for the probe were supplied from many countries, including the United States.

The Cassini program is an 18-year endeavor; the program received a new start from the U.S. Congress in 1990, and the prime mission extends through July 2008. The *Cassini* orbiter and its instruments represent a $1.422 billion investment by NASA. The agency has budgeted a total of $704 million to support the cruise and orbital operations phase of the mission. Other contributions include $54 million in NASA tracking costs and about $144 million from the U.S. Department of Energy in support of the radioisotope thermoelectric generators and radioisotope heater units for the mission. The launch vehicle, provided to NASA by the U.S. Air Force, cost $422 million.

The European Space Agency's contribution to the *Cassini* program totals approximately $500 million for the Huygens probe, its instruments and probe science and engineering operations. The Italian space agency, Agenzia Spaziale Italiana, has contributed the *Cassini* orbiter's dish-shaped high-gain antenna as well as significant portions of three science instruments; its contribution is $160 million.

The Centaur upper stage and launch vehicle performance analysis were managed by NASA's Lewis Research Center, Cleveland, Ohio. Communications with *Cassini* during the mission are carried out through stations of NASA's Deep Space Network in California, Spain and Australia. Data from the Huygens probe will be received by the DSN and sent to a European Space Agency operations complex in Darmstadt, Germany. See also **Deep Space Network**.

At NASA Headquarters, the *Cassini* program executive is Mark Dahl and the program scientist is Dr. Jay Berstralh. At JPL, Robert T. Mitchell is program manager, Dr. Dennis Matson is *Cassini* project scientist and Dr. Linda Spilker is deputy project scientist.

CASSIOPEIA (the chair). One of the most widely known and striking constellations of the northern latitudes, Cassiopeia is easily recognized by the five bright stars forming an irregular W; some observers see not only a W, but also a chair. Since this object is circumpolar for most northern countries (i.e., remains above the horizon at all hours every night), and is easily recognized, it is frequently used as a rough indicator of sidereal time. The leading bright star of W (the star Beta Cassiopeiae) lies almost in zero hours right ascension. Hence, a line drawn through Polaris and Beta Cassiopeiae must pass close to the vernal equinox. The hour angle of this line must be equal to sidereal time. Thus, when Beta Cassiopeiae is on the meridian directly above the pole, the sidereal time is zero; when it is on the meridian directly below the pole, the sidereal time is 12 hours, etc.

One of the brightest novae on record appeared in this constellation in 1572, and was observed and recorded by Tycho Brahe. (See map accompanying entry on **Constellations**.)

CASSITERITE. The mineral cassiterite, chemically tin dioxide, SnO_2, is almost the sole ore of tin. It is a noticeably heavy mineral crystallizing in the tetragonal system, as low pyramids, prisms, often very slender, and as twinned forms. It is a brittle mineral, hardness, 6.0–7.0; specific gravity, 6.99; luster, adamantine; color; generally brown to black, but may be red, gray to white, or yellow; streak whitish, grayish, or brownish; may be almost transparent to opaque. A fibrous variety somewhat resembling wood is called wood tin. Cassiterite occurs in widely scattered areas, but deposits of a size to be commercially important are few. It is associated with granites and rhyolites.

Cassiterite is heavily concentrated in bands and layers of varying thickness, forming economically valuable deposits, such as those found in the Malay States of southeastern Asia; Bolivia, Nigeria, and the Congo are also major producers of tin ore. Cassiterite is also known as tin stone.

CASSOWARIES *(Aves, Casuariiformes, Casuriidae).* A family of birds closely related to the emus; they inhabit the primeval forests of North Australia and New Guinea as well as some of its islands.

There is only one genus (*Casuarius*). With a height at the back of up to 100 centimeters (39 inches) and a weight of 85 kilograms (187 pounds), it is the heaviest bird next to the ostrich. The legs are very strong. There are three toes, the claws of the inner toe being up to 10 centimeters (4 inches) long and straight. The feathers, like those of the emus (see also **Emu**), have an after shaft of equal length; the flight feathers are reduced to mere rods of thick keratin. On the head they have a helmetlike, horny structure. The head and neck are bare of feathers; instead some have skin folds on the neck. The species are distinguished according to the shape of the helmet and the form of the skin folds of the neck. The bare skin differs in color in the various species and subspecies, and can be bright red, yellow, blue and/or white. Males and females are similarly colored. The chicks have a yellow-brown downy plumage with dark brown longitudinal stripes, but after a few months they become uniformly brown. The eggs average 135×90 millimeters (5.3×3.5 inches) and weigh 650 grams (23 ounces); the surface is slightly wrinkled, and the color is a shiny grass green, which later darkens somewhat.

There are 3 species: (a) Australian Cassowary (*Casuarius casuarius*); (b) One-Wattled Cassowary (*Casuarius unappendiculatus*); (c) Bennet's Cassowary (*Casuarius bennetti*).

CASTELLANUS. See **Clouds and Cloud Formation**.

CASTING. A process for producing specific shapes of materials by pouring the material, while in fluid form, into a shaped cavity (mold) where the material solidifies in the desired shape. The resulting shape is also called a *casting*. In terms of metals, the art of casting is one of the oldest methods for making metal parts and is still used extensively even though numerous other methods for producing shaped metal products, such as forging, rolling, and extruding, have been developed. In terms of plastic materials, casting is also widely practiced.

Metal Casting. Production of a metal casting involves the use of a pattern, usually of wood or metal, which is similar in shape to the desired finished piece and slightly larger in all dimensions to allow for shrinkage of the metal upon solidification. The pattern is bedded down in a special damp sand by an operation called molding. When the pattern is removed it leaves an impression of the shape of the desired casting. This impression is completely surrounded by sand and provided with openings called gates through which the molten metal enters. After pouring and cooling the mold is broken open and the casting removed. All adhering sand particles together with any extraneous projections such as those left by the gate system are removed after which the casting is machined to the required finish.

The term is also applied to the casting of pig iron in blast furnace practice and the casting of ingots in steel-mill practice.

Centrifugal casting is applicable to the production of pipe and tubing, wheels, gear blanks, and other castings having rotational symmetry. While the mold is rotated on a horizontal axis for pipe and tubing, and on a vertical axis for wheels and gear blanks, a measured amount of molten metal is added. The mold may be sand or water-cooled metal for more rapid solidification. Centrifugal castings have good structure and density.

Metal molds are also used for making die castings and permanent mold castings. In the latter process a permanent metal mold is filled by gravity in the usual manner, while in die casting considerable pressure is exerted on the molten metal, insuring rapid and complete filling of the mold. Die-casting machines are highly mechanized for rapid and nearly automatic operation. The product is characterized by high dimensional accuracy and clear reproduction of mold details including screw threads, holes, and intricate sections, all of which greatly reduces the machining required. The process is limited in its application by the high cost of making alloy steel dies or molds. The lower melting zinc alloys and aluminum alloys are most successfully die cast; however, certain brasses and bronzes can also be die cast. Tin- and lead-base alloys are easily die cast but have limited application.

The zinc-base die-casting alloys are the most widely used. A typical composition is 1.0% copper, 3.9% aluminum, 0.06% magnesium, balance zinc. This alloy has a strength of about 45,000 psi (3,061 atmospheres) with 3% elongation in 2 inches (5 centimeters). Typical applications are carburetors, fuel pumps, tools, typewriter frames, instrument cases, and hardware often finished by chromium plating.

The investment or "lost wax" process has lately been revived as a method of making precision castings of metals such as steel and zinc having too high a melting point for die casting. A wax pattern is made in a die-casting machine, sprayed with a highly refractory slurry, dried, and embedded in sand. The mold passes through a furnace where the wax is melted or burned

out, and the mold baked. The casting is then poured into the cavity left by the melting out of the wax, resulting in castings that rival die castings for dimensional accuracy.

Vacuum Casting. Although considered theoretically possible for many years, the commercialization of vacuum casting of metals was not demonstrated until the late 1980s. Vacuum casting offers an alternative position between investment and conventional shell-mold or green sand casting. Advantages of vacuum casting include thin-wall, near-net shape; multiple-core, complex shapes; and metallurgical integrity. Costs for vacuum castings appear to be competitive with green sand casting methods.

In the well-established *gravity-pour* process, molten metal is poured into the mold at atmospheric pressure. In the vacuum process, the molten alloy is drawn into the mold through gates in the bottom by a pressure differential between the atmospheric pressure of the melting furnace and a partial vacuum produced in the mold. This increase in molding pressure makes it possible to produce components having wall sections as thin as 1.75 mm (0.07 in.) in near-net shapes with increased metallurgical integrity and consistency. To make the vacuum process cost effective, however, very careful control of all conditions must be maintained, as by controls that have become available through the use of computers and microprocessors.

Heat- and corrosion-resistance materials have not always been compatible when traditional casting methods are used. Vacuum casting, on the other hand, is readily adaptable to a wide range of materials, such as low-nickel heat- and corrosion-resistant alloys. It should be noted that these materials frequently rely on combinations of silicon, chromium, and manganese as alternatives to the higher-cost nickel. These different materials, in the past, have added to casting difficulties. The vacuum process has been well received for making automotive and machinery parts.

Solidification Processing. The microstructure (arrangements of electrons, ions, space lattices, defects, and phases and their morphology) affects an alloy's ultimate properties and performance. As pointed out by Ahmed (Youngstown State University) and a team of research metallurgists, "Phase morphology of a particular microstructure is established during solidification, which essentially is a thermally activated nucleation and growth process requiring simultaneous control of several dependent and independent parameters to achieve a specific end result."

The solidification process is comprised of two principal phases: (1) the *nucleation stage*, the most important parameters of which include: changes in chemical-free energy between the solid and liquid phases, the surface free energy of the solid/liquid interface, the elastic strain energy, the amount of superheating and undercooling, the latent heat of solidification, the thermal conductivities of the phases, and the interdependence among these parameters; and (2) the *growth stage*, which tends to be of even greater complexity. It is during the growth stage that physical defects, such as chemical nonhomogeneities, dislocations, voids, and unwanted phases appear. The aforementioned research team has developed (patent pending) for solidification processing in an applied electric field. It is claimed that this method produces homogeneous nucleation and eliminates porosity.

Improved Melting Practices. Many new alloys were developed to meet the requirements of aircraft-engine manufacture. The principal flurry of activities occurred in the 1940s through the 1970s. As engines' specifications grew tighter to cope with the need for greater performance, the needs for improving the quality of the earlier alloys became evident and, thus, during the 1980s and 1990s, was termed, "cleaner" alloys, was a major goal for metallurgists. Most of these improvements could be achieved during the melting process.

As observed by C.H. White and a team of metallurgists (Inco Alloys Ltd., Hereford, England), "It is well established that the presence of small-scale inclusions limits the maximum stresses at which the material can operate because these inclusions can cause premature failure." To meet these objectives, the principal objectives of melting have been formulated and include: (1) providing adequate deoxidation (via magnesium, calcium, cerium, or zirconium additions) to ensure alloy cleanness and good workability; (2) refining the metal to remove metalloid (sulfur, lead, and bismuth) and gaseous (oxygen, nitrogen, and hydrogen) impurities; (3) minimizing nonmetallic contamination; (4) obtaining a homogeneous mixing of the constituent-alloy ingredients (nickel, iron, cobalt, chromium, tungsten, molybdenum, titanium, aluminum, and niobium) within specified limits; and (5) casting into an ingot suitable for further processing.

A number of melting processes are in use or under consideration. Vacuum induction melting (VIM) substantially reduces gases present in the melt during the melt cycle. Methods under development to improve VIM include gas purging, melt filtering, continuous monitoring of temperatures and pressure, continuous monitoring of furnace atmospheres (residual-gas analysis) by mass spectrometry, and automatic operation and data storage using process-control computers. Remelting also is practiced. Two consumable electrode remelting processes in use are vacuum arc remelting (VAR) and electroslag remelting (ESR). These processes are detailed in the White reference.

Defects that must be appraised continuously include "white spot" and "freckle." White spot is an area of alloy depleted in the lower melting-point alloying additions. Freckle is a mid-radial channel segregation resulting from a deep melt pool and a steeply sloping liquidus profile. This segregation develops in the liquid before solidification.

The C.H. White research group has observed, "Melting without the use of refractories is the only way future cleanness-level requirements are likely to be achieved. Electron-beam cold-hearth refining (EBCHR) possibly is the best candidate for such a melting system. Plasma melting and refining also is being evaluated."

Plastic Casting

Several families of thermoplastic materials are capable of taking form by casting, although the process differs considerably from that used for metals just described. Some plastic casting processes depend upon melting and solidifying, as with metals; others depend upon solubility, as in the case of *solvent casting*.

Acrylic castings usually consist of poly(methyl methacrylate) or copolymers of this ester as the major components, with small amounts of other monomers to modify the material properties. Incorporating acrylates or higher methacrylates, for example, lowers the heat deflection temperature and hardness and improves thermoformability and solvent cementing capability, but with some loss to weathering resistance. Dimethacrylates or other crosslinking monomers increase the resistance to solvents and moisture. Castings are made by pouring the monomers or partially polymerized syrups into suitably designed molds and heating to complete the polymerization. A large reduction in volume, sometimes exceeding 20%, takes place during the cure. The reaction is also accompanied by liberation of substantial heat. At conversion, the polymerization may become auto-accelerated, and the rate of conversion may increase rapidly until about 85% conversion is achieved. Thereafter, the reaction slows down and post-curing may be required to complete the polymerization. On the other hand, with certain materials combinations, a violent runaway polymerization can occur.

The syrups made prior to casting (and final polymerization) can be stored safely at a controlled temperature until required. The preparation of syrups in advance shortens the time in the mold, decreases the tendency for leakage from the molds, and greatly minimizes the chance of dangerous runaways.

The majority of acrylic casting is in the manufacture of sheet. Cast sheet generally is made in a batch process within a mold or cell, but the process can be continuous through the use of stainless steel belts. Molds consist of two pieces of polished (or tempered) plate glass slightly larger in area than the desired finished sheet. The mold (or cell) is held together by spring clips that respond to the contraction of the acrylic material during the cure. The plates are separated by a flexible gasket of plasticized polyvinyl chloride tubing that controls the thickness of the product. Once filled, the mold is moved to an oven for cure. Thin sheet is cured in a forced-draft oven using a programmed temperature cycle, starting at about 45 °C and ending at 90 °C. The curing cycle requires several hours, the period increasing with the size of the sheet.

In continuous casting, a viscous syrup is cured between two highly polished moving stainless steel belts. Distance between the belts determines the thickness of the sheets. Although less versatile, the continuous process eliminates a number of problems in handling and breakage of large sheets of plate glass used for the batch process. Continuous processing produces sheets of more uniform thickness and essentially eliminates warping.

Nylon casting is a four-step process: (1) melting the monomer, (2) adding catalyst and activator, (3) mixing the melts, and (4) casting. Molds must be capable of containing a low-viscosity liquid at temperatures of 200 °C and must allow for normal shrinkage. Two-piece molds are commonly used for simple shapes. More complex shapes require molds that can be disassembled to remove the cast shape. Stresses that develop

during the casting can be controlled by very slowly cooling the casting over a period of 24 hours or longer.

Solvent casting is sometimes used, as in the case of polyvinyl chloride (PVC) film. In this process, resins, plasticizers and other ingredients are added to a solvent (tetrahydrofuran) in an inert, gas-blanketed mixing tank. Thorough mixing and degassing are critical for producing high-quality film. The mixture, below the boiling point, is pumped to a casting tank. The solution is filtered to a particle size not exceeding 5 micrometers. The solution is cast onto a stainless steel belt, which then enters an oven where solvent is evaporated from the film. After cooling, the film is stripped from the belt and wound into rolls. The gage of the film is controlled by the die opening, the pumping pressure, and the speed of the belt, all variables that can be carefully monitored and controlled. Films made by this process have good clarity, low strains, and freedom from pinholes.

CAST IRON. Generic term for a group of metals that basically are alloys of carbon and silicon with iron. Relative to steel, cast irons are high in carbon and silicon, carbon ranging from 0.5 to 4.2% and silicon from 0.2 to 3.5%. All these metals may contain other alloys added to modify their properties.

See also **Iron Metals, Alloys, and Steels**.

CASTOR (α Geminorum). The fainter star of the twins. Since these two stars are always considered together in the ancient literatures, the history and astrological significance will be found discussed under Pollux, the brighter of the two.

Astronomically, Castor is a very remarkable star. It was discovered, in 1719, to be a visual binary, with the magnitudes of the components 2.8 and 2.0. Each of the two components of the binary system is also a spectroscopic binary. Castor has a faint companion, separated from it but having the same parallax and proper motion. This companion is also a spectroscopic binary, with a period of slightly less than 1 day.

Sir William Herschel observed the binary nature of Castor as early as 1803. Later observations indicated that actually there is a group of six stars in the system. Ranking twenty-fourth in apparent brightness among the stars, Castor has a true brightness value of 27 as compared with unity for the sun. Castor is a white, spectral type A star and is located in the constellation Gemini, a zodiacal constellation. Estimated distance from the earth is 45 light years. See also **Constellations**.

CASTOR OIL *(Ricinus communis; Euphorbiaceae)*. Castor oil is obtained from a short-lived perennial tree that occurs wild in tropical Africa and perhaps in India. Cultivation of the tree is widespread not only in the tropics but also in temperate regions, where it is often grown as an ornamental plant. In the tropics it becomes a tree 36 feet tall, with large coarse leaves often of reddish color, and green flowers. An annual herbaceous variety is grown widely and produces a superior oil. The seeds, borne three in each of the smooth or prickly capsules, have a hard mottled shell. These seeds are ejected violently from the mature fruit.

The principal use of the plant is for the oil contained in the seeds. This oil is pressed out without heating the seeds. The particular properties make this oil valuable for specialized uses, such as low temperature lubrication. It is an important constituent of hydraulic brake fluid and other fluids where the degree of compressibility is important. Castor oil also finds medical uses, as an ingredient of special soaps, and in the preparation of some textile dyes. Ricin, an alkaloid present in castor oil, also has been used in insecticides. Prior to the preparation of refined castor oil for medical purposes, ricin must be removed.

CASUARINA TREE. Of the genus Casuarina, there are approximately 30 species of what some authorities regard as among the oldest and robust of trees. The casuarina apparently can thrive and grow under what normally would be considered grossly adverse conditions. Some examples of adverse environments are given by N. Vietmeyer (American Forests, 22–63, February 1986); these include the toxic alumina of New Caledonia, the bare, baking sands of Senegal, the deserts of central Australia, the tropical, often waterlogged clays of Thailand, brackish tidal estuaries, the slag heaps of a cement factory, and so on. Vietmeyer refers to the casuarina as a ruggedly designed survival "machine" developed in the hot, parched soil, and relentless sun and salt of the Australian deserts. Part of this survival stems from its ability to fix nitrogen. Billions of bacteria swarm over the roots, absorbing air trapped in the upper soil and converting its nitrogen into ammonia, which, in turn, fertilizes the tree. Root nodules of the casuarina can swell to a diameter in some trees of more than four feet (1.2 meter) and, in so doing, accommodate great numbers of bacteria. Probably the only great enemy of the tree is frost.

The casuarina is an angiosperm and in most species possesses broad leaves which, however, can be shrunken and coiled to ensheath a branchlet and thus appear like pine needles. The tree bears cones that look like miniature fir cones, even though the tree is not related to the conifers. As pointed out by Vietmeyer, "The cylindrical 'needle' structure is a device that endows resistance to adversity. It reduces surface area, allows desiccation without wilting, and protects against dehydration and pollution."

Under Mao Tse Tung, the Chinese in 1949 planted tens of thousands of casuarinas in an effort to reforest bald regions. A program commenced in 1954 has produced a great wall (green) of Casuarina equisetifolia — a wall that stretches some 2000 miles (3200+ km). In some places, the belt is about 3 miles (nearly 5 km) in width and, in total covers over 2.5 million acres (1 million hectares). This has produced generous supplies of firewood for heating, cooking, crop drying, and brick kiln firing, not to mention use of the wood for poles, posts, and beams for houses, among other structural functions. Similarly, in India, the survivability and utility of the casuarina have served advantageously. Other regions with reforestation problems and desert encroachment have put the casuarina tree to use, including Senegal, Somalia, and Vietnam.

In stark contrast, the tree is essentially despised in Florida, where it is called an Australian pine and regarded as a "weed tree." The trees tend to take over an area and are extremely difficult to eradicate permanently. For example, the casuarina has created thickets in parts of the Everglades where it threatens the sustenance of the former diversity of wildlife. As summed up by Vietmeyer, "Casuarinas are arboreal shock troops, and, as with troops of any kind, we have to choose carefully where to deploy them."

According to the American Forests Big Tree register, the largest casuarina tree in the United States is located in Olowalo, Maui, Hawaii and is a horsetail *Casuarina equisetifolia* with a height of 89 feet (27.1 meters) and a spread of 56 feet (17.1 meters). Its circumference is 207 inches (526 centimeters).

CATACLASTIC. As proposed by Teall in 1887, this term has the same meaning as crush breccias. This term is also applied to the deformation and granulation of minerals such as may take place during dynamic metamorphism.

CATACLYSM. Any of a number of geologic events, such as an exceptionally violent earthquake, that causes sudden and extensive changes in the earth's surface. An overwhelming flood of water (deluge) that spreads over a wide area of land also is sometimes referred to as a cataclysm.

CATALINA EDDY. A cyclonic mesoscale circulation that forms over the coastal waters of southern California. It is most common in the spring and early summer months but can occur at any time of the year. A Catalina eddy circulation is typically associated with a deepening of the marine layer and an associated improvement in the air quality in the Los Angeles Basin. In many cases the marine layer can deepen above 1 kilometer (0.6 mi) and allow marine air to spill through gaps in the coastal mountains and reach interior desert regions. Catalina eddies are often observed to develop on the coast downwind of the coastal mountains during a period of offshore flow. Cyclonic vorticity develops over the bight of southern California in response to lowered sea level pressure produced by offshore, downslope flow across the Santa Ynez and San Rafael Mountains. Southeastward displacement and offshore expansion of the cyclonic circulation typically occur later in Catalina eddy events.

CATALPA TREES. Of the family *Bignoniaceae* (bignonia or trumpet creeper family), catalpa trees are of the genus *Catalpa*. These are American and Asiatic trees although they were introduced into Europe many years ago. There are two principal species in America: a northern catalpa (*C. speciosa*) and a southern catalpa. (*C. bignonioides*). The southern catalpa is the most common in Europe. Several hybrid catalpas involving the crossing of American and Chinese species have been produced. These include the "J.C. Teas" (*C.* × *erubescens*); a purplish-colored cross (*C.* × *e*. 'Purpurea'); and the golden cultivar (C.b. 'Aurea'). Some gardeners consider the latter species the most spectacular of all yellow-leafed trees.

C. speciosa is also called the catawba tree, cigar tree, and hardy catalpa. The tree can attain heights approaching 100 feet (30 meters). See accompanying table. This northern species does best in the Ohio basin, becoming a somewhat smaller tree in the eastern states. Catalpa flowers are trumpet-shaped with fluted edges, 4 to 5 inches (10 to 12.7 centimeters) long, snow white or pink-tinged, with purple veins and they are in clusters. The fruit is pod-shaped, tapered at each end (thus the name cigar), approximately 8 to 12 inches (20 to 30 centimeters) in length. The leaves are heart-shaped, quite large, 5 to 7 inches (12.7 to 17.8 centimeters), in length, toothless, with an extended sharp point. The upper side of the leaf is light green; the underside is of a slightly lighter color and covered with hair-velvet. With proper moisture, the tree is fast-growing. The wood is quite light, weighing about 26 pounds per cubic foot (416 kilograms per cubic meter).

C. bignonioides, sometimes referred to in the United States as the common catalpa, is usually smaller, less hardy, and ranges from Pennsylvania south to Florida and the southeastern states. Aside from its lesser height and stature, the tree is similar in many other respects to the northern species. See Table 1. The golden *C. bignonioides* "Aurea" previously mentioned is also called the golden Indian bean tree.

Although the common catalpa is beautiful when it blooms, with its countless white, tropical-shaped white flowers, it is not a favorite of landscapers and lawn fanciers because of its frequent shedding of very large leaves and drupes of long, cigar-shaped seed pods, not to mention its propensity for attracting large, green caterpillars. Common catalpa wood is sought by woodcarvers because it is lightweight and possesses an attractive grain pattern which can be polished to a silky texture. Catalpa competes well with cherry and walnut woods for carving.

Of a different genus (*Paulownia*), but related to the catalpas in the bignonia family is the so-called empress tree (*Paulownia tomentosa*). This tree is a native of the Far East and is known for its light wood (15 to 16 pounds per cubic foot; 240 to 256 kilograms per cubic meter) and also as a garden tree. The tree has been introduced into Europe and North America and, under proper conditions, does quite well. See accompanying table. A different species, *P. fargesii*, has recently been introduced into Europe and possibly may offer more satisfying blooms. The empress tree tends to develop flower buds in the fall, subsequently killed off by frost.

The jacaranda (*Jacaranda acutifolia*) is also a member of the bignonia family. This tree is native to tropical America and is mainly found in the northern part of South America. The tree also grows on the southwestern coast of California, on the southern tip of Florida, in the extreme south of Texas and the nearby Gulf coast of Mexico. The tree thrives in tropical areas, but can withstand months of dry weather. The tree may be described as rather exotic in appearance, ranging to a height of 50 to 100 feet (15 to 30 meters). The leaf is doubly compounded, narrow, and sharp. There are numerous leaflets, which are fern-like in appearance. The flower is showy, a bell-shaped, blue, and hangs in clusters. The blossoms are about 2 inches (5 centimeters) long. The fruit is a flat capsule. There are about 50 species of the jacaranda. Several of these trees are the sources of excellent wood used for fine cabinetry work, pianos, and expensive furniture. A Brazilian wood called *caroba*, for example, comes from the *Jacaranda copia*. The wood sometimes is confused with rosewood, which is obtained from various species of the genus *Dalbergia*.

CATALYSIS. Major portions of this article were prepared by S. Ted Oyama and Prof. Gabor A. Somorjai, Center for Advanced Materials, Lawrence Berkeley Laboratory, The University of California, Berkeley, California.

Catalysts have been employed since antiquity in such activities as wine, bread and cheese making. In many cases it was found that the addition of a small portion from a previous batch, a "starter," was necessary to begin the next production. In 1835, Berzelius published an account which tied together earlier observations by chemists, such as Thénard, Davy, and Döbereiner, by suggesting that minute amounts of a foreign substance were able to greatly affect the course of chemical reactions, both inorganic and biological. Berzelius attributed a mysterious force to the substance which he called *catalytic*. In 1894, Ostwald proposed that catalysts are substances that accelerate the rate of chemical reactions without themselves being consumed during the reactions. This definition is still applicable today.

The scope of catalysis is enormous. Catalysts are widely used in the commercial production of fuels, chemicals, foods and medicines. They also play an essential role in processes in nature, like nitrogen fixation, metabolism and photosynthesis.

Classification of Catalysts

Catalysts can be protons, ions, atoms, molecules, or larger assemblages. Traditionally, catalysts have been classified as homogeneous, heterogeneous, and enzymatic, reflecting an increasing hierarchy of complexity.

TABLE 1. RECORD CATALPA TREES IN THE UNITED STATES[1]

	Circumference[2]		Height		Spread		
Specimen	Inches	Centimeters	Feet	Meters	Feet	Meters	Location
Northern catalpa (1990) *(Catalpa speciosa)*	242	615	107	32.6	85	25.9	Michigan
Northern catalpa (1993) *(Catalpa speciosa)*	264	671	86	26.2	79	24.1	Washington
Southern catalpa (1999) *(Catalpa bignonioides)*	221	561	86	26.2	81	24.7	Maryland

[1]From the "National Register of Big Trees," American Forests (by permission).
[2]At 4.5 feet (1.4 meters).

Homogeneous Catalysts: The first of the aforementioned species may be considered examples of *homogeneous* catalysts. In addition, metal complexes and organometallic compounds are important members of this class of catalysts. As the name implies, these catalysts are uniformly dispersed or dissolved in a gas or liquid phase together with the reactant of the reaction.

Heterogeneous Catalysts: In contrast to homogeneous catalysts, *heterogeneous* catalysts are usually solid surfaces, attached to solid surfaces, or part of insoluble matrices, such as polymers, and are thus phase-separated from the fluid medium surrounding them. Regardless of their form, the active catalytic component is located at the interface between the solid and the fluid and may consist of a wide diversity of species. Examples are: One or two atoms of the total surface; a larger ensemble of such surface atoms; an organometallic compound attached to the surface atoms; an organometallic compound attached to the surface by covalent bonds; or a molecular cluster lying on the surface.

Enzymatic Catalysts: These are like homogeneous catalysts in being dissolved in liquid media, but enzymatic catalysts are of biological origin and possess the highest level of complexity among the three types. Ironically, as mentioned in the opening sentence of this article, they were probably the first catalysts to be utilized commercially and industrially. Enzymatic catalysts are proteins composed of repeating units of amino acids, often twisted into helices, and in turn folded into 3-dimensional structures. The protein structures often surround a central organometallic structure. See also **Enzyme**.

Fundamentals of Catalysis

The action of catalysis can be illustrated by an example-the water gas shift reaction catalyzed by iron and chromium oxides.

$$H_2O + CO \longrightarrow H_2 + CO_2$$

This reaction is used in the production of hydrogen in several commercial processes. It is an example of a heterogeneous catalytic reaction, but the principles derived from it are also applicable to homogeneous and enzymatic catalytic reactions. A simplified scheme for the reaction is given as follows:

$$H_2O + {}^* \longrightarrow H_2 + O^*$$

$$CO + O^* \longrightarrow CO_2 + {}^*$$

In the first step, one of the reactants, H_2O, reacts with an empty catalytic site, denoted by * to produce a product, H_2, and a reactive intermediate consisting of an oxygen atom associated with the site, denoted by O^*. In the second step, the other reactant, CO, reacts with the intermediate to produce the product, CO_2, and regenerating the catalytic site, *. The energetics associated with this process are given in Fig. 1. A key aspect of this scheme is that it represents a cycle that occurs many times as the reaction proceeds.

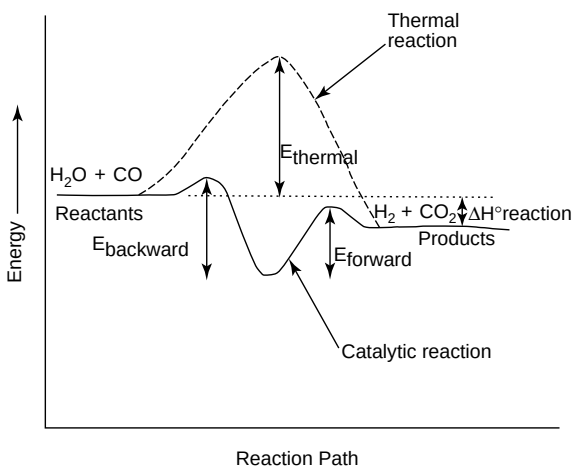

Fig. 1. Energy level diagram for the hypothetical catalytic and thermal water gas shift reaction. The overall heat of reaction is given by $\Delta H°_{reaction}$, the activation barriers in the forward and backward direction by $E_{forward}$ and $E_{backward}$, respectively; and the activation energy for the thermal reaction by $E_{thermal}$.

Each repetition of the cycle is called a turnover. A good catalyst will have millions of turnovers. In contrast, a stoichiometric reactant will have only one. Several important points are to be made concerning the energetics and scheme just presented.

1. The energy level diagram shows that the catalyzed reaction has a *lower activation barrier* than the uncatalyzed thermal reaction. This is the origin of the enhancement in the rate and it applies both in the forward and reverse directions of the reaction.
2. Regardless of the details of the mechanism and the energetics of the transformation of R into P, their relative energies, as shown by $\Delta H°_{reaction}$, do not change. [*Strictly speaking, it is a free energy of reaction*, $\Delta G°$. The equilibrium constant is given by $K = \exp(-\Delta G/RT)$.] This means that the thermodynamic equilibrium between them does not change. Catalysts increase the *rate of approach to equilibrium*, but do not alter the thermodynamic equilibrium.
3. As shown by the overall reaction stoichiometry, there is no net consumption or production of the catalytic site,*. The reaction proceeds by repetition of the catalytic cycle or chain, with the catalytic species remaining *unchanged* at the end. This explains the observation noted earlier that miniscule amounts of catalyst can give rise to very large amounts of product.
4. The intermediate, O^*, must be neither too stable nor too unstable. If it is too stable, it will not decompose to form the product; if it is too unstable, it will not form in the first place.

Nomenclature of Catalysis

The performance of catalysts is generally described by their activity, conversion, selectivity and yield. *Activity* is a measure of the rate at which the catalyst is able to transform reactants into products and is given in terms of an extensive property of the catalyst, such as mass, volume or number of moles. *Active sites* are the atomic or molecular species responsible for catalytic activity (represented by the symbol* as mentioned previously). Their identity and number are in general very difficult to measure. Various examples of the type of entities they might be are given in the definitions of the three kinds of catalysts. *Turnover frequency*, also known as turnover number or turnover rate, is the most fundamental measure of the activity, and represents the rate at which the catalytic cycle proceeds. It is equivalent to the number of molecules undergoing transformation per active site per unit time. The term *conversion* refers to the percentage of a reactant that is reacted to form all products. The term *selectivity* is applied to a specific product and refers to the percentage of that product among the total products formed. Equivalently, it is equal to the percentage of the product formed of the total reactant consumed. A high selectivity implies little waste of reactant. *Yield* is the product of conversion and selectivity, and is a measure of the efficiency of carrying out a particular transformation. *Specificity* is used mainly with enzymatic catalysts and describes their propensity to carry out only one type of reaction or to act upon only one isomer of a particular compound.

Other terms chiefly pertain to industrial applications of catalysts. *Stability* and *lifetime* refer to the ability and length of time that a catalyst is able to maintain the conversion and selectivity necessary to run a process. *Deactivation* refers to the loss of catalytic function by any of a number of causes, such as decline in surface area, decomposition of active species, or poisoning. *Denaturization* describes the deactivation of an enzyme by the loss of its 3-dimensional folded structure. This is generally caused by extremes in temperature or pH. *Poisoning* is a type of deactivation caused by the strong binding of a foreign substance to the active site of a catalyst in competition with the reactant. *Regenerability* refers to the ability to chemically or physically treat a catalyst that has lost its activity.

Industrial Usage of Catalysts

The most important catalysts employed commercially are listed in Tables 1 and 2. The remainder of this article is devoted to specific industrial uses of catalysts. The segment dealing with *fuels* covers the major operations used in the refining of petroleum. This is followed by descriptions of a few of the major processes used to produce *industrial* chemicals. The segment covering *foods and medicines* deals exclusively with enzymes.

TABLE 1. PRINCIPAL USES FOR CATALYSTS

Petroleum Refining	
	% of Total
Catalytic cracking	7.9
Reforming	≪1
Hydrocracking	≪1
Hydrotreating	≪1
Alkylation	91.2
Chemical Production	
Polymerization	44.3
Alkylation	12.1
Hydrogenation	8.0
Dehydrogenation	2.4
Oxidation, ammoxidation, and oxychlorination	21.1
Ammonia, hydrogen, and methanol production	12.1

Note: It is estimated that in 1991, approximately 2400 million kilograms of catalysts were consumed by the petroleum industry; approximately 110 million kilograms were consumed for chemical production. Approximately 650 million kilograms were used strictly for emission and pollution control by various industries.

TABLE 2. PRINCIPAL USES FOR ENZYME (CATALYSTS)

	% of Total
Alkaline protease	53.6
Glucose isomerase	9.7
Rennets	18.3
Glucoamylase	12.2
Other amylases	6.2

Note: It is estimated that in 1991, approximately 2 million kilograms of enzymes were consumed by the chemical and food production industries. Note included in the foregoing figures are enzymes for leather-bating, papain, pectinase, bromelain, and several others.

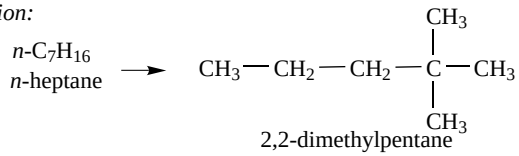
Fuels. *Catalytic Cracking*: Catalysts are used to refined a moderately heavy crude oil fraction known as gas oil to gasoline. The net result of the process is a lighter product with a high content of branched-chain and aromatic hydrocarbons, the species responsible for raising gasoline octane levels. The transformations are complex, but can be considered to involve the following major acid-catalyzed reactions:

1. C−C *bond breaking*: $\underset{\text{paraffin}}{C_{18}H_{38}} \rightarrow \underset{\text{paraffin}}{C_{10}H_{22}} + \underset{\text{olefin}}{C_8H_{16}}$
2. *Dealkylation*: $\underset{\text{alkylaromatic}}{ArC_4H_9} \rightarrow \underset{\text{olefin}}{C_4H_8} + \underset{\text{aromatic}}{ArH}$
3. *Hydrogen transfer*: $\underset{\text{cycloparaffin}}{C_6H_{12}} + 3\ \underset{\text{olefin}}{C_8H_{16}} \rightarrow \underset{\text{aromatic}}{C_6H_6} + 3\ \underset{\text{paraffin}}{C_8H_{18}}$
4. *Isomerization*: $\underset{\text{olefin}}{n\text{-}C_{10}H_{20}} \rightarrow \underset{\text{isoolefin}}{i\text{-}C_{10}H_{20}}$

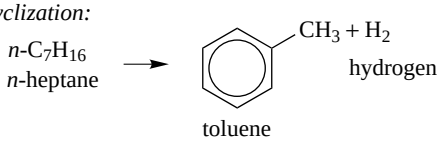
The heterogeneous catalysts employed in cracking are acidic materials composed of 3 to 25% (wt) of zeolites embedded in a silica-alumina matrix. Zeolites are crystalline aluminosilicates possessing a network of uniform pores whose walls hold the catalytically active acid sites. The reactant molecules pass through the pores and react within the zeolites.

Reforming: The catalysts are used to treat naphtha, a fraction of crude oil somewhat lighter than gas oil and containing large amounts of straight-chain paraffins. Several examples of typical reactions carried out by these catalysts are given below. The result of these reactions is to reconstruct or "reform" the hydrocarbons in the feed so as to increase the octane level. The catalysts used here differ from cracking catalysts because they tend not to alter the carbon number of the reactants and also because they produce a substantial amount of byproduct hydrogen gas.

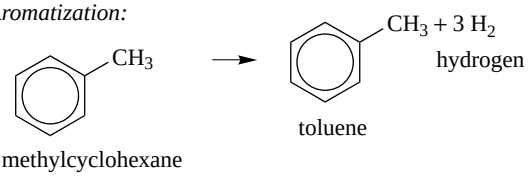
1. *Isomerization:*



2. *Dehydrocyclization:*



3. *Aromatization:*



These heterogeneous catalysts consist of multimetallic clusters, containing metals, such as platinum, iridium, or rhenium, supported on porous acidic oxide supports, such as alumina. The catalysts are said to be bifunctional because both the metal and the oxide play a part in the reactions. The metal is believed to carry out reversible dehydrogenation of paraffins to olefins, while the oxide is believed to carry out isomerization.

Hydrocracking. In hydrocracking, catalysts are used to reduce the molecular weight of a feedstock. A typical use is the conversion of light gas oil to naphtha for gasoline production through reforming. An example of a characteristic reaction is given as follows.

$$\underset{n\text{-hexadecane}}{n\text{-}C_{16}H_{34}} + H_2 \longrightarrow \underset{n\text{-heptane}}{n\text{-}C_7H_{16}} + \underset{iso\text{-nonane}}{i\text{-}C_9H_{20}}$$

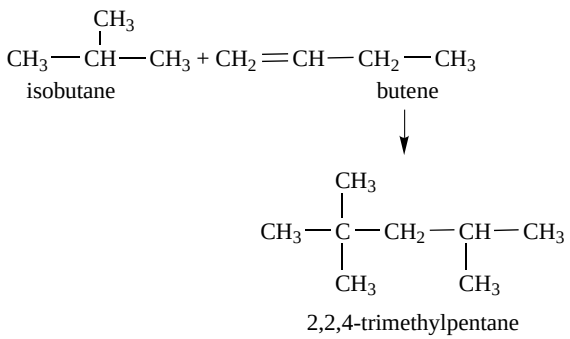
These heterogeneous catalysts contain nickel, cobalt, molybdenum, tungsten, platinum, or palladium on acidic aluminum silicate or zeolite supports. As with reforming catalysts, the catalysts here are also believed to be *bifunctional* — with the metal component carrying out the reversible dehydrogenation of paraffins to olefins. Hydrocracking is carried out in the presence of hydrogen and produces saturated products.

Hydrotreating. This process comprises a mild hydrogenolysis of nitrogen, oxygen and sulfur compounds prior to catalytic cracking. The reactions carried out in this step are as follows.

1. *Desulfurization*: $R{-}SH + H_2 \longrightarrow RH + H_2S$
2. *Denitrogenation*: $R{-}NH_2 + H_2 \longrightarrow RH + NH_3$

Hydrotreating catalysts are composed of cobalt or nickel molybdate or nickel tungstate on an alumina or zeolite support. The materials are sulfided with hydrogen sulfide (H_2S) before use, but the final catalysts may retain some oxide and be of complex composition.

Alkylation: This process converts isobutane and butylenes produced in the catalytic cracking step into a mixture of dimers known as alkylate. This product is a gasoline blending stock of high octane value. Alkylation catalysts are homogeneous liquid catalysts, either sulfuric or hydrofluoric acids.



Chemicals. *Polymerization*: Catalysts are used in the production of polymers, such as linear and low-density polyethylene (LLDPE). An example of these catalysts are Ziegler-Natta catalysts, which are combinations of

titanium halides with aluminium and magnesium alkyls.

$$\underset{\text{ethylene}}{n\text{-}CH_2{=}CH_2} \longrightarrow \underset{\text{LLDPE}}{(-CH_2{-}CH_2)_n{}^-}$$

Alkylation: Catalysts are used to make carbon-carbon bonds, as in the liquid phase alkylation of benzene to ethylbenzene, a styrene precursor. The catalyst used in this case is aluminum chloride.

$$\underset{\text{benzene}}{C_6H_6} + \underset{\text{ethylene}}{CH_2{=}CH_2} \longrightarrow \underset{\text{ethylbenzene}}{C_6H_5{-}CH_2{-}CH_3}$$

Hydrogenation: These catalysts are used to add hydrogen to unsaturates, as in the hydrogenation of vegetable oils to form hardened oils. Most catalytic systems consist of nickel or a noble metal on a support.

$$\underset{\text{linoleic acid}}{CH_3(CH_2)_4CH{=}CH{-}CH_2{-}CH{=}CH(CH_2)_7COOH} \longrightarrow$$

$$\underset{\text{oleic acid}}{CH_3(CH_2)_7CH{=}CH(CH_2)_7COOH}$$

Dehydrogenation Catalysts are used to remove hydrogen from hydrocarbons. Many catalysts have been developed, including metals and oxides. An example of the latter is chromia-alumina used in the dehydrogenation of butane.

$$\underset{\text{butane}}{CH_3{-}CH_2{-}CH_2{-}CH_3} \longrightarrow \underset{\text{butadiene}}{CH_2{=}CH{-}CH{=}CH_2}$$

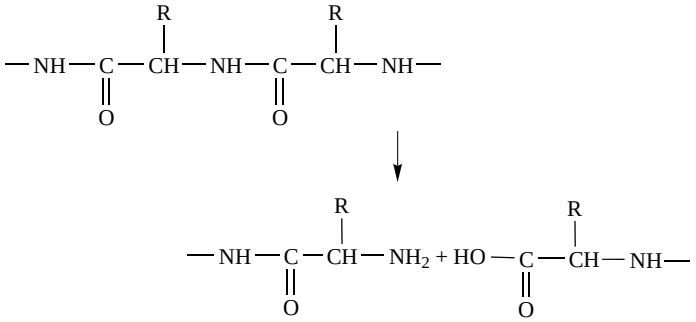
Oxidation, Ammoxidation, and Oxychlorination: Numerous catalysts have been developed for a number of processes in this category. Examples are supported vanadium oxide, complex multimetallic oxides, and supported cupric chloride, used respectively for the following reactions:

1. *Butane oxidation*: $\underset{\text{butane}}{C_4H_{10}} + O_2 \rightarrow \underset{\text{maleic anhydride}}{C_4H_2O_3}$
2. *Ammoxidation*: $\underset{\text{propylene}}{C_3H_6} + O_2 + NH_3 \rightarrow \underset{\text{acrylonitrile}}{CH_2{=}CH{-}CH}$
3. *Oxychlorination*: $\underset{\text{ethylene}}{C_2H_4} + Cl_2 + O_2 \rightarrow \underset{\text{1,2-dichloroethane}}{ClCH_2{-}CH_2Cl}$

Ammonia, Hydrogen, and Methanol Production: The ammonia synthesis catalyst is metallic iron promoted with Al_2O_3, K_2O, MgO, and CaO. The hydrogen-producing (methane reforming) catalyst is supported nickel. The methanol synthesis catalyst is ZnO promoted with Cr_2O_3 or Cu(I)−ZnO promoted with Cr_2O_3 or Al_2O_3. The respective reactions are cited as follows.

1. *Ammonia synthesis*: $N_2 + 3\ H_2 \longrightarrow 2\ NH_3$
2. *Methane reforming*: $CH_4 + H_2O \longrightarrow CO + 3\ H_2$
3. *Methanol synthesis*: $CO + 2\ H_2 \longrightarrow CH_3OH$

Foods, Medicines, and Other Products. *Proteases*: The function of these enzymes is to hydrolyze the peptide bond in proteins. Considerable variety exists in source, specificity, and reaction conditions for these enzymes. An example follows.



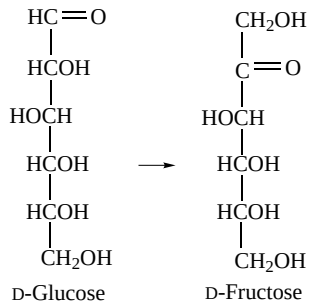
1. *Alkaline Proteases* — derived from bacteria. They find wide application in detergents, leather tanning, protein hydrolysis, brewing, and silver recovery from film.

2. *Papain* — a plant protease derived from the papaya fruit. The enzyme is used in digestive aids, wound debridement, tooth-cleaning and, most importantly, as a meat tenderizer.

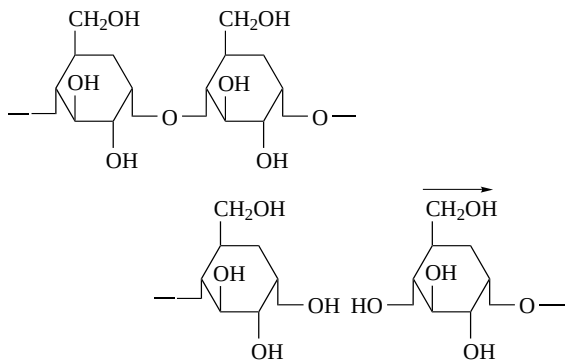
3. *Bromelain* — a plant protease with uses similar to those of papain. Bromelain is obtained from stumps left over from pineapple harvest.

4. *Rennet or rennin* — an animal protease derived from the stomachs of calves as well as from microorganisms. Rennet is used in the manufacture of cheese to clot milk.

Glucose Isomerase: This enzyme is found in many organisms and, in practice, is used in the form of entrapped cells or bound to ion-exchange resins. Glucose isomerase converts glucose to fructose, one of the principal components of table sugar.



Leather Bating Enzymes: Enzymes used in leather manufacture to remove flesh from hides. The enzymes generally are derived from hog and beef pancreas and consist of mixtures of enzymes that attack both proteins and lipids.



Amylases. These enzymes hydrolyze the D-glycosidic linkage in starch.

1. *Glucoamylase* — found in blood, molds, and bacteria. This enzyme produces glucose by removing the end glucose unit in long-chain carbohydrates, such as starch, glycogen, dextrins, and maltoses. The main commercial use of glucoamylase is in the production of glucose syrup, glucose paste, and crystalline glucose.
2. *Other amylases*, constituting a large family of enzymes that act on different substrates, are found in saliva, animal tissues, plants, yeast, and other microorganisms. They find wide use in the manufacture of glue, starchy syrups, and in various steps in the production of brewery and bakery products.

Pectinases: These enzymes carry out the hydrolytic degradation of the D-glycosidic linkage in pectins. The latter substances, also known as pectic substances, are polymeric components of plant cell walls and, like starch, are composed of sugar residues linked by glycosidic bonds. The chemistry is the same as that shown for the amylases previously described. The main application of pectinases is in the production of fruit juices, wines, and certain other food products.

CATALYTIC CONVERTER (Internal Combustion Engine). A combination of the Clean Air Act Amendments of 1970 and the Energy Policy and Conservation Act of 1975 (United States Congress) has promoted the widespread use of catalytic aftertreatment to control automotive exhaust emissions with a concomitant increase in fuel economy. The catalytic converter, comprised of a ceramic catalyst and the necessary stainless steel hardware to ensure that the exhaust gases pass through the catalyst, permits the conventional spark-ignition automobile engine to run at near optimum efficiency to afford good fuel economy. The catalyst itself has the capability of promoting (or accelerating) the rate at which reactions occur. In the case of an oxidation catalyst, the function is to cause the carbon monoxide (CO) and hydrocarbons (HC) which result from incomplete combustion to be converted to CO_2 and water. In the case of a three-way catalyst, the oxidation reactions (HC and CO) are promoted as well as the reduction reaction of oxides of nitrogen (NO_x).

Converters now in use contain noble metals on a ceramic substrate (e.g., platinum dispersed on alumina). The converter is typically located in the exhaust system in one of two general locations: an underfloor location, or a close-coupled location near the manifold. The operating temperature range for noble metal catalyst is from 600 to 1200 °F (316 to 649 °C), which is similar to the exhaust pipe skin temperature range normally encountered on standard automobile engines.

Catalytic materials can be physically supported on either pelleted or monolithic substrates. In the case of the pelleted catalyst, the support is an activated alumina. A typical monolithic catalyst is composed of a channeled ceramic (cordierite) support having, for example, 300 to 400 square channels per square inch on which an activated alumina layer is applied. The active agents (platinum, palladium, rhodium, etc.) are then highly dispersed on the alumina.

In the case of pelleted catalyst, the pellets are confined by screens (Fig. 1); the monolithic-type catalyst (Fig. 2); being a single rigid material, needs no such confinement. The arrangement within the container, regardless of which type of catalyst is used, is intended to ensure that the exhaust gases pass through the catalyst bed without bypassing it or "channeling" along outside walls of the catalyst.

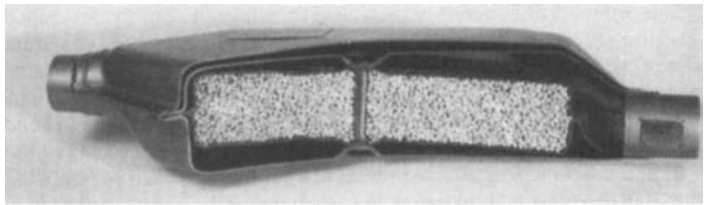

Fig. 1. Converter to use pelleted catalyst.

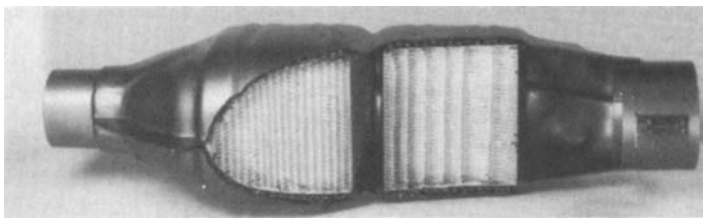

Fig. 2. Converter to use monolithic catalyst.

Exhaust emission standards since the 1981 model year vehicles have required the use of three-way catalysts, either alone or in combination with an oxidation catalyst. Three-way catalysts are designed to operate in a very narrow range about the stoichiometric air/fuel ratio. In this range the HC and CO are subject to oxidation and the NO_x compounds undergo reduction. The downstream oxidation catalyst in a dual bed system is generally used as a "clean-up" catalyst to further control HC and CO emissions. The most common catalytic combination in three-way uses is platinum/rhodium. Current production applications use these elements in a relatively rich proportion of 5:1 to 10:1, whereas the respective mine ratio is about 19:1.

Since the introduction of catalytic converters on passenger cars in the 1973 model year in the United States and in the 1974 model year in Japan, the demand for improved air quality has grown worldwide. With that demand has grown converter usage to control mobile source emissions. Several European countries are in the process of drafting and enacting legislation that requires catalytic converters. Australia uses catalytic converters, Korea will soon require them, Brazil is also developing emission control strategies, and several other countries are studying the need for emission controls.

CATARACT. The lens of the eye, the part that helps focus light onto the retina which in turn sends the visual signals to the brain, is made mostly of water and protein. When too much protein builds up, it clouds the lens blocking some of the light and impairing vision. That protein build-up is the formation of a cataract. It is not a growth, but rather a clouding or hazing of the lens.

A significant number of people ages 65 or older have some degree of cataract. In fact, developing cataracts is a normal part of aging. That does not mean, however, that every senior will need treatment for cataract problems.

The cause of cataracts is generally unknown. Most often, cataracts occur as a person ages, called age-related cataracts or more scientifically, nuclear sclerotic cataracts. Cataracts can also result from a variety of environmental conditions and injuries and are called either secondary or traumatic cataracts. Some babies are born with cataracts, called congenital cataracts. Generally, potential risk factors for developing cataracts include but are not limited to: 65 years of age or more; family history of cataracts; smoker or former smoker; grossly over- or underweight; diabetes; have taken steroids or certain other medications; suffered a blunt or penetrating eye injury; and excessive, long exposure to UV light.

Some people compare cataracts to looking through a frosted piece of glass, fog, or film covering their sight. Many do not even know they have cataracts if the cloudiness has not greatly altered their eyesight. Others with cataracts, however, have lost their ability to perform routine activities. Glare may also be a problem, and many people with cataracts complain of halos around lights.

Additional symptoms include colors that seem faded, a temporary symptom called "second sight" which occurs when people can read again close up without glasses even though they have not done this for years, decreased night vision, and frequent changes in eyeglass or contact lens prescription.

It is important to note, however, that although these symptoms can indicate the formation of cataracts, they can also signal other vision problems. Cataracts develop and grow slowly and cause more pronounced symptoms as they "mature."

The first step in treating cataracts is detection. To determine whether or not a person has cataracts, an eye care professional conducts a comprehensive eye exam, which includes a visual acuity test, pupil dilation, and a tonometry test to measure the pressure inside the eye. The early stages of cataracts can sometimes be treated with eyeglasses, alternative lenses, or a simple change in environmental lighting. For more advanced cataracts that have caused a loss of routine activities or other problems, surgery is the only effective treatment option.

Surgery. Cataract removal is one of the most popular surgeries performed in the United States today. It is safe and highly effective in improving vision. The most common procedure is called *extracapsular cataract extraction* (ECCE) or *phacoemulsification* (phaco). In phaco, after making a $\frac{1}{4}$-inch incision, the surgeon uses sound waves or ultrasonic vibrations to break up the cloudy lens so it can be removed by suction through a tiny hollow tube.

In some instances, eye care professionals may choose an older method of cataract removal in which the entire lens is removed through a $\frac{1}{2}$-inch surgical incision. After a lens is removed, it must be replaced. The most common lens replacement is called the *intraocular lens* (IOL). An IOL is a clear plastic lens implant that is placed inside the eye permanently, thus requiring no care. Patients do not feel or see the new lens.

When an intraocular lens implant is not the best solution, the doctor may prescribe contact lenses or, in rare cases, corrective eyeglasses as lens replacement.

Prior to surgery, an eye care professional conducts a comprehensive eye exam or cataract exam to determine eye health and to use as a guide during the surgery.

The patient is given eye drops to enlarge the pupil of the eye to be operated on, giving the surgeon better access to the lens. Some people choose to remain awake during the procedure and select local anesthesia. The anesthesia may be administered as eye drops, injections close to the eye, or both. Others require general anesthesia to keep them relaxed throughout the procedure.

Depending on the type used, anesthesia may be given about half an hour before surgery in a pre-operation (pre-op) room or immediately before surgery at the operating table. The anesthesia prevents any pain and helps keep the eye from moving.

When ready, the patient lies back on a table and the eye is gently washed. Then a sheet is placed over the patient's face with an opening for the surgeon to access the eye. Often, a member of the eye care team (surgeon, nurses, and assistants) provides additional air for increased comfort.

The surgeon generally sits behind the patient and uses a surgical microscope unit that can be swung over the table, in order to obtain a clear, enhanced image of the eye. Lighting is dimmed. With extracapsular or phaco surgery, an incision less than $\frac{1}{4}$ inch in measurement is made and the surgeon uses the phaco ultrasonic instrument to break up the cloudy lens, then removes the pieces using suction through a tiny hollow tube. Although the cloudy lens is removed, the surgeon leaves intact the lens capsule or outer covering and inserts an intraocular lens (IOL) through the incision to replace the cloudy lens. The incision heals on its own without stitches. Anesthesia helps prevent any pain or discomfort. Overall, the entire surgical procedure usually takes less than 30 minutes. Sometimes a protective covering is placed over the eye when surgery is completed.

Recovery time is scheduled immediately following surgery to allow recuperation from the procedure and anesthesia. Patients generally go home afterward. So someone should accompany the patient home. Vision may still be impaired.

For a day or two following surgery, patients may experience mild discomfort such as itching or stickiness when blinking. These symptoms usually disappear within 1 to 2 days.

Usually patients return to their surgeon the day after the procedure for their first follow up examination. Surgeons often prescribe eye drops to help minimize the mild inflammation that occurs in the eye after surgery.

The healing process may take weeks, but shortly after surgery many patients begin to resume visual activities, such as reading and watching television even with some blurred vision.

As with any surgery, there are some risks involved in cataract surgery. A rise in the eye's pressure is why it is essential for patients to follow a strict post-surgery check-up schedule. Because an incision is made in the eye, infection is also a risk, though managed easily with oral or eye-drop antibiotics. Other risks are hemorrhage or retinal detachment. It is important to point out that cataract surgery is common and risks are considered minimal. CATAWBERITE. The term applied by Lieber to a metamorphic rock chiefly composed of magnetite and talc.

CATENARY. The locus of the transcendental equation

$$y = \frac{a}{2}(e^{x/a} + e^{-x/a}) = a \cosh \frac{x}{a}$$

The curve can be generated by the focus of a parabola rolling along a straight line and its shape is that taken by a uniform, heavy flexible cable freely suspended from its ends. See Fig. 1. The involute of the catenary is called the tractrix. See also **Funicular Polygons and Catenaries**; **Parabola**; and **Tractrix of Huygens**.

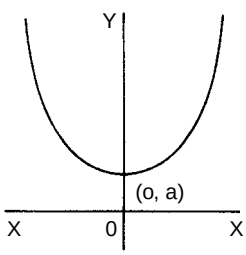

Fig. 1. Catenary.

CATENATION COMPOUND. See **Compound (Chemical)**.

CATERPILLAR. The larval form of the butterflies and moths. See Fig. 1. These animals are of very simple construction. Their main task is eating, and they have no organs not associated with this function: they have no wings, no highly developed sense organs, and only short legs. They lack compound eyes; on either side of the head they have only a row of six ocelli which are barely able to distinguish light from dark. Nevertheless, they are capable of perceiving the trunk of a tree, so that they can proceed from the ground into the foliage of the tree on which they feed. Of the mouthparts, the mandibles are always large and powerful, admirably suited for chewing up plant food, even solid wood. As weapons

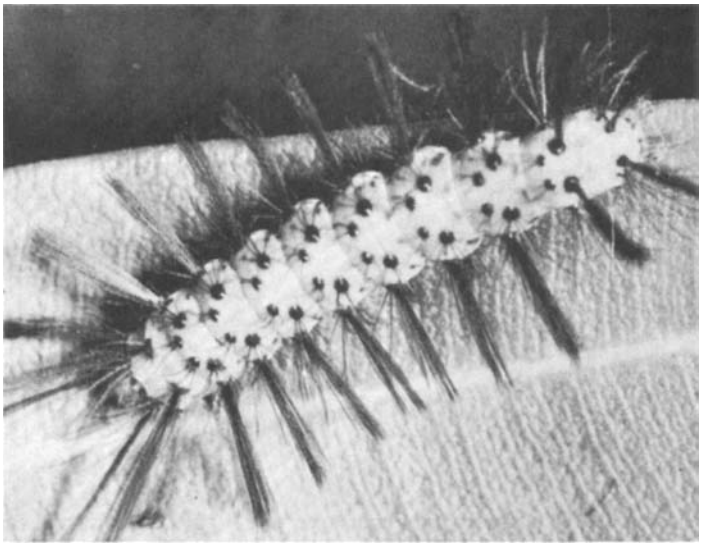

Fig. 1. Caterpillar. (*A.M. Winchester*.)

of defense, though, they are of little use, and even less as aggressive weapons. The remaining mouthparts are small and poorly developed; they bear sense organs for touch and taste and serve to guide the caterpillar to an appropriate food plant. The caterpillars of many lepidopteran species are restricted to certain plants and would starve before accepting any other plant as food.

In the middle of the labium of the caterpillar there is a small papilla, the spinneret, with the openings of the two silk glands. These glands are often very large, in some cases extending throughout the body. All caterpillars, without exception, are able to produce silken threads, though the amount they can produce varies. The thread extruded from a silk gland consists of two substances that harden on contact with the air. The silk marketed commercially is this substance; true silk is produced by the silkworm (*Bombyx mori*), but the silk of other caterpillars is also used. The threads are usually white but often yellowish or, in the case of many large caterpillars, even dark brown.

These silk threads play a central role in the life of a caterpillar. Many caterpillars actually live on an endless string, which they produce continuously; they attach it to the substrate and clasp it with their legs. Thus they can creep about on even the smoothest surfaces. If such a caterpillar falls from its position, it spins the thread out a bit more, still hanging from it, and then uses it like a rope to climb back into place. The same technique allows it to escape from enemy attacks. Species that live in hiding, and others that build communal nests, use the thread as a guideline to and from the feeding place. The caterpillar of course uses large quantities of silk to build cocoons and other woven structures, and the threads are also used to line mines in leaves and tunnels in wood.

The caterpillar's worm-like body is often decoratively colored and sometimes oddly shaped, with various outgrowths or with wart-like verrucae, thorn-like scoli, or hairs on the upper surface. Presumably all these devices serve as protection from enemies, whether by camouflaging the caterpillar of frightening the predator. Some caterpillars also have organs specially designed for defense. One of these is the eversible osmeterium of the swallowtail caterpillars, which produces a repugnant smell. Other weapons of defense are urticating hairs (hairs that cause irritation when touched) and hard, sharp bristles, whose painful stab may be accentuated by poisonous substances.

CATFISHES *(Osteichthyes).* Members of the suborder *Siluroidea*, catfishes are of many species. As a general description, they are without scales, although the skin has bony plates in some species. Barbels (feelers) occur on the head. They are represented in the fresh waters of all continents with exception of Australia and gain great diversity in the Americas. The catfishes are important food fishes in some parts of the world. In North America, the channel cats are especially desirable. They reach a large size in some of the larger rivers and lakes.

The various species of catfishes may be categorized along the following lines:

Armored Catfishes
- Doradid Catfishes (Family *Doradidae*)
- allichthyid Catfishes (Family *Callichthyidae*)
- oricariid Catfishes (Family *Loricariidae*)

Naked Catfishes
- Banjo Catfishes (Family *Aspredinidae*)
- Ariid Marine Catfishes (Family *Arridae*)
- Plotosid Marine Catfishes (Family *Plotosidae*)
- Clariid Catfishes (Family *Clariidae*)
- Silurid Catfishes (Family *Siluridae*)
- Pimelodid Catfishes (Family *Pimelodidae*)
- Bagrid Catfishes (Family *Bagridae*)
- Parasite Catfishes (Family *Trichomycteridae*)
- North American Catfishes (Family *Ictaluridae*)
- Schilbeid Catfishes (Family *Schilbeidae*)
- Upside-Down Catfishes (Family *Mochocidae*)
- Electric Catfish (Family *Malapteruridae*)

There is not full agreement on methods for classifying catfishes. In some classifications, the group may range from 25 to 31 for coverage of over two thousand species.

The doradids occur in South America and are known for their heavy armor, comprised of a series of overlapping plates. One of the better known members of this family is the *Acanthodoras spinosissismus*, which produces grunt-like sounds when in or out of the water. The sounds are derived from activity of its air bladder. The callichthyids are also South American, possessing a smooth armor made up of plates. A favorite of tropical-fish fanciers is the 3-inch (7.5-centimeter) — or less — *Corydoras*, which is reasonably peaceful in captivity. They are not brilliant in coloration, but do display interesting patterns. Another South American variety is loricariid catfishes. They have a high dorsal fin and a V-shaped tail fin. They appear somewhat like a North American minnow and are of appropriate size for aquariums, but require special attention and diets. The heavier genus *Plecostomus* (averaging 4 to 5 inches; 10 to 12.5 centimeters in length) is popular with tropical-fish fanciers, as well as being well liked by some Indians in South America as a food.

Among the naked catfishes (no armor), the banjo catfish is well named because of its appearance. Most members of this catfish family are freshwater species, but a few can tolerate brackish water and seawater. Very few banjo catfish spawn in captivity. *Bunocephalus coracoideus* (5-inch; 12.5-centimeter fish) is an exception.

Found widely distributed throughout tropical and subtropical waters, the arid marine catfishes are fast-moving and often travel in schools. They are frequently used as food. The *Plotosus anguillaris*, colorful and an inhabitant of tropical reefs and well distributed throughout the Indo-Pacific region, is considered dangerous in that deaths have been reported as the result of making contact with the fine spines of the fish.

The distinguishing characteristic of the clariids is incorporation of an auxiliary breathing apparatus, which permits them to live out of water for periods much longer than tolerable to other catfishes. They are found from Africa to the East Indian archipelago. More recently, they have become established in the waters around the Hawaiian Islands and Guam. Reaching an average length of about 16 inches (40 centimeters), this catfish is considered quite hardy, frequently living in captivity for several years. Also classified as clariids are the *Gymnallabes typus* and *Channallabes apus*, very strange, specialized fishes, sometimes referred to as West African eelcats. They possess very long dorsal and anal fins. When mature, they reach a length of about 1 foot (0.3 meter). The body is no thicker than an average pencil and thus they appear much as eels.

The pimelodids represent the largest family of South American catfishes and inhabit waters from Mexico southward, including most of South America. There are many variations. One of particular interest is the *Typhlobagrus kronei*, a blind cave catfish that inhabits the Caverna das Areias in Sao Paulo, Brazil. Some pimelodids are of the proper size and other qualities to be of interest to tropical-fish fanciers, but they require a lot of aquarium space and are quite aggressive, often attacking other fishes.

The bagrids as a general family are much like the pimelodids just described, except they are inhabitants of the Old World. The *Leiocassis siamensis* found in Thailand and of beautiful brown coloration and yellow and white band stripping is well known for the croaking sounds it creates. The fish is usually about 7 inches (18 centimeters) in length. The similar

striped *Mystus vittatus* is found in Thailand, Burma, and India. Also among the bagrids is the unusual *Bagrichthys hypselopterus*, an inhabitant of the rivers of Borneo and Sumatra. A fully-grown fish reaches about 16 inches (40 centimeters) in length and is characterized by a dorsal fin which extends obliquely upward almost the full length of the fish. Biologically, the need for such a development remains unaccounted for even though the species have been known for over a hundred years.

The ictalurids are what one might term the average catfish of the North American continent. Among the largest is the flathead (*Pylodictis olivaris*). This fish has been reported to weigh as much as one hundred pounds, with a length of nearly $5\frac{1}{2}$ feet (1.7 meters). This is a square-tailed species and is found widely throughout the central United States. The smaller variety of ictalurids is known as the madtoms, and they are dangerous because their pectoral spines and associated venom glands can cause serious and painful wounds. They are of small size, usually not exceeding 5 inches (12.5 centimeters) in length. The bullhead *nebulosus*) (*Ictalurus nebulosus*) is a favorite among fishermen. See Fig. 1. At one time limited to the eastern United States, it is now well distributed over the western portion of North America. It is also widely found throughout the Hawaiian Islands and Europe. The brown bullheads mature at 6 inches (15 centimeters), but reach an average length of about 16 inches (40 centimeters). The brown bullheads are known for the tender care of their young. The dense school of free-swimming juveniles is amply protected by one or both parents.

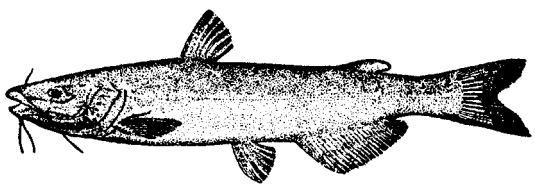

Fig. 1. Bullhead catfish (*Ictalurus nebulosus*).

The white catfish (*Ictalurus catus*) at one time was limited to the Atlantic seaboard. It is now found throughout the central United States, as well as in an increasing number of areas to which it has been introduced. It is a large fish, weighing up to nearly 60 pounds (27 kilograms) and attaining a length of about 4 feet (1.2 meters). It is considered perhaps the most valuable of the catfishes in North America as a source of food.

One of the largest catfishes in the world is found among the schilbeids. This is a heavy-bodied herbivore without teeth (*Pangasianodon gigas*) that can attain a length in excess of $7\frac{1}{2}$ feet (2.3 meters) and a weight of about 250 pounds (113 kilograms). Studies have shown that spawning migrations are made up the Mekong River, possibly to Yunan province in China. Spawning may take place in Lake Tali. The Cambodian people call it the giant fish. Some other species among the schilbeids are quite small, as represented by *Etropiella debauwi* (3 inches; 7.5 centimeters long). Typical characteristics of the schilbeids include: (1) short barbels about mouth — usually two or three pairs, (2) adipose fin is quite small, (3) long anal fin distinct from tail fin, (4) short, high dorsal fin, and (5) a forked tail.

Members of the catfish family *Mochocidae* frequently reverse their swimming position; hence the "upside-down" name for them. They inhabit tropical African fresh waters, where they also are known as "squeakers" because of grunting noises sometimes made by rotation of the dorsal and pectoral spines in their sockets. The variety *Synodontis nigriventris* (speckled brown) has become attractive to tropical-fish hobbyists.

The *Malapterurus electricus* (electric catfish) is the only known species of catfish to possess electrogenic powers. It is a very pugnacious fish. It had a special regard among ancient Egyptians who inscribed likenesses of the fish in their various art forms. The electric catfish is found in the Nile valley and in tropical central Africa. When mature, it can measure up to 4 feet in length and weigh up to 50 pounds (23 kilograms). It is believed that these fish can discharge up to 100 volts in one major jolt. It is interesting to note that the electrical polarity of the electric catfish differs from that of the South American electric eel. In the eel, the charge is positive on the head; negative on the tail. This situation is reversed in the electric catfish. It is not believed that the electric catfish uses the electric organs as a means of detection, as is true of some other electrogenic fishes. The *Malapterurus* survives well in captivity if not overfed.

The raising of catfish for commercial purposes is discussed in some detail in entry on **Aquaculture**. See also **Fishes**; and **Plecostomus**.

CATHETER. A tube for removing or injecting fluids through a natural body passage; made of plastic, rubber, glass, metal, or other appropriate materials.

CATHETOMETER. A form of optical comparator used for the accurate measurement of vertical distances. Some cathetometers also have been adapted for horizontal measurements. More sophisticated instruments are available which measure two coordinates in a vertical plane. Cathetometers are used whenever the object or action is not accessible by ordinary means, or when other methods of measurement introduce errors due to parallax or physical contact. Cathetometers are well suited to inspection and layout work, especially in inspection departments, model shops, and industrial research laboratories.

The vertical cathetometer essentially consists of a telescope (or for close work, a microscope) that is horizontally mounted on a guide bar whose length is parallel to the displacement to be measured. The height of the telescope and hence that of the object is read on a precision scale attached to the guide bar. For most precise measurements, a separate standard scale, supported at the same distance as the object and as close to the object as possible, is used. The height of the object then is determined by reading the scale through the telescope with the aid of a filar micrometer eyepiece.

A typical precision cathetometer, which utilizes an accurately calibrated guide bar, will have a measuring range of 100 centimeters and can be read to 0.01 millimeter. The typical precision micrometer slide cathetometer will have a measuring range of 100 millimeters and can be read to 0.001 millimeter. Typically, a coordinate cathetometer will have a measuring range of 30 inches (76 centimeters) in both the vertical and horizontal dimensions and can be read to 0.001 inch (0.025 millimeter).

CATHODE. 1. In general, the electrode at which positive current leaves a device which employs electrical conduction other than that through solids. 2. In an electron tube, the electrode through which a primary stream of electrons enters the inter-electrode space. 3. The negative terminal of an electroplating cell (i.e., the electrode from which electrons enter the cell, and thus at which positively charged ions (cations) are discharged). 4. The positive terminal of a battery. See also **Battery**.

CATHODE DARK SPACE. In a gas dis‘1charge tube, the dark band between the cathode glow and the negative glow. Also known as Crookes dark space or Hittorf dark space.

CATHODE GLOW. At sufficiently high voltage, a glow exists about the negative terminal of an arc. By operating the arc at low pressure (in partial vacuum, as in a gas discharge tube), this glow may fill much of the tube, lying between the cathode dark space and the Aston dark space. A substance placed on the cathode will produce its characteristic spectrum in the cathode glow. Also called *Glimmschicht method*. However, in many discharges both the Aston dark space and the cathode glow will be absent or indiscernible.

CATHODE RAY. A stream of electrons usually associated with their emission from a heated filament in a tube; or their emission by the cathode of a gas-discharge tube upon bombardment of the cathode by positive ions. After the discovery of the cathode ray in high-vacuum discharge tubes by Plücker in 1858, there developed, with the experiments of Goldstein, Crookes, Hertz, Lenard, and Schuster, a controversy over the nature of the rays. The British physicists thought they were negatively charged particles. A predominately German school held that the rays were a peculiar form

of electromagnetic rays. The controversy provides a classic "case history" of the typical scientific controversy in which two quite different models both explain most, but not all, of the observable facts.

The proponents of each model designed ingenious experiments and in some cases were so trapped in their preconceptions that they badly misinterpreted their observations. The Germans were especially impressed by the fact that the rays could go through thin foils — something no known particles could do. The British were firm in pointing out that the rays could be deflected by magnetic fields — fields — something not possible with electromagnetic waves. Hertz, in what he thought was a crucial experiment, was unable to detect deflection of the rays by electric fields, but this very phenomenon was demonstrated by J.J. Thomson and made the basis for his conclusive experiments that the rays had velocities less than that of light. Thomson showed, further, that if one assumed that the rays were composed of particles, then the particles had the same ratio of charge to mass regardless of the cathode material or the nature of the residual gas. Perrin's classic experiment, meanwhile, proved that the rays did indeed convey negative charge. In the decade between 1896 and 1906, Thomson and others showed that negatively charged particles from sources other than cathode rays had the same ratio of charge to mass; this included the negative particles emitted by hot filaments in the Edison effect, the beta rays emitted by some radioactive materials, and the negative particles emitted in the photoelectric effect(which had so ironically been discovered by Heinrich Hertz, in his great experiment that demonstrated the electromagnetic rays predicted by Maxwell's equations).

An emission from the cathode in a vacuum tube becomes more conspicuous as the tube is cleared of gas molecules with diminishing pressure. At pressures of 0.01 millimeter of mercury or lower, the rays leave the cathode normally to its surface and move in straight lines across the tube as demonstrated by early experiments with the Crookes tube. By using a concave cathode, they may be brought to a focus, and any obstacle placed at the focus becomes intensely hot. Thomson determined the charge-mass ratio, known now to be about 1.76×10^8 coulombs per gram. The rays move with speeds varying with the voltage, but commonly of the order of one-third the speed of light.

Lenard showed in 1898 that cathode rays will penetrate thin aluminum or gold leaf and can thus be allowed to pass outside the tube. Electrons so escaping are termed Lenard rays.

Numerous electronic devices take advantage of cathode ray phenomena, including cathode-ray tubes, used in oscilloscopes, television receivers, in connection with computer display systems, and in telecommunications systems.

CATHODE-RAY TUBE. A special form of vacuum tube (CRT) used in a large variety of electronic applications, e.g., the television receiver picture tube, oscilloscope tube, and as a display device for numerous process control and data processing instrumentation systems that are described by many terms — computer graphics, color graphics, work stations, data terminals, etc. For several years, the CRT has been the principal machine/process interface with human operators, replacing to an unusual degree former means of indicating critical and support information. The CRT has enjoyed a universality of applications rarely achieved by any device, electronic or nonelectronic. Even prior to the appearance of black/white and, later, color television, the CRT was extremely well established in that widely used research and test instrument, the oscilloscope. Without the availability of the CRT, it is unlikely that many of the revolutionary schemes associated with solid-state electronics and computing would have reached their present high state of development. The CRT is so ubiquitous in modern electronics that it is often simply taken for granted. Yet the fundamental principles of the CRT date back well over a century to the work of Pucker, Goldstein, Crookes, Hertz, Lenard, Thomson, and Perrin, as described in the preceding article.

CRTs and Competitive Technologies. Traditionally, the CRT has been burdened with a few innate limitations. Probably the most undesirable feature of the present CRT is its requirement for considerable space to the rear of the tube face (display surface). To some extent, this also contributes to a large mass. Thus, the conventional CRT poses problems of mounting and portability.

Comparatively small units, of course, have been used in oscilloscopes, but as the face of the CRT becomes larger, as desired for office, industrial, and home entertainment applications, the depth requirements increase. The desirability of a "picture frame" TV set that could be "hung on the wall," or even a display that could be "worn on the wrist," has been a research goal dating back to the 1950s. Other forms of display, including liquid crystal displays (LCDs) owe their tremendous development over the last 25 years largely to the aforementioned limitations of the CRT. LCDs and other flat panel concepts, of course, have been found to be quite adequate for displaying digital data where true motion is not a requirement. However, according to market reports in the mid-1990s, the CRT remained the predominant electronic display device. Although all display technologies are becoming better, it is only comparatively recently that a few changes in CRT technology achieved the flat-screen targets of prior CRT designers.

Fundamentals of the CRT. A fundamental function of the CRT is to convert information contained in an input signal to electron beam energy and finally to convert that energy into light energy to provide a visual information output. As will be noted from Fig. 1, a basic cathode ray tube is divided into five sections. Electrons are emitted from a thermionic cathode and controlled by the triode section. The electrons are then formed into a beam and accelerated in the focus section. The deflection section deflects the beam, typically on vertical and horizontal axes, by internal electrostatic deflection plates, or by external electromagnetic deflection coils. The acceleration or drift area controls (often with some further acceleration) the electron beams until the energy arrives at the CRT screen. The electrons upon striking light-emitting phosphor coated on the inside face of the CRT screen cause the phosphor to fluoresce and emit visible light. The phosphors used in CRTs have the characteristic of phosphorescence, i.e., emitting light energy for a short interval after the electron beam has been removed. It is this effect which permits image persistence, thus allowing a repetitive pattern to appear as a stationary display. In addition to presenting x and y information on the deflection plates, a cathode ray tube utilizes the cathode or grid of the gun to present z axis information (intensity). A representative gun is shown in Fig. 2.

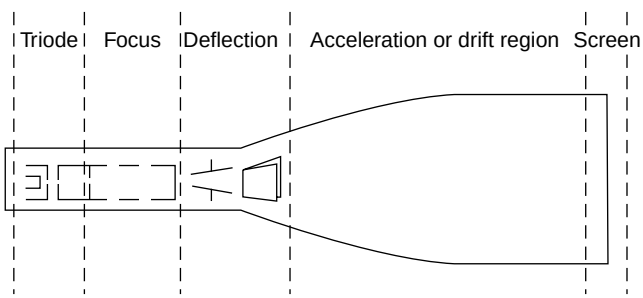

Fig. 1. Principal sections of a cathode-ray tube.

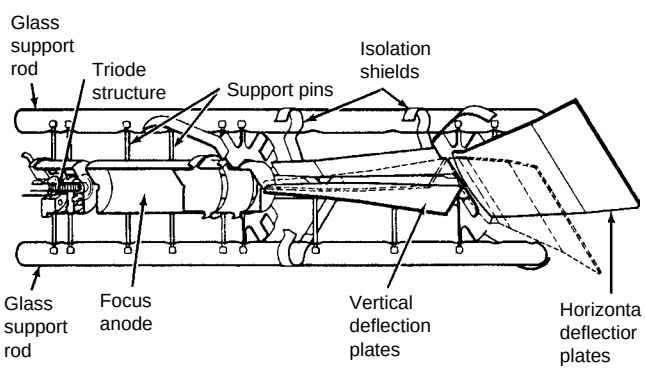

Fig. 2. Representative cathode-ray tube electron gun.

Two major subgroups of cathode-ray tubes are: (1) *monoaccelerators*, and (2) *postaccelerators*. In mono-accelerators, generally a high voltage of from 3 to 4 kV is applied to the second (focus) anode. In postaccelerators, from 10 to 14 kV will be applied to a high-voltage electrode near the CRT screen. The latter tubes typically have a higher light output inasmuch as the light output from a phosphor increases with voltage through which the electrons have been accelerated. Postacceleration also permits the

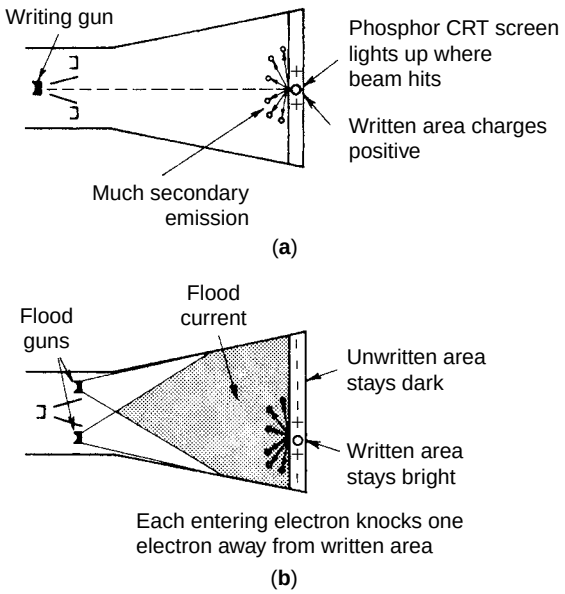

Fig. 3. Direct-view bistable storage cathode-ray tube: (**a**) action of writing gun; (**b**) action of flood gun.

deflection region to be maintained at a relatively low voltage, thus helping deflection sensitivity.

Postacceleration tubes are usually "aluminized" with a thin coating of aluminum. This acts as a mirror and reflects to the screen light energy that would otherwise be lost.

Phosphors. Originally, natural substances were used in cathode ray tubes for converting energy of the scanning electron beam into light. It was during this early period that the word "phosphor" was coined. Synthetic phosphors have been used for many years. They are usually zinc, cadmium, calcium, and magnesium compounds (as sulfides, selenides, silicates, and tungstates). The materials must withstand "bakeout" temperatures of 400 °C or greater. They must have a low vapor pressure and an ability to hold up over long periods of time against the bombardment of electrons. Variation in the quality of specific phosphors is obtained through the use of accelerators, notably copper, silver, magnesium, chromium, and bismuth, among others. The activators enable a selection of efficiency, color of luminescence, and decay time.

There are many commercial phosphors from which to select the best suited for a given need. Many of these compounds are made up of Periodic Group Elements 2 (formerly IIA), 12 (IIB), and 16 (VIA and VIB). Zinc sulfide activated by magnesium produces a blue emission, whereas zinc and/or cadmium sulfide activated by copper or aluminum produces a green emission. Zinc sulfides activated by silver or copper can convert up to 20% of electron beam energy to light. These compounds are important in color

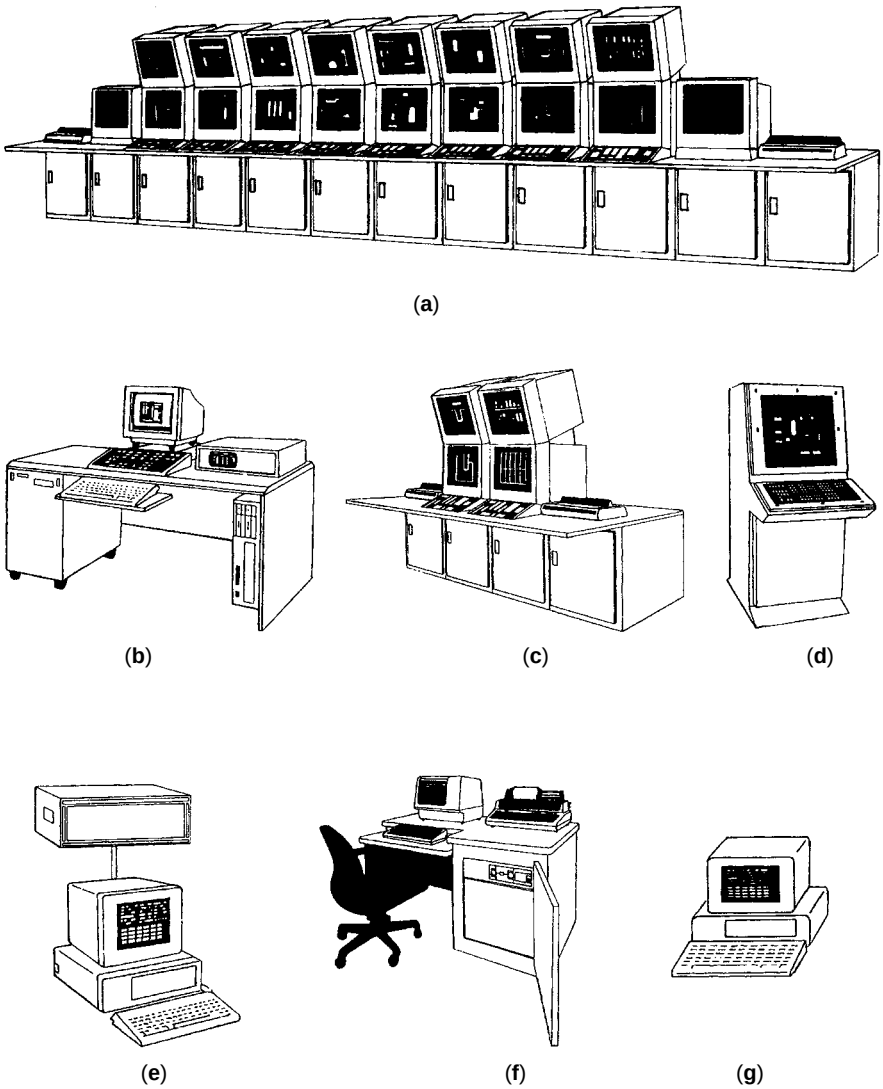

Fig. 4. Examples of how the flexibility of CRT-based panels contributes to various interface configurations and distributed display architecture. (**a**) Central configurable CRT station with distributed historian, (**b**) engineer's workstation, (**c**) area CRT station, (**d**) field-hardened console, (**e**) independent computer interface (serial-interface-personal computer), (**f**) batch management station, and (**g**) general-general-purpose computer. (*D.M. Considine, P.E., Systems Integrator*.)

television tubes. Where particularly long periods of electron bombardment are involved, the compound $ZnSiO_4$ activated by manganese is well suited and thus finds wide application in oscilloscopes and aircraft instruments, which require bright displays. A green luminescence is produced.

In recent years, some of the rare-earth elements, such as terbium and europium, have found use in color tubes. These compounds emit a red color that is comparably efficient with the well-established green and blue emitting compounds. Other rare-earth element compounds include La_2O_2S activated by terbium (green emission) and Y_2O_2S, also activated by terbium (white emission). An outstanding advantage of rare-earth phosphors is their ability not to become saturated at high power levels. Confinement of their emission to rather narrow bands is also advantageous in providing images with high contrast even in the presence of high ambient light levels.

The desired persistence time of phosphors varies with application. Whereas a time of 30–40 milliseconds is satisfactory for television, a longer time (up to a second or even longer) is desirable for radar displays. Zinc-cadmium sulfide activated by copper persists for a number of seconds with a yellowish-orange color. For extremely short persistence, as required in flying-spot scanners, a material such as calcium-magnesium silicate, with persistence in terms of a fraction of a microsecond, is desirable. This compound emits in the violet and ultraviolet range.

Phosphor particles range in diameter from 1 to 10 micrometers. Image resolution varies inversely with the diameter of the particle, but efficiency decreases when particles are too small.

Storage Cathode-Ray Tubes. Tubes of this type have two electron sources. There is a writing gun to provide the electrons for writing and a flood gun to provide broad coverage of low velocity of electrons that bombard the storage screen uniformly. This flood of electrons holds the writing gun information in the written mode by means of secondary emission electrons and thus maintains the stored image for an indefinite period after the writing beam has been cut off. Tubes of this type are used for displaying signals that occur only once (transients), or signals that have low repetition rates. Much of the need for formerly photographing transients on oscilloscope screens no longer is required with the availability of storage-type oscilloscopes. High-resolution storage is also useful for presenting graphic and alphanumeric displays in computer readout applications. This eliminates the bulk of local storage that may be required for continually refreshing displays and to provide a flicker-free display.

Storage-type cathode-ray tubes are classified as bistable or as halftone tubes. On a bistable tube, the stored display has one level of intensity. In a halftone tube, a stored signal may be displayed at different levels of intensity. The intensity of a halftone tube depends upon beam current and the time that the beam remains on a particular phosphor particle. A bistable tube either stores or does not store, with all stored events having the same intensity.

A direct-view bistable storage CRT is shown in Fig. 3. Action of the writing gun shown in (a); of the flood gun in (b). The writing gun bombards the screen. High-energy electrons light the phosphor and also knock loose many secondary electrons. The written area, losing electrons, charges positive. Electrons from the flood-gun hit unwritten areas too slowly to activate or light the phosphor. They simply accumulate, driving the area negative. But, the written area (positively charged) attracts electrons at high speed, keeping the phosphor lit, as well as knocking sufficient secondaries away to hold the area positive.

Character-generation tubes pass the electron beam through an aperture of an appropriate shape. Basic methods used to generate character information include: (1) *raster scan technique*, which involves controlling the intensity of the electron beam during sweep. The process is similar to facsimile recording where the characters are generated in segments; (2) *Lissajous technique*, in which the electron beam serves as a pencil; (3) *shaped-beam technique*, in which the tube incorporates a number of stencil-type openings that are used to shape the electron beam. Raster scan is discussed in greater detail in articles on **Computer Graphics**; and **Television**.

Although not display tubes in themselves, scan conversion tubes are an important link in some display systems. For example, a scan conversion tube will convert radar blips display to a television signal for viewing on a TV screen. The scan conversion tube enables information to be put in at one rate and taken out at another rate, thus providing some storage. The technique is particularly useful for retaining aircraft locations in an air traffic control instrument so that the path of an aircraft can appear as a dotted line.

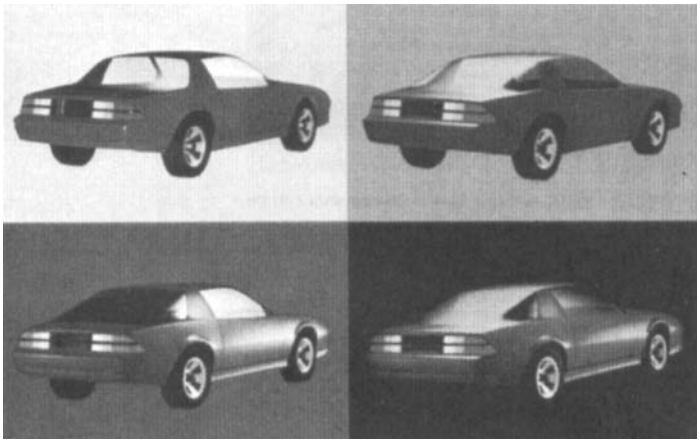

Fig. 5. With system developed by GM Research Laboratories, users can synthesize three-dimensional, shaded images of design concepts on a color display and then quickly explore how major or minor changes affect the overall aesthetic impression. The system is completely interactive. By choosing from a menu on the screen, the designer can redefine display parameters, select a viewing orientation, or mix a color. Each part of an object can be assigned a surface type with associated color and reflectance properties. Built-in lighting controls generate realistic "highlights" on simulated surfaces composed of differing materials. Prior to this system, a computer scientist observed the complex lighting effects achieved in the studio of a professional photographer. By simulating these effects, the *Autocolor* system can produce results unattainable by conventional synthetic image display systems. Prior systems used a point source model of light, which allowed adjustments only in position and brightness. This illustration shows four *Autocolor* images, simulating the view of an automobile as background and lighting change. (*General Motors Research Laboratories*.)

Wide Range of CRT Applications. Familiar settings for the CRT include home television and computer stations found in business offices. Industrial data receiving and controlling centers, as found in industrial production (chemicals, petroleum, electric power, automotive and aircraft manufacturing, et al.), depend upon the reliability of the CRT and its entire electronic backup system. See Fig. 4. CRTs are an integral part of most computer-aided drafting (CAD), computer-assisted engineering (CAE), and computer-integrated manufacturing (CIM) systems. See Figures 5 and 6.

During the 1990s, much success was achieved, not only in entertainment and educational television, but also in industrial communications and control networks, in split-display screens, in which different types of data or "scenes" can be effected. In a large, complex network, one or two sections of the screen can be set aside for special communication of information between two or more processes or machine operators. See Fig. 7.

A liquid crystal display (LCD) is described in the article on **Television**. A plasma planel is shown in Fig. 8.

CRT Terminology. Some frequently used terms in connection with CRT technology include:

Angle of Deflection — The angle through which the beam is deflected.

Angle of Divergence — The maximum angle of deflection experienced by electrons in an electron beam due to debunching.

Black Level — In television, that level of the picture signal corresponding to the maximum limit of black peaks.

Blanking — In television, the substitution for the picture signal, during prescribed intervals, of a signal whose instantaneous amplitude is such as to make the return trace invisible. The term is also applied in connection with laboratory cathode-ray oscilloscopes.

Blooming — The mushrooming of an electron beam (with consequent defocusing) produced by too high a setting of the brightness control.

Brightness Control — The manual bias control of a cathode-ray tube. The brightness controls affects both the average brightness and the contrast of the picture.

Cathode Disintegration — The destruction of the active area of a cathode by positive-ion bombardment.

Cathodoluminescence — The excitation of luminescence in a solid through the action of an electron beam impinging on the luminescent

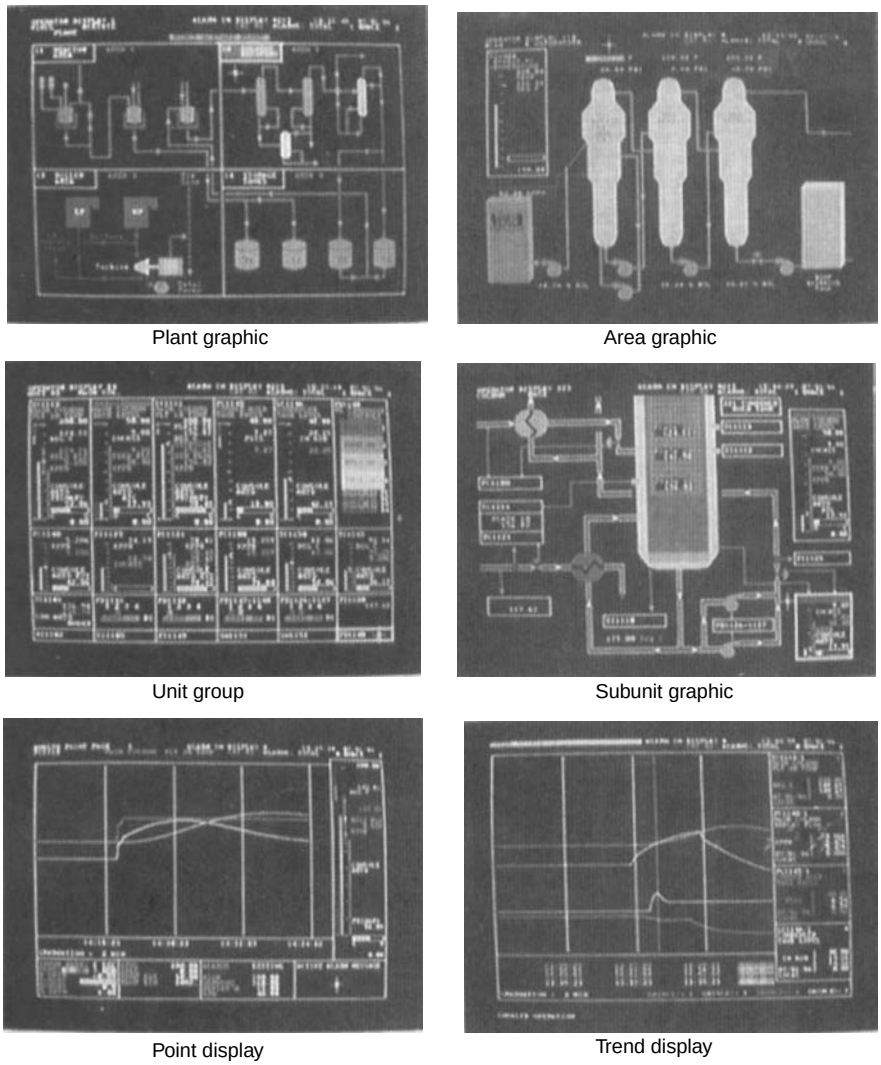

Fig. 6. The CRT screen can be used in total for a given "scene," or more commonly, the screen area can be divided into "windows" or screen segments. These arrangements are accomplished via the software program. By way of menu-driven techniques, the entire operation can be brought into view (plant graphic), followed by close-ups of areas, units, subunits, as well as provide point and trend displays. Interactive graphic principles can be planned into the program when desired. (*D.M. Considine, P.E., Systems Integrator*.)

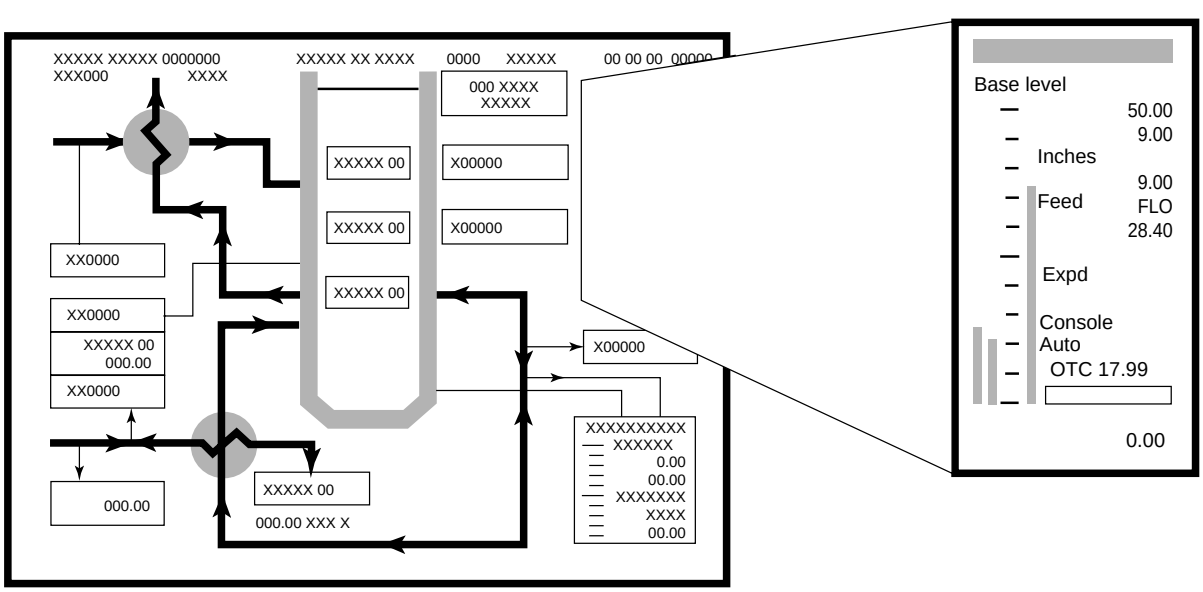

Fig. 7. By means of software, a portion of a CRT display (window or segment) can be singled out for detailed viewing. In this scheme, one or more segments can be designated as "dedicated" for use on a network, making it possible for several stations along the network to obtain instant information that may be of interest to several operators in a manufacturing or processing network.

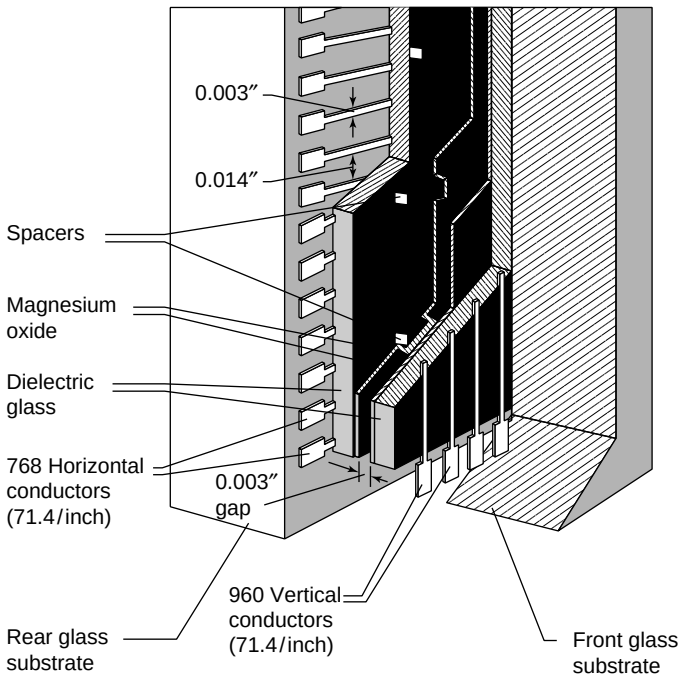

Fig. 8. Cross section of plasma panel showing narrow conductor lines on opposing glass substrates. Unique points on the panel can be ionized by applying low voltages to the appropriate horizontal and vertical conductors. This technology (invented at the University of Illinois) uses alternating current plasma. The panel is a sealed sandwich of two glass plates, the rear plate is embedded with 768 parallel horizontal conductors and the front plate with 960 vertical conductors, thus forming a large grid. The narrow space separating the two plates is filled with inert neon-argon gas, which glows as electrical voltages are selectively applied to any of the over 700,000 intersections on the grid. This locally ionized gas (plasma) produces tiny dots of orange light. When combined in matrix patterns, these precisely located dots form images. Because the plasma technology operates in memory mode, the images do not have to be refreshed, eliminating any susceptibility to flicker.

Special manufacturing techniques are required to place 2400 feet (732 meters) of very narrow conductors on each panel. The panel, a composite of glass, metal, and thin-film oxide layers, is made by sequential thermal process steps, with each step conducted at a temperature suitably lower than the prior process step. To reduce material interactions, lower-temperature dielectric glass and seal material had to be developed. To maintain a uniform chamber gap between the sandwiched glass plates, a new metallic space technology was required. The spacers, about the thickness of a human hair and 1/4-inch (6+ millimeters) long, are automatically bonded by a tool that uses a laser to keep placement tolerances within several ten-thousandths of an inch ($0.002 \pm$ mm). The metallic spacers are nearly invisible in an operating display and do not interfere with the ionization process. (*IBM Corporation*.)

material or phosphor. This is the type of luminescence present in television picture tubes, in radar cathode-ray tubes, and in oscilloscopes.

Cathodophosphorescence — Phosphorescence resulting from cathode-ray bombardment.

Damping Tube — A tube used with magnetic deflecting-coils to prevent any transient oscillations from being set up in the tube or its associated circuits.

Dark Trace Tube — A cathode-ray tube, on which the face is bright, and signals are displayed as dark traces or dark blips.

Deflection Sensitivity — 1. Of an electrostatic-deflection cathode-ray tube, the quotient of the spot displacement by the change in deflecting potential. 2. Of a magnetic-deflection cathode-ray tube, the quotient of the spot displacement by the change is deflecting magnetic field. 3. Of a magnetic-deflection cathode-ray tube and yoke assembly, the quotient of the spot displacement by the change in deflecting-coil current. Deflection sensitivity is usually expressed in millimeters per volt applied between the deflecting electrodes, or in millimeters per gauss of the deflecting magnetic field.

Electron Image Tube — A cathode-ray tube used to increase the brightness or size of an image or to produce a visible image from invisible radiation, such as infrared. A large, light-sensitive cold cathode serves as the focal plane for the optical image. The resulting emission from the cathode is accelerated through an appropriate lens system before striking a fluorescent screen, where it produces an enlarged and brightened reproduction of the original image. This device has been used in electron microscopes and telescopes, infrared microscopes and telescopes, and fluoroscope intensifiers.

Grass — The pattern on the cathode-ray tube display of a radar or similar system, which is produced by the random noise output of the receiver.

Holding Beam — A diffuse beam of electrons for regenerating the charges retained on the dielectric surface of an electrostatic memory or storage tube.

Horizontal Blanking — The interruption of the electron beam of a cathode-ray tube during horizontal retrace.

Horizontal Centering Control — A control that enables the operator to move a cathode-ray image in a right or left direction across the screen.

Horizontal Deflecting Electrodes — The pair of electrodes located in the vertical plane in an electrostatic-deflection cathode-ray tube which is used to produce beam deflection in the horizontal plane.

Horizontal Line Frequency — In television, the number of horizontal lines per second: 15,750 for standard black-and-white television in the United States.

Horizontal Hold Control — The control that varies the free-running period of the horizontal-deflection oscillator in a television receiver.

Horizontal Resolution — In television, the number of light variations or picture elements along a line which can be distinguished from each other.

Horizontal Retrace — In cathode-ray equipment with linear, horizontal time-bass, the rapid right-to-left motion of the electron beam at the end of each sweep.

Horizontal Sweep — Sweep of an electron beam in the horizontal plane.

Ion Burn — A deactivation of a small spot of the phosphor of a cathode-ray tube, caused by bombardment by heavy negative ions in the beam. The effect is noticeable only in magnetic-deflection systems, since an electrostatic deflection system deflects the negative ion through the same deflection angle as the electrons. Magnetic-Magnetic-deflection tubes require an ion trap to prevent permanent damage.

Radarscope — The CRT indicator of a radar apparatus on which echoes from targets detected by the radar by visually displayed. The A scope is a type of radar indicator that presents the signal strength of a target signal and range of a target in rectangular coordinates. The R scope gives information similar to that of the A scope on an expanded horizontal scale. It takes a limited portion of the A scope presentation at any range and expands the horizontal coordinate so that a more detailed study that of portion may be made. It is distinguished from the A scope in that the zero range of the A scope is always presented.

Retrace Line — The line traced by the electron beam in a cathode-ray tube in going from the end of one line or field to the start of the next line or field.

Scanning — "Flying Spot" — The subject is illuminated by a "flying spot" light source of constant intensity, developed on the face of a cathode-ray tube with a short-persistence phosphor. The spot of light is made to follow the conventional raster pattern so that a phototube receiving transmitted or reflected light from the subject will have a signal output proportional to subject brightness and subject position as required.

CATHODIC PROTECTION. See **Corrosion**.

CATION. A positively charged ion. Cations are those ions that are deposited, or which tend to be deposited, on the cathode. They travel in the nominal direction of the current. In electrochemical reactions they are designated by a dot or a plus sign placed above and behind the atomic or radical symbol as $H\cdot$ or H^+, the number of dots or plus signs indicating the valence of the ion.

In electrolysis, the cathode is negative, and attracts cations. In a battery, the transfer of charges of cations to the cathode makes it the positive terminal.

CATKIN. An inflorescence, also called ament, composed of many flowers, aggregated into long, often tassel-like masses. The perianth is completely lacking, or may be present in a scale-like form. The flowers of willows (pussy willows), poplars, alders, beeches, oaks, and birches are familiar examples. Most of them are wind-pollinated flowers. See also **Flower**.

CAT SCANNER. See **Central and Peripheral Nervous System and the Brain; X-Ray CAT Scan and Other Medical Imagery**.

CATSCRATCH DISEASE. A self-limited localized lymphadenitis commonly preceded by a cat scratch or bite. No cause for the infection is known. Usually indolent, the lyphadenitis may come to suppuration. Most cases involve children who present with a visible, distal skin lesion, usually a pustule or an inflamed crusted residual lesion of a cat scratch.

Regional lymphadenopathy appears 1 to 3 weeks after the inoculation, the nodes involved usually being axillary, epitrochlear, or inguinal and are usually mobile. Mild constitutional symptoms may be present for a few days at the time of lymph node enlargement. The lymphadenopathy persists for up to eight months and then regresses spontaneously. In a few cases, gross suppuration is seen, which leads to spontaneous drainage and healing with minimal scarring.

An unusual complication is oculoglandular involvement (Parinaud's syndrome) where the inoculation site is seen as a single granulomatous lesion of the conjunctiva which is accompanied by pre-auricular lymphadenopathy.

Encephalitis, the most serious of the uncommon complications, develops three to six weeks after the onset of lymphadenopathy and usually resolves without sequelae.

No specific treatment is available, although aspiration or surgical removal of the lymph gland may be necessary.

However, in 1991 researchers at the Centers for Disease Control (U.S.) characterized the bacterium which causes the fever, *Afipia felis*. Because the organism is difficult to culture in the laboratory, progress is being made in testing it to find an antibiotic that will be effective against it.

Also of interest to cat fanciers is that progress is slowly being made toward better understanding the allergens that are created by cats and that produce sensitivity responses in some humans. A major cause has been found to be a protein that forms a coating over the animal's skin. Pharmacological research is continuing in an effort to explain allergen's biological function and thence to find an agent that will control the immune response process. Approximately 6000 people in the United States suffer in varying degrees from catscratch infections, and many additional thousands suffer an allergic reaction when in the presence of cats.

R. C. V.

CAT'S-EYE. This name is applied to varieties of several mineral and gemstone species that enclose fine fibers or cellular structures in parallel arrangement, causing, particularly when cut and polished *en cabochon*, a band of reflected light to play on the surface of it. Because of fancied resemblance to the eyes of cats, such stones are called cat's-eyes, and the effect is referred to as chatoyancy. The stone is said to be chatoyant. True cat's-eye is a variety of chrysoberyl, but tourmaline and quartz are also found which show this same effect. Ordinary quartz cat's-eyes are a pale yellowish or greenish, but a beautiful golden-yellow sort, known from South Africa and called tiger's-eye, probably represents a replacement of crocidolite by quartz.

When the term *tiger's eye* is used, this applies only to chrysoberyl. Other gemstones that exhibit this phenomenon include sillimanite, scapolite, cordierite, orthoclase, albite, and beryl. See also **Chrysoberyl**; and **Crocidolite (Blue Asbestos)**.

CATS *(Mammalia, Carnivora).* Over fifty species of cats (*Felines*) have been described. They are all assigned to the single family (*Felidae*). The general organization of the cats is shown in Table 1. The position of the cats with reference to other families in the order *Carnivora* is given in the entry on **Carnivora**. Cats, of course, are flesh-eating mammals; they have simple dentition; the claws are sharp, curved, and retractable. In most species, the claws can be withdrawn completely into sheaths. Considering the domestic cats as well as the lesser cats and lynxes, it can be stated that cats occur essentially worldwide with the exception of Australia and the oceanic islands.

TABLE 1. GENERAL ORGANIZATION OF THE CATS FELINES

Great Cats (*Panthera*)
Lions (*Panthera leo*)
Tigers (*Panthera tigris*)
Leopards (*Panthera pardus*)
Snow Leopard (*Panthera uncia*)
Jaguar (*Panthera onca*)
Lesser Cats (*Felis*)
Ocelots (*Felis pardalis*. . . .)
Leopard-Cats (*Felis bengalensis*. . . .)
Tabby-Cats (*Felis lybica*. . . .)
Desert Cats (*Felis manul*. . . .)
Plain Cats (*Felis planiceps* and *badius*)
Marbled Cats (*Felis marmorata*)
Other Cats (*Profelis*)
Pumas (*Profelis concolor*)
Clouded Leopard (*Profelis nebulosa*)
Golden Cats (*Profelis temmincki* and *aurata*)
Lynxes (*Lynx*)
Jungle-Cats (*Lynx chaus*)
Caracals (*Lynx caracal*)
Northern Lynxes (*Lynx lynx*. . . .)
Bobcats (*Lynx rufa*. . . .)
Servals (*Leptailurus*)
Jaguarondis (*Herpailurus*)
Cheetahs (*Acinonyx*)

Included among the Great Cats (*Panthera*) are the lion, tiger, leopard, snow leopard, and jaguar. The lion is certainly one of the best-known species of large cats and sometimes is referred to as the "King of the Beasts." See Fig. 1. This reference, however, is highly debatable and possibly the term may have stemmed from their most impressive appearance. They are exceeded in size by the north Manchurian tigers, particularly when sans manes. It has been said that children terrify lions, and that lions are easily disturbed by comparatively innocuous events

Fig. 1. Lioness and cubs. (*A.M. Winchester*.)

and situations. One authority has mentioned the flapping of laundry on a clothesline as frightening to these animals. Although a female lion (females usually do the killing) may claim an antelope or two per month, lions have been known to lie down peacefully among antelopes during the day. While highly publicized, the man-hunting, man-killing escapades of lions would seem to occur most infrequently, probably precipitated by a maddening disease or extreme hunger. Unmated juveniles are often identified in such rare escapades. It is recorded that the lion will not approach within 20 feet (6 meters) of the very small zorille (similar to the American skunk) even though the animal may be casually inspecting fresh kill in which the lion(s) is deeply interested. Of course, this observation may be a credit to the lion's judgment rather than a criticism of lack of courage.

The lion reaches a length of some 10 feet (3 meters) from tip to tip and a weight of about 500 pounds (227 kilograms). The animal is uniformly tawny (brownish-yellow) in color, but the shades range from light yellows to dark brown. The male usually has a full mane, but this also is a variable characteristic. Some males with no mane have been found. The lion is nocturnal in habit and is generally regarded as shy, unless provoked. Possibly to a degree more noticeable than in many other mammals, a lion shows age, its physical condition showing up in contour, posture, and condition of mane (in the male). The older lion usually subsists on small rodents, scorpions, and fairly small creatures, a limited diet that may contribute to the aging process. Lions hunt in groups, sharing the animals that they kill, and sometimes eat the carcasses of animals that they have not killed, even when badly decomposed.

The lion thrives and reproduces well in captivity and there is rarely a short supply. Lion populations in Africa are high and frequently are regarded as a serious menace to domestic stock. Unlike some popular portrayals of lion habitats, the lion does not inhabit forests or jungles, but prefers grassy plains, savannas, scrub land, and even semi-desert areas. At one time, lions were found in Eastern Europe, the Near East, and the northern portions of Africa, and across to India. The population in India today is quite limited, but lions are found widely in the habitats they prefer in Africa south of the desert belt.

As do all of the Great Cats, the lion has some small bones called hyoids located at the base of the tongue, which gives the animal the ability to make roaring sounds, as contrasted with the lesser sounds of the lesser cats. It is interesting to note that lions and tigers can interbreed, producing *Ligers* (lion is male parent) or *Tigons* (tiger is male parent).

The tiger rivals the lion in size and strength. The fur normally varies from reddish to brownish yellow, with transverse black stripes and a black-ringed tail. See Fig. 2. The total length of adult males, including the tail, is from 9 to 10 feet (2.7 to 3 meters). The tiger is an Asiatic animal, found chiefly in the warm southern countries, but also northward into Turkestan and southern Siberia. It is by no means a tropical species. In fact, the tiger originated as an Arctic animal, coming from eastern Siberia. The largest tigers are found in the colder areas of Siberia in an area between the Altai and Stanovoi Mountains. Inasmuch as the tiger is from colder climes, it is not unusual for tigers to bathe as a means of keeping cool in the warmer regions. A litter of tigers usually contains five babies, but often only two are permitted to live, the parents sometimes eating the others. The young

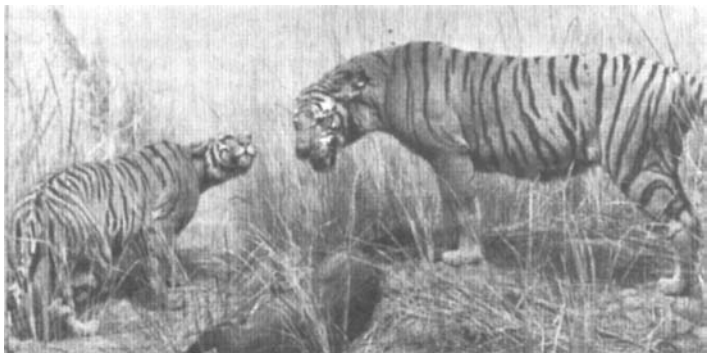

Fig. 2. Tigers. (*A.M. Winchester*.)

travel with the mother for at least a year. Occasionally tigers have become man-eaters, but generally they are considered timid and make great efforts to stay out of the realms of humans. The tigers in India prefer the great nilghai as a favorite dietary item, but when necessary can subsist on smaller creatures, including mice, locusts, and fish. The ability of the tiger to climb trees has been overstated. They are not considered good climbers except in emergency situations for escape. Tigers are known for rather poor vision and sense of smell, but do possess excellent hearing capabilities. Thus, the prey they are seeking are generally safe if they remain motionless and quiet. In killing, the tiger leaps on and hugs the victim, biting at the throat. Tigers are known to consume 200 pounds (91 kilograms) of flesh within a short period, followed by huge quantities of water. Among their natural enemies are packs of feral dogs, water buffaloes, elephants, and wild holes.

The leopard is found throughout most of Africa with exception of the big desert areas. They are considered far too numerous in some of the cultivated and industrialized areas of Africa. As shown in Fig. 3, the leopard is marked with black rings and spots, although a black variety occurs in which the spots are faintly traceable. The basic coloration of most leopards is tawny. Although numerous albino tigers have been reported, there are no records of albino leopards. As compared with the lions and tigers, the leopard is faster and less fearless in most situations, and tends to be much less discriminate. The animal tends to attack monkeys, baboons, even humans when opportune rather than seeking certain types of dietary favorites. Leopards will often eat only the choicest parts of a meal at first, dragging the remains to a thicket or even hiding it in the branches of a tree for later consumption, a practice known as hoarding. Closely related to the common leopard is the snow leopard, which lives at high altitudes in central Asia. This leopard is also spotted, but the basic color is a grayish-white. The skull is characteristically shaped. Another relative is the clouded leopard, which is found in southeastern Asia. Its legs are shorter than the other species, is basically gray or grayish-yellow in coloration, with what might be termed blotches of dark brown. This animal has not been fully studied, but it is believed to subsist mainly on birds and makes it home in trees. More detailed coverage on the status of the leopard can be found in a news item in *Science*, **208**, 18 April 1980.

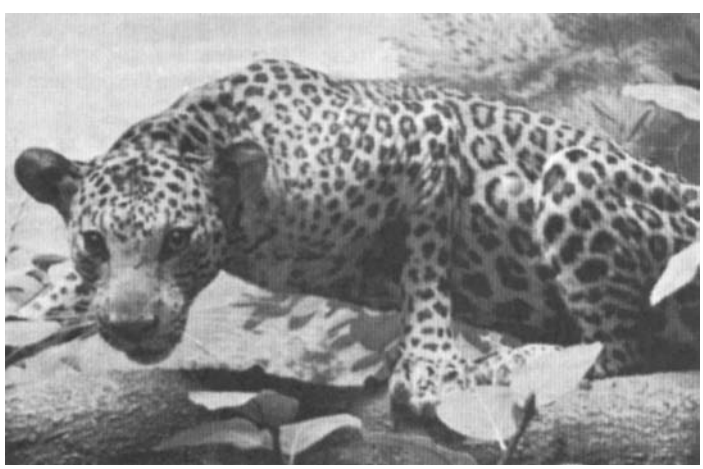

Fig. 3. Leopard. (*A.M. Winchester*.)

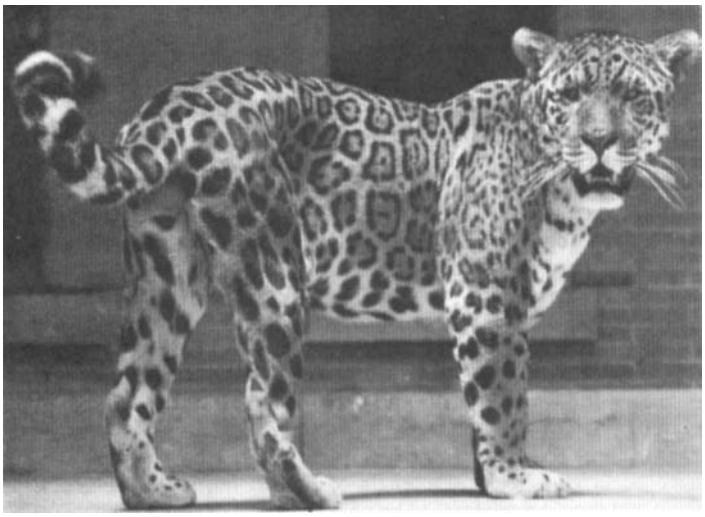

Fig. 4. Adult jaguar. (*New York Zoological Society photo.*)

Sometimes disputes have arisen concerning the terms *leopard* and *panther*. The terms can be used interchangeably.

The last of the Great Cats to be described here is the jaguar, a large South American cat, found chiefly in the jungles, but also in open country. As shown by Fig. 4, this cat is tan, marked with rings and dots of black, resembling the leopard. The jaguar is larger than the leopard and differs in details of structure and markings. The animal has a deep and hoarse cry, usually used at mating time. It feeds on wild horses, tapirs, capybara, dogs, and cattle. The animal reaches a length of about 4 feet (1.2 meters) and a height of from $2\frac{1}{2}$ to 3 feet (0.8 to 1 meter). It is heavily built, a rapid runner, graceful, and agile. It should be pointed out that there is some controversy pertaining to the aforementioned measurements, some authorities attributing sizes approaching those of tigers to this animal. The jaguar prefers the forest and is an excellent tree climber, the best of the Great Cats. It ranges from the southwestern United States southward to Argentina. The animal tends to vary its behavior with its habitat, becoming almost as water-loving as the tiger in the Amazonian region. Two to four cubs are produced annually. The cubs closely follow their mother for about 35 days.

The ocelot is a moderately large cat of South America, but also occurring in Central America and the southern part of the North American continent. The animal is tawny or reddish, marked with black spots and blotches. Reports of the animal as far north as southwestern Arkansas, Texas, and Arizona have been recorded. The adult is from 40 to 50 inches (102 to 127 centimeters) in length, not including the tail of some 13 to 15 additional inches (33 to 38 centimeters). There are two black bars on the cheeks, black spots on the head, and from four to five parallel stripes on the neck. The underpart of the animal is white. The ocelot prefers forest or brushy regions and feeds on small animals and reptiles. There usually are two young per season. Some varieties of ocelot can be tamed, but they are not necessarily fully reliable in captivity. The pelts are considered of economic value.

Leopard-cats are small spotted cats of many varieties. They are found well distributed throughout the tropical regions. These animals seldom exceed 2 feet in length (0.6 meter), rarely 3 feet (1 meter). Closely associated with this loosely-knit group of leopard-cats are the tabby cats, typified by the common wild cats of Africa (*Felis lybica* and *ocreata*). *Felis lybica* is essentially unchanged in the Abyssinian domestic cat breed. This animal is believed to be the ancestor of European house cats. The ancient Egyptians and early Greeks and Romans domesticated the animal and had a high regard for it. The animal was called the "Mu" (a familiar sounding word in terms of cats) and was trained to retrieve fallen waterfowl, and to control the mice population. It is of interest to note that a popular concept to the effect that cats do not like water is untrue. However, it is true that cats do not like cold water. The true wild cat, pretty, shy, but savage when provoked, yellowish with tabby markings, blue eyes, and pink nose, still exists in the wild in isolated parts of Europe, but it is not found in Italy or the Scandinavian countries. Tabby-marked wild cats (tabby = gray or brown with dark stripes) are found in the Altai Mountains (Siberia) and over a large part of Africa. Some authorities believe that the present domestic cats of the Oriental region may have been bred from imported wild cats from Africa or Europe, or possibly have stemmed from the so-called waved cat (*F. torquata*), commonly found throughout northern India. Authorities are yet to agree upon the cause for a breed of cat from the Isle of Man and another from Korea to have lost their tails. The grass-cat (*F. pajeros*) is a tabby-like cat found in southern Argentina.

The marbled cats found in the forests of Tibet and into Southeast Asia appear much like the previously mentioned clouded leopard, but they are much smaller. Authorities have yet to establish if these cats are miniaturized leopards or simply small cats that look like the clouded leopard.

The various lynxes bear no ready anatomical distinctions that make them differ from the previously described Lesser Cats. The lynx is essentially limited to the Northern Hemisphere and is characterized by conspicuous ear tufts and a fringe of long fur about the throat. Among the several North American species, most are called wildcats or bobcats. The Canada lynx (*Lynx canadensis*) alone is known as the lynx. Several species of lynx also occur in Europe, Africa, and Asia. The margay is a wild cat of moderate size, reddish marked with black spots; it occurs from Mexico to Paraguay. The manul is a wildcat found in Siberia, Mongolia, and Tibet. It is about the size of the domestic cat and varies from buff to silver-gray in color. It is also called Pallas' cat.

The serval is an equatorial African cat that can attain a length of 5 feet (1.5 meters). It is light tawny and spotted with black. It eats birds, lizards, and insects.

The cheetah is a large cat found in Africa and India and is marked by its slender build. It is tawny with black spots, thus somewhat resembling the leopards. The cheetah sometimes is referred to as the hunting leopard and has been tamed for use in the chase. The animal attains a length of from 3 to 4 feet (1 to 1.2 meters), with another $2\frac{1}{2}$ feet (0.8 meter) for the tail. The fur is coarse and crisp, with white underneath. The animal was domesticated hundreds of years ago in Asia for coursing game. The cheetah prefers to feed on young animals, but sometimes will tackle an adult animal to the size of a small antelope. The cheetah is swift, its legs are long and muscular, and its back is curved. Cheetahs have been recorded at speeds of over 60 miles (96.5 kilometers) per hour. The animal possesses a springiness in its running and the strides are long. Although very fast, the cheetah is best for short sprints, and can be overtaken by slower animals, such as a horse, over long distances.

Cheetahs today are outnumbered by their enemies; they are largely defenseless, and, where unprotected, they are likely headed for extinction. Cheetahs have been exterminated from large portions of their former range in Africa and the Middle East. Once plentiful in India, cheetahs have totally disappeared there, the victims of hunters and loss of habitat. Further detailed coverage of this topic can be found in an article by Frame, G. and L. Frame: "Cheetahs: In a Race for Survival," *National Geographic*, **157**, 5, 712–728 (May 1980).

Cheetahs have been used for killing coyotes in the southwestern United States, but not extensively because a pair of highly trained cheetahs is quite costly.

Pumas are of several types. The puma proper (*P. concolor*) originally inhabited the eastern half of the North American continent, ranging from Virginia into Canada. The animal is now considered extinct in the settled parts of the country, but possibly may still exist in wilder areas. This animal is of uniform tawny to brownish color. A darker species (*P. coryi*) is found in Florida; the *P. arundivaga* is found in Louisiana; and the western puma or mountain lion (*P. oregonensis*) ranges from Mexico into Canada. The eastern species has been variously called the cougar, mountain lion, panther, catamount, and painter. The puma is generally considered a menace to stock and sheep. However, it is shy in terms of the human realm.

Cougars are considered to have originated in Peru, the term being a native Brazilian name. The South American variety measures from 6 to 8 feet (1.8 to 2.4 meters) in length from tip of nose to tip of tail. The color is red-tawny, pale around the eyes, with a white throat and legs and white underneath. The animal is considered exceptionally intelligent. The cry of the cougar when it is hunting at night is described as terrifying. Cougars are considered excellent tree climbers.

CATTAIL. Of the family *Typhaceae*, genus *Typha*, there are several species of plants that grow in marshy places and along the margins of ponds and slow-flowing streams. Usually, they form extensive stands, crowding out nearly all other plants. The cattail plant has a thick horizontal rhizome, which grows along the surface of the ground or just beneath it, generally in several inches of water. From this rhizome, the long linear leaves grow in erect bunches. The leaves of the *Typha latifolia* have widely overlapping bases and are from 3 to 6 feet (0.9 to 1.8 meters) long. The flower stem rises stiffly erect in the center of the bunch of leaves and is from 3 to 8 feet (0.9 to 2.4 meters) tall. Near its tip, the cattail bears two dense cylindrical spikes of flowers, one above the other, which are unisexual. The pistillate flowers are found below the staminate flowers. Each staminate flower consists of from 2 to 5 or more stamens surrounded by a number of hairs. Soon after the pollen grains are shed, the staminate flowers drop off, leaving the naked tip of the stem projecting above the pistillate spike. Each pistillate flower consists of a single pistil surrounded by a group of long hairs. Cattails are entirely wind-pollinated. After pollination, the ovaries develop to 1-seeded achenes surrounded by the fine hairs. These fruits form the familiar black or dark brown cattail of late summer and fall. The seeds are blown about by the wind, the long hairs greatly aiding in distribution.

The dried leaves of cattails were formerly used in making the seats of rush-bottomed chairs. The hair-covered seeds have been used to a slight extent for stuffing for pillows and small things. The entire fruiting stem is often used as an ornament.

The cattails are related to the rushes and sedges.

CATTLE (Beef and Dairy). The phylogeny and taxonomy of beef and dairy cattle are discussed in entry on **Bovines**. The development of modern beef breeds began in the 1600s in Europe and, in particular, the British Isles. Farmers in an area selected cattle of a kind they considered best for the locality. They continued to grow them consistently over a period of years, and these selections often resulted in the formation of a breed. Some breeds resulted from crosses of existing breeds; others from crosses of cattle that had not attained breed status. The most desirable animals tended to be gathered into a few herds that were bred by introducing little or no other stock. As they gained popularity, numbers increased and eventually a breed society was formed. In this way, highly useful and efficient kinds of animals were developed that survived as breeds. A breed may be defined as a group of animals having a common origin and possessing certain well-fixed and distinctive characteristics not common to other members of the same species; these characteristics are uniformly transmitted.

Some beef breeds are horned and some polled (hornless). Mutations have occurred in certain animals of several horned breeds, causing them and their descendants to be polled. In some cases, breeders developed these polled strains and established separate breeds.

Mating Systems Used in Breeding. There are three general mating systems used to produce crossbred market cattle: (1) mating females of one breed to males of another breed, to produce F_1 market animals; (2) terminal crossbreeding, whereby F_1 females (as produced according to the first step) are mated to bulls of a third breed, to produce a three-breed terminal cross, or to bulls of one of the parent breeds, to produce a backcross or (3) rotational crossbreeding, where a breed of sire is rotated each generation or at specific time intervals.

Heterosis, sometimes referred to as *hybrid vigor*, is a phenomenon that is most important in crossbreeding, but is essentially an extension of hybrid techniques used for centuries in connection with plants. See Table 1.

TABLE 1. HETEROSIS (HYBRID VIGOR) VERSUS CROSSBREEDING SYSTEM

	Percent of Total Possible Heterosis	
Crossbreeding System	In Brood Cow	In Calves
1. Two-breed cross	0	100
2. Three-breed terminal	100	100
Backcross	100	50
3. Two-breed rotational	67	67
Three-breed rotational	86	86

Fundamental Categories of Breeds. For convenience of classification, there are four fundamental categories of beef and dairy cattle. The categories, although commonly used, are not consistent because two of the categories reflect the origin of the cattle, and the other two reflect the purpose of the cattle.

1. British and continental European breeds (beef).
2. North American breeds (beef).
3. Dual-purpose (beef and dairy) breeds.
4. Dairy breeds.

The foregoing classification is not fully satisfactory for the entire world because it does not reflect the so-called exotic cattle, as found in Asia, and does not fully parallel cattle found elsewhere.

Detailed descriptions of the scores of breeds are well beyond the scope of this encyclopedia, but a cross section will be given briefly.

Angus Cattle. Principal characteristics are: (1) black, smooth-hair coat; (2) polled; (3) generally alert and vigorous; (4) produce well-marbled beef. Angus cattle are known to have existed as early as 1523 in the county of Aberdeenshire in Scotland. In this region, the breed developed in a rigorous climate and on rolling to rough land that was not particularly fertile, except in the valleys. The first Angus bulls were imported into the United States in 1883. An Angus bull is shown in Fig. 1. In the American Southwest, the Angus cattle were crossbred with Texas Longhorn cattle. See Fig. 2.

Fig. 1. Angus bull. (*USDA photo.*)

Charolais Cattle. Principal characteristics are: (1) white, or very light straw-color coat; (2) mature purebred bull weight ranges from 2000 to 2500 pounds (907 to 1134 kilograms) or more; (3) mature cow weight ranges from 1250 to 1600 pounds (567 to 725 kilograms); (4) a high rate of efficiency of growth; and (5) a high percentage of lean meat with a minimum of excess fat at a young age. See Fig. 3. In France, Charolais is one of the most important beef cattle breeds. The breed did not arrive in the United States (by way of Mexico) until 1936.

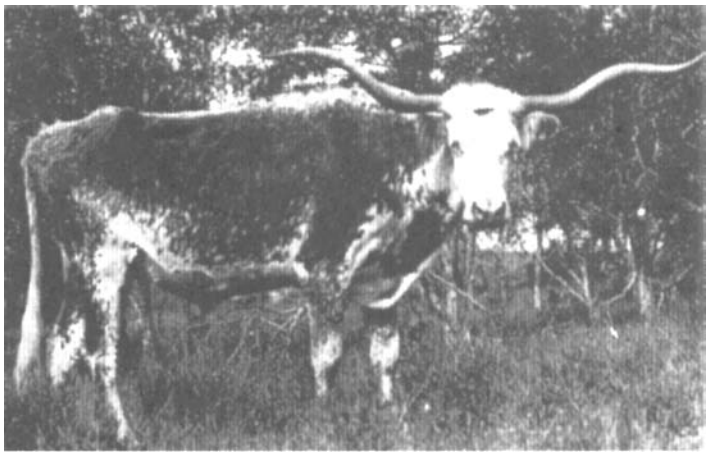

Fig. 2. Texas Longhorn steer. (*USDA photo*.)

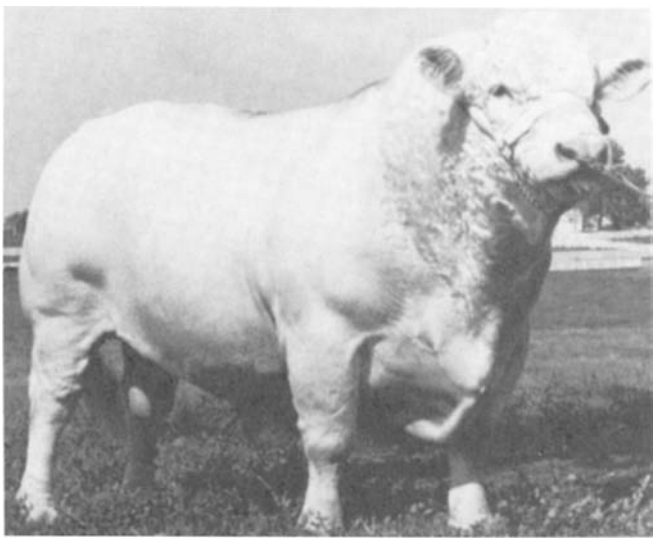

Fig. 3. Charolais bull. (*USDA photo*.)

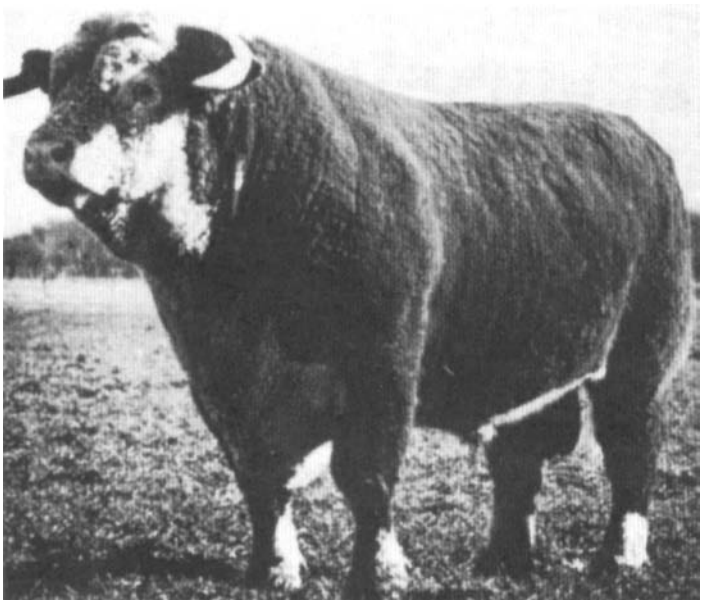

Fig. 4. Hereford bull. (*USDA photo*.)

Hereford Cattle. Principal characteristics are: (1) white face, crest, dewlap, underline, and switch; white legs below the hocks and knees; red bodies; (2) medium-size horns; and (3) docile nature, easily handled. See Fig. 4. This breed originated in the County of Hereford in England. In 1817, Henry Clay (statesman from Kentucky) imported the first Herefords. The breed has been popular in the United States since the 1870s.

North American Beef Breeds. Development of beef breeds in North America has taken place mostly since the early 1900s. The Brahman was developed by combining several breeds or strains of zebu (*Bos indicus*) cattle of India. In other cases, new breeds have been developed from Brahman-European crossbred foundations. Principal characteristics: (1) distinctive appearance, a hump over shoulders, loose skin (dewlap) under throat, and large drooping ears; and (2) light gray color or red to almost black; prevailing color is light to medium-gray. Environmental adaptation, longevity, and mothering ability are the Brahman's strongest traits. A Brahman bull is shown in Fig. 5.

Fig. 5. Brahman bull. (*American Brahman Breeders Association*.)

Beefmaster Cattle. Principal characteristics: (1) Color is variable, with more reds and duns than other colors; and (2) most animals are horned, but polled individuals do occur. See Fig. 6. Development of this breed was commenced in 1931 in Texas. The foundation herd was developed from three breeds — the Hereford, the Shorthorn, and the Brahman.

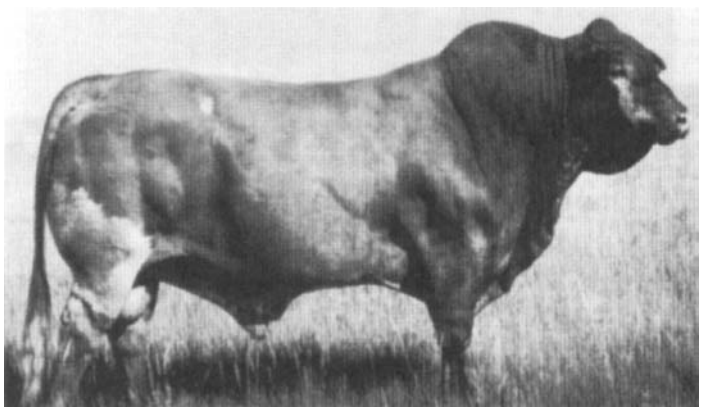

Fig. 6. Beefmaster bull. (*USDA photo*.)

Santa Gertrudis Cattle. Principal features: (1) cherry red color; (2) the majority are horned, but polled individuals occur; (3) hides are loose, with surface area increased by neck folds and sheath or navel flap; and (4) hair is short and straight in warm climates, long in cold climates. See Fig. 7. Development of this breed dates back to the early 1900s on the King Ranch in Texas.

Wagyu Cattle. In Japan, these cattle are the source of the well-known Kobe beef. Traditionally, about 2.5 years are required to feed a Wagyu up to time of slaughter.

Dual-Purpose (Beef and Dairy) Breeds. Among the better-known breeds of this type the Milking Shorthorn cattle, the Red Poll cattle, the

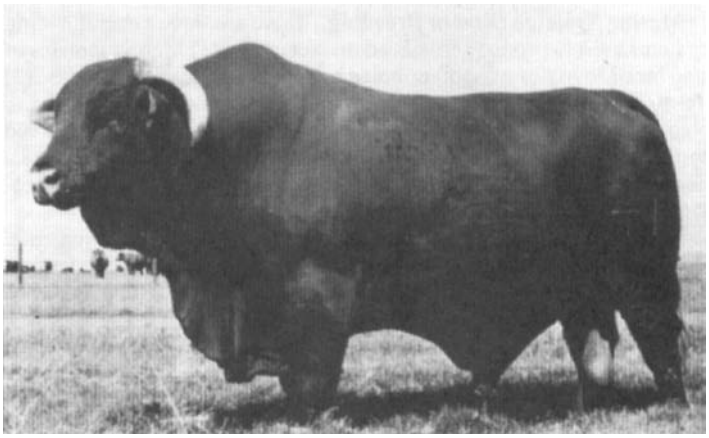

Fig. 7. Santa Gertrudis bull. (*USDA photo*.)

Brown Swiss cattle, and the Holstein-Friesian cattle. These breeds have reasonably good beef conformation and they are also capable of producing milk and butterfat in reasonably large quantities.

Dairy Cattle. About 70% of the dairy cattle in the United States are grades of purebreds of six breeds — Ayrshire, Brown Swiss, Guernsey, Holstein-Friesian, Jersey, and Red Danish. Two of these breeds, as previously mentioned, are dual-purpose breeds.

Guernsey Cattle. This breed originated on the island of Guernsey, off the coast of England. Over 13,000 of these animals were imported into America prior to 1914. A mature cow in milk should weigh at least 1100 pounds (499 kilograms). A mature bull in breeding condition should weigh about 1700 pounds (771 kilograms). A Guernsey cow (*Ideal's Beacon's Rosette*) produced 224,800 pounds (101,080 kilograms) or 25,912 gallons (980 hectoliters) of milk; and 10,941 pounds (4963 kilograms) of butterfat in her lifetime. See Fig. 8.

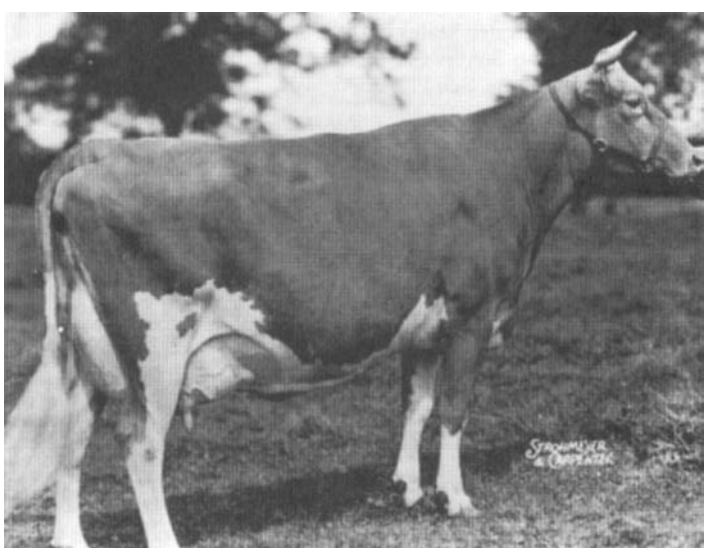

Fig. 8. Guernsey cow. (*American Guernsey Cattle Club*.)

Jersey Cattle. This breed originated on the island of Jersey, off the coast of England. Jerseys were imported into the United States as early as 1800. They are a little smaller than the Guernsey cattle. A Jersey cow (*Marlu Milady's*) produced 191,226 pounds (86,760 kilograms) or 22,236 gallons (842 hectoliters) of milk; and 9444 pounds (4284 kilograms) of butterfat in her lifetime. See Fig. 9.

Note: A number of cattle breeding associations offer a variety of literature, periodically updated, on various breeds. These organizations would include American Angus Association, Saint Joseph, Missouri; American Brahman Breeders Association, Houston, Texas; American Hereford Association, Kansas City, Missouri; American National Cattlemen's Association, Denver, Colorado; American Shorthorn Association, Omaha, Nebraska; Brown Swiss Cattle Breeders' Association, Beloit, Wisconsin; International Brangus Breeders Association, San Antonio, Texas; and Santa Gertrudis Breeders International, Kingsville, Texas; among others. Periodic publications also are available from the U.S. Department of Agriculture and equivalent governmental agencies in a number of other countries, as well as the Food and Agriculture Organization of the United Nations.

CAUCHY, AUGUSTIN-LOUIS (1789–1857). Cauchy was a French mathematician who did important work on partial differential equations, the wave theory of light, and the mathematical theory of elasticity. The "Calculus of Residues" was his invention. He is remembered as the founder of the theory of functions and put differential calculus on a logical basis.

Cauchy was also a pioneer in extending the application of mathematics to physical science, especially to molecular mechanics, optics, and astronomy.

CAUCHY CONVERGENCE TEST. If

$$\lim_{n\to\infty} |s_n|^{1/n} < 1$$

then the infinite series

$$\sum_{n=1}^{\infty} s_n$$

converges absolutely. It diverges if the limit is greater than unity. This is also known as Cauchy's criterion of the first kind. His second test is more commonly called d'Alembert's test.

CAUCHY DISTRIBUTION. A frequency distribution of the form

$$f(x) = \frac{1}{\pi(1+x^2)}, \quad -\infty \le x \le \infty$$

CAUCHY-RIEMANN EQUATION. If

$$\partial u/\partial x = \partial v/\partial y$$

and

$$\partial u/\partial y = -\partial v/\partial x$$

where u and v are both functions of x and y, these equations will be satisfied for an analytic function $(u + iv)$ of the complex variable $z = (x + iy)$. They are often used to show that such a function is analytic. See also **Laplace Equation**.

CAUCHY THEOREM. A basic formula in the calculus of residues. If $f(z)$ is an analytic function of a complex variable z which has no singular point within or on a given closed curve C, then

$$\int_C f(z)\,dz = 0$$

where the integral is extended over the entire contour C.

An extension of the Cauchy theorem, known as the Cauchy integral formula or residue theorem, is also of importance. See **Residue**.

CAUDATA *(Salamanders). (Amphibia, Urodela).* The order *Caudata* is the amphibian group comprising the living salamanders (including newts, mud-puppies, axolotls, sirens, congo eels and the olm) and their extinct relatives back to their divergence from the Salientia (frogs). The term *Urodela* is similar in use but applies only to the crown group, i.e., living salamanders and the fossil forms falling within the group from the point where the living forms started to diversify.

Salamanders share the characteristics of *Lissamphibia* including a pulmocutaneous circulatory system associated with respiratory gas exchange through the skin, toxin-secreting granular glands in the skin, pedicellate bicuspid teeth in the adults, very reduced straight ribs, a four-fingered hand, and vertebrae composed predominantly of membrane bone without a cartilage precursor. Unlike the frogs and caecilians, most salamanders retain a body form resembling that of primitive terrestrial vertebrates in that they have a long trunk and tail combined with short limbs splayed out to the side. They progress by lateral undulation of the trunk with the limbs acting as anchors rather than major thrusting devices. A few aquatic salamanders have a long eel-like body with limbs rudimentary (*Amphiumidae*) or absent (hind limbs in *Sirenidae*) but still progress by undulation of the trunk. See also **Amphibia**; **Gymnophiona (Caecilians)**; and **Frogs and Toads**.

Until the 1980s, the *Caudata* were diagnosed by a combination of lissamphibian and primitive morphology and even now, very few morphological features characterize the group as a whole, although molecular data strongly support their unity. One such feature is the remodeling of the palate at metamorphosis. In larval and some neotenous salamanders each vomer is an elongate crescent of bone medial to the choana and bearing a row of teeth paralleling the marginal teeth. At metamorphosis, the posterior region of the vomer is resorbed and an anterior outgrowth fills in the medial region of the palate. A second outgrowth of the vomer extends posterior to the choana. These larval and adult configurations are one of the few osteological features to unify the salamanders. The postmetamorphic dental patterns are diverse in salamanders, with different families characterized by different arrangements of the palatal teeth in the adults.

A specialization shared by most salamanders is internal fertilization based on the transfer of a spermatophore from male to female. The spermatophore is produced by characteristic cloacal glands in the male and picked up and stored in a characteristic spermathecal sac in the female. This occurs in all forms except sirenids, cryptobranchids and hynobiids, which fertilize externally, though males of the latter two families possess some cloacal glands. See also **Amphibia: Reproduction**.

The ears of salamanders are characteristic, though diverse. They comprise the low-frequency system also found in frogs, but lack the high-frequency tympanic system. The middle ear comprises an operculum in the fenestra ovalis which is connected to the shoulder girdle by a muscle in many metamorphosed forms. The muscle involved varies between families. Low-frequency sound is transmitted from the substrate through the limbs and girdle to the operculum and thence to the papilla amphibiorum in the inner ear. The stapes is present in larvae and may or may not be retained in the adult.

One family, the *Plethodontidae*, are notable in lacking lungs. They are all slender-bodied animals and most are small. They have highly vascular skin and throat membranes, through which gas exchange occurs.

Diversity and Distribution

By the late 1990s, 410 species of living salamander had been recognized, distributed among 10 families. Six of these families are made up largely of species with metamorphosed adults with some neotenous species falling within the family, while four small families are entirely composed of neotenous species.

Families with Complete Metamorphosis in Most Species. The *Hynobiidae* (Asiatic salamanders) comprises 33+ species found mainly in eastern Asia with a few species extending into western Asia, north of the Himalayas. The *Dicamptodontidae* (four species of Pacific giant salamanders) and *Rhyacotritonidae* (four species of torrent salamanders) are both restricted to the north Pacific coastal ranges of North America. The *Ambystomatidae* (35+ species of mole salamanders and the axolotl) range across North America, southwards into Mexico. The *Plethodontidae* (260+ species of lungless salamanders) are also found primarily in North America with one tribe — the Bolitoglossini — extending through Central America into the North Amazon basin of South America. A further small cluster of bolitoglossine species occur in Italy and Sardinia. Much of the species diversity of the *Plethodontidae* is centered on the Central American cloud forest genera. Finally the *Salamandridae*, comprising 55 species of salamander and newt, have their principal diversity in Europe but two species occur in the Atlas region of North Africa, about 20 species occur in southeast Asia and six species occur in North America. *Caudata* are absent from subSaharan Africa and Australasia. See also **Newt**.

Families Composed of Neotenous Species. The four small families of neotenous salamanders have the following distributions. The *Cryptobranchidae* (three species of giant salamanders) are found in East Asia and eastern North America, but extinct species are known from Europe and western North America as well. The *Proteidae* comprises five species of mud-puppy from North America and one cave-dwelling species — the olm from southeastern Europe. They resemble oversized gill-bearing larvae of conventional salamanders. The *Sirenidae* (three species of siren) and *Amphiumidae* (three species of Congo eel) are both restricted to southeastern North America. The members of both families are superficially eel-like, sirenids retaining external gills but having forelimbs only, while amphiumids have no external gills and four rudimentary limbs.

Habitats and Lifestyles

Though a comparatively small group, the salamanders have diverse lifestyles, the major constraints being that all require moist habitats, all are intolerant of salt or brackish water and most require cool climates associated with temperate or montane tropical conditions. The majority of Eurasian and North American species are associated with damp woodland or vegetated montane regions, but always in the vicinity of ponds, sluggish or fast streams. Further south, they shift more obviously to montane regions and the *bolitoglossine plethodontids* occur in cool cloud forest conditions from Mexico to the Andes with only a few species in lowland tropical conditions. Many bolitoglossines are arboreal and have sucker-like feet enabling them to move over leaf surfaces. They include the Mexican genus *Thorius*, notable as the smallest known tetrapod with a snout–vent length of 18 mm (0.7 in).

Correlated with this association with cool, moist climates, salamanders have the lowest optimal temperatures of any terrestrial vertebrates, preferring environmental temperatures below 20°C (68°F). However, the permanently aquatic neotenous families include some large species that are rather more tolerant of subtropical conditions and both the *Sirenidae* and *Amphiumidae* extend into subtropical swamps such as the Florida Everglades.

Several salamander lineages have moved into troglodytic (underground cave-dwelling) niches, namely plethodontids such as *Typhlomolge* and *Haideotriton* in North America and the proteid *Proteus* in southeastern Europe. These forms are not only neotenous but also pigmentless and blind.

Habits and Life Histories

Feeding. Salamanders are all carnivores in the broad sense, feeding primarily on insects, worms and small crustaceans. They are relatively nonselective feeders and will eat anything small that moves, including other vertebrates. In concentrations of salamander larvae, cannibalism is normal. Food is detected by sight and smell and, in larvae and neotenous adults, by use of the lateral-line system. Most salamanders simply grab the prey with the jaws and sticky tongue but others use a tongue projection mechanism that has probably evolved separately in the different terrestrial families; certainly it is different in the salamandrids and plethodontids. Some *plethodontid* genera (e.g. *Hydromantes*) use a ballistic tongue projection system in which part of the tongue skeleton is propelled out of the mouth in the tongue as a projectile and can thus flip the tongue out up to 40 mm (1.6 inches) ahead to secure insects on the sticky tip.

Anti-predator Mechanisms. Most salamanders are small, slow-moving and potentially vulnerable to a range of natural predators, including shrews, birds, snakes, salamanders and water-beetles. The eggs are most vulnerable and their predation is the main source of mortality in forms such as the European newts. Many adults and most larvae survive by camouflage and immobility but in some families, the adults have evolved a range of defense mechanisms centered on the use of the alkaloid-secreting granular glands in the skin of the head, trunk or tail. Many salamanders and newts have aposematic (warning coloration) of black and yellow or orange. Warning displays include tail-lashing in *Ensatina* and *Echinotriton*, while some genera such as *Taricha* will deliberately curl up to display a brightly colored underside (the 'unken' reflex). If this fails, salamanders may spray the threat (*Salamandra*), head-butt the threat (*Ambystoma, Pleurodeles*) pressing the toxin-secreting glands against it, or rely on rib-spines which will push through the skin glands under pressure delivering toxin-coated punctures to a predator. Other defensive mechanisms include tail autotomy (shedding) in some two-thirds of the species of plethodontid, and curling into a ball and rolling down a slope in the montane plethodontid *Hydromantes platycephalus*.

Life Histories. The primitive life history pattern is a simple egg–larva–adult cycle. The larva hatches at an early stage of development bearing external gills but with only forelimb buds present. For the first few days, many salamander larvae possess a pair of elongate adhesive organs on the head, called *balancers*. These may be a basic salamander feature but their distribution is too intermittent for this to be certain. Once the yolk sac is consumed, the mouth becomes functional as a shallow anterior gape for suction-gulping, and the hind limbs develop. In larvae, the eyes are lidless, the lateral-line system is functional and there is generally a deep tail fin. Metamorphosis is a relatively rapid event of a few days. The tail fin is lost, the legs become stouter, the eyes move laterally, enlarge and develop lids, the gills are resorbed. The gape deepens as the gill openings close and the animal switches from feeding by suction-gulping, pushing water out through the gill-slits, to feeding by grabbing food with the tongue or jaws.

The above is the basic pattern found in many salamandrids, hynobiids and ambystomatids but the majority of species do not conform to it. One major modification is a trend to viviparity. In *Salamandra salamandra* the larvae develop in the oviduct but are borne as advanced larvae. In some other salamandrids they are borne as miniature adults. In most plethodontids, eggs are laid in damp soil and the larval phase is suppressed, metamorphosed juveniles hatching from the egg. Neoteny has occurred many times in salamander diversification and in these forms, various patterns of reduced metamorphosis take place. Four families (listed above) and some genera in other families are characterized by obligate neoteny but 15 species of salamander are known to be facultatively neotenic with every individual having the option to metamorphose or not.

Two other reproductive patterns may be noted. In the European newts (*Triturus*) the adults over winter on land but spend spring and summer in water bodies, reverting to the larval condition of having a large caudal fin, which is resorbed again in the autumn. Several species of salamander are now known to have dimorphic larvae, a small-mouthed plankton-feeding morph and a large-headed cannibalistic morph. It appears that in ephemeral water bodies containing only small planktonic food organisms, this is a mechanism for utilizing such food to produce a few large individuals rapidly, the plankton-feeding larvae eating the plankton and the cannibals feeding on them.

Fossil Record and Phylogeny

Morphological analyses of salamander relationships conclude that they are the sister-group of the frogs, while molecular analyses suggest that they are the sister-group of caecilians. Caudates can be theorized as having first appeared at some time between the late Permian (earliest known frog in Lower Triassic) and the late Triassic (earliest known caecilian in early Jurassic). In fact, the first certain fossil salamanders do not appear under the Middle Jurassic. Salamanders may have initially evolved in the Triassic in the far northern temperate region of Laurasia, an area not yet well sampled for Triassic fossils. The Jurassic salamanders include a series of stem-forms such as *Karaurus* from Kazakhstan and *Marmorerpeton* from England. Salamanders have been collected recently from the Upper Jurassic of China and descriptions of them are in the process of being published. See also **Fossils in Phylogenetic Reconstruction**.

In the Cretaceous, recognizable crown-group salamanders appear, mostly in the northern continents, although fossil sirenids have been described from the mid-Cretaceous of North Africa and appear to represent an early ephemeral range extension of this family. *Valdotriton* from the Lower Cretaceous of Spain is a primitive member of the *salamandriform clade*, *Proamphiuma* from the Upper Cretaceous of North America is an early amphiumid, and a late Cretaceous salamandrid has been reported from France. Other Cretaceous salamanders cannot yet be placed with certainty in a set of relationships based on modern forms. It is likely that all families had differentiated during the Cretaceous. In Palaeocene strata, there are fossil cryptobranchids in Mongolia, proteids and dicamptodontids from Canada and more salamandrids from Europe. Ambystomatids first appear in the Oligocene of North America, plethodontids in the Miocene of North America and hynobiids in the Miocene of Europe. Rhyacotritonids have no fossil record.

The fossil record is consistent with an early dichotomy into the *cryptobranchiforms* in East Asia and the *salamandriforms* in the rest of the northern continents in the late Jurassic, probably effected by the Turgai Straits. Within the *salamandriforms*, later inland seas and continental drift resulted in vicariant evolution through isolation, leaving the salamandrids in Europe, ambystomatids, plethodontids and amphiumids in eastern North America, and dicamptodontids and rhyacotritonids in western North America. Later range extensions enabled cryptobranchids, plethodontids and salamandrids to reach continental areas outside their original range during the Tertiary. See also **Continental Drift**.

Combined morphological and molecular studies have not yet produced a consensus on the relationships of the living salamander families. There is general agreement that the sirenids are the most primitive offshoot followed by the cryptobranchiforms (*Hynobiidae* and *Cryptobranchidae*). The relationships of the *salamandriforms* are more controversial. Amphiumids and plethodontids are either a clade or primitive grade of higher salamanders;

dicamptodontids, ambystomatids and salamandrids are generally agreed to be close relatives; rhyacotritonids and proteids appear in diverse positions.

CAULDRON-SUBSIDENCE. A term proposed by E.B. Bailey and other Scottish geologists for the sinking of the portion of the roof or cover of a deep-seated igneous intrusion, aided by circumferential faults.

CAUSALITY. Causality is the hypothesis that a precisely determined set of conditions will always produce precisely the same effects at a later time. Classical physics was based on firm belief both in philosophical causality and in the idea that the precise determination of the initial conditions was possible in principle. The impossibility of such precise determination is a basic result in quantum mechanics.

CAUSTIC (Chemical). A corrosive substance, almost always of an alkaline nature, such as sodium hydroxide, NaOH; potassium hydroxide, KOH; or calcium oxide, CaO. Such substances attack many metals, plastics, and other materials, including human tissue, and generally fall in the category of *corrosives*.

CAUSTIC (Optical). An envelope curve giving the boundaries of an initially parallel beam after reflection or refraction by an optical system that has spherical aberration.

CAUSTIC POTASH. See **Potassium**.

CAUSTIC SODA. See **Sodium**.

CAUTERIZATION. The purposeful destruction of tissue.

CAVE. A natural opening in the earth's surface, chiefly developed in limestone regions where, because of the easy solubility of calcium carbonate, the groundwater dissolves and carries away large quantities of this otherwise resistant rock. The water enters through the joint cracks or bedding planes, passing downward by gravity until it becomes saturated with calcium carbonate or reaches the ground water level where more or less complete saturation exists. With the continued solution of the limestone, large channels and even great underground chambers are formed. The steady removal of the limestone in solution thus tends to weaken the whole formation, with the result that the roofs of underground channels or chambers frequently collapse, forming depressions varying in size from a few feet (meters) in depth and of small area to those of many acres and 100 feet (30 meters) or more in depth. Such fallen-in areas are called sinkholes or simply sinks. If they contain water they are then referred to as sinkhole lakes. Sometimes after the continued collapse of the roofs of caverns a small portion will remain, thus forming a natural bridge, the classical example of which is the Natural Bridge, Virginia.

Wherever limestone occurs, if there is a sufficient supply of groundwater, underground drainage will develop.

Among the more famous caverns of the United States are the Luray and Shenandoah Caverns in Virginia, Mammoth Cave, Kentucky, and Carlsbad Caverns in New Mexico.

Carlsbad Caverns are on three levels and possess the largest natural cave "room" known in the world, 1500×300 feet (457×91 meters) and 300 feet (91 meters) high. Mammoth Cave has 150 miles (241 kilometers) of passageways and rooms with 200-feet (61-meters) high ceilings. The Echo River runs through the cave, 360 feet (110 meters) below ground level.

Certain parts of Florida abound in sink holes and sink-hole lakes. An important feature in caverns is the so-called rock icicles or stalactites and their associated stalagmites.

Other well-known caves throughout the world include:

1. *Aggtelek* (Northern Hungary), featuring a stalactitic cavern approximately 5 miles (8 kilometers) in length.
2. *Altamira* (Sanatander, Spain), featuring Old Stone Age art on the walls and roof.
3. *Antiparos* (Grecian Archipelago), featuring brilliant colors and stalactites some 20 feet (6 meters) long.
4. *Blue Grotto* (Capri, Italy), featuring hollowed-out limestone caused by sea wave action and blue light that permeates the cave. The cave is half-filled with seawater as result of a sinking coast.
5. *Fingal's* (New South Wales, Australia) features basaltic columns about 40 feet (12 meters) in length, with cave penetration of about 200 feet (61 meters).
6. *Ice Cave* (Dobsina, former Czechoslovakia), noted for its ice-crystal effects.
7. *Jonolan Caves* (Blue Mountain plateau, New South Wales, Australia) feature outstanding stalactitic formations.
8. *Kent's Cavern* (Torquay, England), historical source of early man.
9. *Peak Cavern* or *Devil's Hole* (Derbyshire, England), a mountain cave of considerable depth (600 feet; 183 meters) from the entrance.
10. *Postojna* (Postumia) Grotto (Julian Alps, approximately 25 miles (40 km) from Trieste, noted for beautiful stalactites. The Piuca (Pivka) River flows through the cave.
11. *Singing Cave* (Iceland), noted because of echoes produced in cave.

CAVENDISH, HENRY (1731–1810). Cavendish was an English chemist and physicist who performed numerous scientific investigations with experiments on electricity. He measured the strength of a current by shocking himself and then estimating the amount of pain.

Cavendish investigated "fixed air" and isolated "inflammable air", in 1776 he discovered hydrogen. He produced dew (water) by exploding a mixture of hydrogen and air with an electric spark. He also found that a small volume of air did not combine with nitrogen while using electric sparks. Later, Ramsay repeated Cavendish's work and discovered argon.

Cavendish is also known for a sensitive torsion balance, known as the Cavendish balance, to measure the value of the gravitational constant, which defines the strength of the force of gravity.

See also **Torsion Balance**.

J. M. I.

CAVITAND. As defined by Cram (1983), a cavitand is a synthetic organic compound that contains an enforced cavity of dimensions at least equal to those of the smaller ions, atoms, or molecules. As Cram points out, if organic compounds that contain such rigid cavities are to be designed and prepared, they must be composed of units that are concave on parts of their surfaces. Very few organic compounds have concave surfaces of any size. Among the most studied of the naturally occurring compounds that contain rigid cavities are the cyclodextrins. In these cyclic oligomers of the 1,4-glucopyranoside unit, from 6 to 8 monosaccharide units are contained in a torus-shaped cavity. Organic hosts are now being designed and synthesized which contain enforced cavities sufficiently large to complex and even surround simple inorganic or organic guest compounds. This new field of investigation is of interest in enzyme and catalytic systems.

CAVITATION. Cavities may form, grow, and collapse in a liquid when variational tensile stresses are superimposed on the prevailing ambient pressure. Pure liquids have theoretical tensile strengths, which are estimated on various grounds to be of the order of 300 to 1500 atmospheres (bars), but the observed tensile strengths of real liquids are much lower. It is presumed, therefore, that the observed tensile strength is a measure of the stress required to enlarge the minute cavities, or cavitation nuclei, which already exist in the liquid rather than the stress required to form new interior surfaces.

The transient cavities formed by tensile stress are unstable and would grow indefinitely if the stress were maintained. After the cavitation nuclei have been expanded to many times their original size, however, they may collapse violently if the stress is reduced or removed. The kinetic energy of the liquid that follows each inwardly collapsing interface becomes highly concentrated as the cavity collapses. If such transient cavities contain very little permanent gas, the peak pressures at collapse may reach thousands of bars, the temperature may reach thousands of degrees, and strong shock waves may be radiated to a distance of several cavity radii. Similar cavities formed in saturated liquids will usually contain more gas and their collapse will be less violent, but the peak pressures attained are sufficient to produce unique mechanical effects, such as the corrosion and pitting of metallic surfaces (as in marine propellers and sonar projectors) and the beneficial removal of embedded dirt (as in ultrasonic cleaners). In the latter case, the soil to be removed provides a prolific source of cavitation nuclei at exactly the sites where cavitation is desired.

In hydrodynamic cavitation, the tensile stress is of relatively long duration and plenty of cavitation nuclei are usually available. As a result, cavitation occurs when the total net pressure, or the stagnation pressure, becomes approximately equal to the vapor pressure of the liquid. In acoustic cavitation, the cyclic pressure required to produce cavitation is a function of the frequency, the partial pressure of any dissolved gas, and the population of cavitation nuclei. For frequencies above about 200,000 Hz, the threshold pressure for cavitation increases with the square of the frequency and is almost independent of the degree of gas saturation. For frequencies below 200,000 Hz, the threshold pressure is a function of the partial pressure of the dissolved gas. In saturated liquids at sound pressures less than a few bars, stable bubbles can grow from cavitation nuclei by the process of rectified diffusion. At higher levels of acoustic excitation, transient cavities can be formed. The threshold sound pressure at which they appear and the violence of their collapse increase as the partial pressure of the dissolved gas is lowered.

Cavitation in Process Control Valves. Serious cavitation problems are sometimes encountered in valves designed to automatically control the flow of fluids in chemical and other processing plants. See Fig. 1. Much research has been directed by valve manufacturers and users to the alleviation of these problems. While the damage rate and the total damage from cavitation in valves are not highly predictable, a number of strategies may be used to reduce hardware damage. These measures involve system design, material selection, and using anticavitation products.

Consideration of potentially damaging cavitation conditions at the time a system is designed is the primary and preferred strategy. For example, the placement of control valves in high back-pressure locations, when possible, reduces the tendency of a valve to cavitate. When placement is not flexible, downstream "breakdown" orifices may be inserted to "artificially" increase the back-pressure. This is not a preferred method because the effective flow velocities through the breakdown orifice may be so low as to eliminate its effectiveness and, at high flow rates, the orifice plate may become the primary restriction and, in turn, limit or completely choke off the flow. If properly sized to a particular valve, the downstream orifice may prevent the valve from cavitating, but the orifice itself may cavitate. In another strategy, the use of a sacrificial member may be considered. In some situations, economics may warrant the installation of a lower-cost valve which is allowed to cavitate. Immediately downstream of such a valve where cavitation damage is likely to occur, a comparatively inexpensive pipe or fitting may be installed and periodically replaced. This method does not afford relief from the other side effects of cavitation, such as noise, vibration, and choking, but in certain cases does permit more economical control of damage.

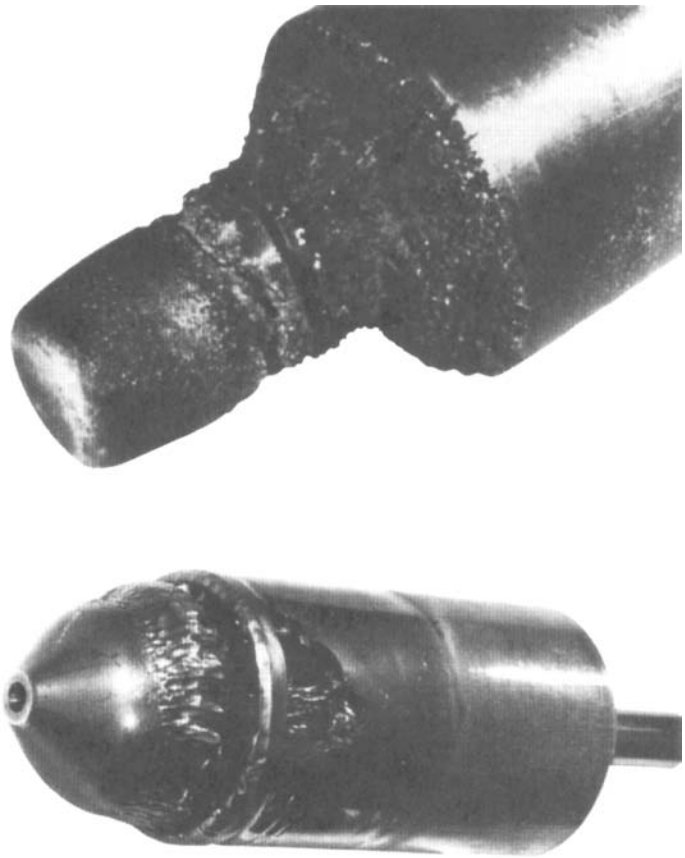

Fig. 1. (*Top*) Typical appearance of Cavitation damage caused by repeated attack by millions of micro-jets and shock waves. (*Bottom*) The term *cavitation* also is used to describe a variety of related phenomena that involve bubble or cavity formation. Examples include effervescence or outgassing, the boiling of a liquid, and flashing, the results of which are shown in bottom view. (*Fisher Controls*.)

A second category is material selection. However, this does not offer a full solution because no material is completely immune to cavitation damage. Mechanical attack interacts synergistically with corrosion to create a different situation for nearly every application. In general, metals with greater hardness, ultimate resilience, or strain energy to failure offer better resistance to cavitation. Elastomers and compliant surfaces, in general, exhibit an ability to withstand levels of cavitation attack greater than their standard structural indicators may suggest. This apparently results from an interaction between the surface and the bubble, which orients the microjet away from the surface, thus reducing mechanical attack. The temperature and pressure limitations of these materials, however, place restrictions on their use.

The most effective means for controlling cavitation is the use of cavitation control equipment. Valve manufacturers in recent years have employed two basic strategies along these lines: (1) control energy transformations, and (2) isolate cavities. The former is usually attained by *staging*. This approach to damage control routes the flow through several restrictions in series, as opposed to a single restriction. Each restriction dissipates a certain amount of available energy and progressively lowers the inlet pressure to each succeeding stage. This enables the valve to take a large pressure differential, yet maintain the minimum fluid pressure above the vapor pressure of the liquid, and thus may eliminate cavitation. Traditional valve design, on the other hand, was targeted for maximum efficiency and not for cavitation prevention.

In other modern valve designs, the objective may not be that of preventing cavitation fully, but to control the cavitation that does occur. A mechanical component of attack is always present in cavitation damage, taking two forms — microjet impact and shock wave impact — both of which must occur in close proximity to the surface in order to be damaging. Thus, it follows that, if they occur far enough away from the surface, no mechanical attack will occur, thus controlling damage.

CAVITY RADIOMETER. A modern, self-calibrating pyrheliometer or device for measuring direct solar radiation. The receiver (cavity) is typically conical in shape with precision temperature sensors and heaters. Operating at an equilibrium temperature, direct electrical power to the heater is decreased if solar radiation is added to the receiver (or added if solar radiation is removed). The electrical power necessary to maintain equilibrium is equivalent to the change in incident solar radiation.

CECH, THOMAS R. (1947–). Thomas Cech's forebears came from Czechoslovakia — he is a third generation American on one side of his family and a second generation on the other. Cech was born in Chicago on 8 December 1947 but grew up in Iowa City, Iowa. His father was a physician who was interested in physics and it was through his father that Cech became inculcated with a scientific approach to life, writing later that his father "interjected a scientific approach and point of view into most every family discussion." As with many young scientists, Cech's scientific career began as a naturalist-collector, in his case a collector of rocks and minerals when in fourth grade (aged about 10 years).

Cech went to Grinnell College, lowa, to study chemistry, inspired, perhaps, by the structures of the crystals he had been collecting. Like some other Nobel Laureates, Cech enjoyed English literature and history, but he stayed with chemistry, especially physical chemistry. He carried out undergraduate research projects at both Argonne National Laboratory, Illinois, and Lawrence Laboratory, Berkeley, California, but his experiences there persuaded him that the equipment design and manufacture involved in experimental work in chemical physics was not for him.

Instead, Cech turned to biological chemistry, attracted by "the almost daily interplay of experimental design, observation, and interpretation," He carried out his PhD research in the Department of Chemistry at the University of California, Berkeley, in the laboratory of John Hearst. Hearst was interested both in the repetitive sequences found in eukaryotic chromosomes and in using biophysical techniques to study the structure of chromosomes. He had been using *Drosophila* chromosomes but Cech worked on mouse chromosomes.

After completion of his PhD, Cech took a postdoctoral fellowship in the laboratory of Mary Lou Pardue at the Massachusetts Institute of Technology. Pardue was an expert on chromosome structure and Cech used the electron microscopic techniques that he had acquired in Hearst's laboratory to examine inverted repeat sequences in *Tetrahymena* DNA.

In 1978, Cech moved to the University of Colorado at Boulder as an assistant professor in the Department of Chemistry, becoming a full Professor in 1983. He was awarded a lifetime American Cancer Society Research Professorship in 1987, and became an Investigator of the Howard Hughes Medical Institute in 1988. Cech was appointed a Distinguished Professor at the University in 1990.

During this period, Cech continued studies of *Tetrahymena*, turning to the ribosomal RNA genes. By this time, Philip Sharp and Richard Roberts had demonstrated splicing of RNA in adenovirus and others had shown that this was a widespread phenomenon. Cech examined the splicing of *Tetrahymena* ribosomal RNA and discovered that this RNA splicing reaction did not require an enzyme but was carried out by the RNA molecule itself. This was a remarkable finding. Catalytic activity was thought to be the exclusive property of proteins and Cech's work led to a paradigm shift, especially in research on the evolution of life. Now, it was thought possible, if not probable, that the first self-replicating, informational molecule was an RNA. At about the same time, Sidney Altman showed that the active subunit of the enzyme RNAase P was its RNA component. In 1989 Altman and Cech shared the Nobel Prize in Chemistry for this work. See also **Altman, Sidney (1939–Present)**.

Ribozymes — catalytic RNA molecules — are being studied intensively in many laboratories, including Cech's. There are hopes that they may be used therapeutically to destroy RNA involved in disease processes.

In 1997, Cech's interests in the catalytic activities of RNA and his earlier interests in chromosome structure came together when he began to study telomerase. This is an enzyme with protein and RNA components that synthesizes telomeres, the repeated DNA sequences at the ends of chromosomes.

In 1999, in a significant change of career, Cech was appointed President of the Howard Hughes Medical Institute, with responsibility for administering a program awarding some $500 million per year in grants for research and education.

As well as the Nobel Prize for Chemistry, Cech has received many other awards, including the Albert Lasker Basic Medical Research Award in 1988, and the US National Medal of Science in 1995. He was elected to the National Academy of Sciences in 1987.

J.A. WITKOWSKI, Cold Spring Harbor Laboratory, Cold Spring, NY

CECUM (or Caecum). A sac-like, blind pouch of the large intestine, situated below the level of the junction of the small intestine into the side of the large intestine. At the lower portion of the cecum, but variable in position, is the appendix. See also **Digestive System (Human)**.

CEDAR TREES. The term *cedar* is not scientifically specific, but as will be noted from the following list of cedar trees, cedars are found in several families and comparatively few are of the genus Cedrus (true cedars).

Cedars are characterized by having in the woody tissue an aromatic volatile oil, which persists for a long time after the tree is cut down and dried. The wood of many cedars is very resistant to rotting. Therefore, cedar always has been a favored material for rail fences. The oil present in the wood is repulsive to insects. Cedars are found widely distributed in the United States, Asia, and North Africa. They grow best in warm areas, but principally in mountain climates. The trees are conifers, with cones of approximately 4 to 6 inches (10 to 15 centimeters) in length at maturity. The trees are narrow and erect. The leaves bear naked seed on cone scales. See also **Conifers**.

The weight of the wood from most cedars ranges from 22 to 33 pounds per cubic foot (352 to 529 kilograms per cubic meter) when dried. Where plentiful, the wood is used for construction and cabinetry work, interior trim, and closets and chests (with advantage of being insect repellent). The excellent condition of some temples in India 400 or more years old is exemplary of the durability of cedar wood. The Spanish cedar is related to the true mahogany tree and at one time was used extensively for making cigar boxes. This wood is frequently cut into thin sheets and applied as a veneer over cheaper woods.

Common Name and Family	Species
Alaska cedar (*Cupressaceae* — cypress family)	*Chamaecyparis nootkatensis*
Atlantic cedar (*Pinaceae* — pine family)	*Cedrus atlantica*
Chinese cedar (*Meliaceae* — mahogany family)	*Cedrela sinensis*
Deodar cedar (*Pinaceae*)	*Cedrus deodara*
Eastern red cedar (*Cupressaceae*)	*Juniperus virginiana*
Eastern white cedar (*Cupressaceae*)	*Thuja occidentalis*
Incense cedar (*Cupressaceae*)	*Libocedrus decurrens*
Japanese cedar (*Taxodiaceae* — swamp cypress family)	*Cryptomeria japonica*

TABLE 1. RECORD CEDAR TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
Alaska-cedar (1994) *(Chamaecyparis nootkafensis)*	451	1105	124	37.8	27	8.23	Washington
Eastern cedar (1997) *(Juniperus virginiana)*	242	615	57	17.4	69	21	Georgia
Southern cedar (1995) *(Juniperus silicicola)*	195	495	75	22.9	52	15.8	Florida
Western cedar (1993) *(Thuja pliccata)*	761	1930	159	48.5	45	13.7	Washington
Atlantic white cedar (1985) *(Chamaecyparis thyoides)*	186	472	88	26.8	42	12.8	Alabama
Northern cedar (1978) *(Thuja occidentalis)*	216	549	113	34.4	42	12.8	Michigan

Cedar of Goa (*Cupressaceae*)	*Cupressus lusitanica*
Cedar of Lebanon (*Pinaceae*)	*Cedrus libani*
Port Orford cedar (*Cupressaceae*)	*Chamaecyparis lawsoniana*
Spanish cedar (*Meliaceae*)	*Cedrela odorata*
Western red cedar (*Cupressaceae*)	*Thuja plicata*
White cedar (*Cupressaceae*)	*Thuja occidentalis*
Yellow cedar (*Cupressaceae*)	*Chamaecyparis nookatensis*

Champion cedars as reported by The American Forestry Association are listed in Table 1. On the West Coast of the United States, the cedar is often a companion of the giant sequoias.

The incense cedar grows along the West Coast of North America from upper Mexico through California into Washington. The northern white cedar grows in the northeastern United States, Canada, and as far west as Minnesota. The western cedar is found close to the Pacific Coast in northern California and into Alaska. Although not so numerous, the Atlantic white cedar is found on the eastern coast of the United States from Florida to Massachusetts. The eastern red cedar grows in abundance from Colorado to the East Coast and from Florida to the Great Lakes. As will be noted by the accompanying table, there is quite a spread in the dimensions of the various types of cedars.

The cedar of Lebanon grows in the mountains of Lebanon about 100 miles (161 kilometers) along the Syrian coast and in Turkey. It is found at altitudes up to 6,000 feet (1830 meters). The tree was first grown in Berkshire (England) in about 1646. The tree still stands. In Herefordshire, a cedar of Lebanon stands 140 feet (42 meters) high and has a circumference of 38 feet (11.4 meters).

Male and female flowers are found on the same tree. The cone may take two years to ripen. It has broad scales, two seeds to each scale. The seed is about the size of a grain of wheat. The bark of the tree is thin and insect-free. The bark has shallow fissures in the pattern of squares. The heartwood is soft and of a warm-brown color. The sapwood is pale. The wood is durable and moderately strong. It is characterized by an attractive wavy pattern in the grain. The wood is in short supply, the only source being the large groves in Lebanon and on the Taurus Mountains in Turkey.

The tree grows slowly, but may attain an age of some 2,000 years. At one time, grazing cattle destroyed many of the young trees. All large, old trees are now protected by the Lebanese Government. Although some of the cedars of Lebanon have survived from Biblical times, it is generally regarded as one of the least hardy of the cedars.

The engineering characteristics of several commercial cedar woods are given in Table 2.

CEELLULAR NETWORKS. See **Telephoney (Telecommunications**; and **Wireless Communication Applications**.

CEILING CLASSIFICATION. See **Meteorology**.

CEILING HEIGHT. See **Meteorology**.

CEILING *(Meteorological).* 1. After U.S. weather observing practice, the height ascribed to the lowest layer of clouds or obscuring phenomena when it is reported as broken, overcast, or obscuration and not classified "thin" or "partial." The ceiling is termed unlimited when the foregoing conditions are not satisfied. Whenever the height of a cirriform cloud layer is unknown, a slant / is reported in lieu of a height value. At all other times, the ceiling is expressed in feet above the surface, which is a horizontal plane with an elevation above sea level equal to the airport elevation. At stations where this does not apply, "surface" refers to the ground elevation at the point of observation. For obscurations, the ceiling height represents vertical visibility into the obscuring phenomena rather than the height of the base, as in the case of clouds or obscuring phenomena aloft. In an

aviation weather observation, the ceiling height is always preceded by a letter that designates the ceiling classification.

2. The greatest altitude to which an airborne object (aircraft, balloon, rocket, projectile, etc.) can rise, under a given set of conditions. The ceiling of an aircraft is that altitude where the stalling Mach number and the buffeting Mach number approach identical value. See also **Ceiling (Performance)**.

AMS

CEILING (Performance). Vertical operating limits of an aircraft, rocket, balloon, etc. An airplane flies by virtue of expenditure of a certain amount of power. When the power available from the engine exceeds that required to overcome the air resistance due to motion of the craft, the excess power may be used for increasing the velocity, or for climbing at a constant velocity. However, as the altitude is increased, the performance of the engine may be affected by rarefied air, with the result that the power available has reduced to the point where it is just sufficient to maintain horizontal flight. This altitude is the *absolute ceiling* of the airplane, above which it is not possible to climb. Since theoretically it requires a plane an infinite time to reach absolute ceiling, the *service ceiling* is a more practical measure of performance. This is generally considered to be the altitude at which the rate of climb has diminished to 100 feet (30.5 meters) per minute. Ceiling performance varies markedly with different types of power plants, of course.

CEILOMETER. An automatic, active, remote-sensing instrument for detecting the presence of clouds overhead and measuring the height of their bases. For optically thin clouds, such as most cirrus, more than one layer may be detected, but when optically thick clouds, such as liquid water stratus, are present, the light beam is unlikely to penetrate much beyond the base of the lowest liquid layer. Laser ceilometers use intense pulses of light in a very narrowly collimated, vertically directed beam, and have collocated transmitter and receiver systems. The cloud base heights may be displayed in a variety of time-height section images or backscatter intensity profile plots. Some older ceilometers use separated transmitter and receiver units. The instruments are designed to work during the day or night.

AMS

CELERY. Of the family *Umbilliferae* (carrot family), wild celery (*Apium graveolens*) has been known since ancient times. This biennial or annual herb is believed to be native of the Mediterranean area and cultivated there prior to the Christian era. The plant grows wild in the marshes of Western Europe and has a rank taste and strong characteristic odor. Through centuries of cultivation, these undesirable characteristics have been eliminated, and the leaf stalk has been greatly enlarged. The improved, present-day table celery is *Apium graveolens* L. var. *dulce* Pers.

The wild celery plant has numerous leaf stalks, odd-pinnate leaves, and branching, leafy flower stalks, which may achieve a height of 2 to 3 feet (0.6 to 1 meter) or more. The leaf stalks in the cultivated plant are much more solid, less stringy, and possess a much-improved flavor and odor.

Occasionally, celery plants develop as annuals and produce seed stalks the first season. The condition is called *premature seeding* or *bolting*. The affected plants are unmarketable unless seed stalk elongation is slow and occurs when plants have almost reached harvest stage. It is a potential problem in any California celery crop, for example, which matures from mid-March through late June. Exposure of plants to relatively low temperatures (about 40 to 55 °F; 4.4 to 12.8 °C) for as little as 10 days or so near the lower temperature results in bolting when subsequent favorable conditions predominate for the rest of the growing period. Celery varieties differ in their susceptibility to bolting.

In the normal development of the cultivated celery plant, a well-developed root system, a short, fleshy crown stem, and a rosette of leaves are produced the first year. The thick, fleshy petioles, or leaf stalks, of the rosette leaves comprise the principal edible portion of the plant. Commercial handlers of celery usually refer to petioles as *ribs*, *shanks*, or *stems*, and to the whole marketable plants as *stalks* or *heads*. During its second year, the main stem elongates and branches to produce a seedstalk and eventually a shrubby plant about 3 feet (0.9 meter) or more in height. The plant bears compound clusters of small white flowers, which produce seeds toward the end of the flowering season.

Celery produces a well-developed root system (consisting of a taproot and laterals) when the crop is grown from seed to market maturity without transplanting. When transplanting is practiced, the tap root is destroyed and the root system is comprised of a large number of lateral fibrous roots growing from the base of the plant. A large part of this system occupies the upper 6 inches (15 centimeters) of soil, with many of the roots within 2 to 3 inches (5 to 7.5 centimeters) of the surface. Some roots penetrate to a depth of 2 feet (0.6 meter) or more.

Cultivation of the plant for food was first recorded in France in 1623. By the early part of the eighteenth century, there had been improvement of the wild type of celery previously transported to Italy, France, and England, and as early as 1726, the plant was being used in England to flavor soups and stews. Celery was first cultivated in Europe for medicinal purposes.

Celery varieties grown in the United States belong either to the golden (or yellow class), or to the green class. Commercial celery production in California and Florida is of the green class. The yellow class is grown in other states and as a garden plant in several areas of the country.

Celeriac. Also known as turnip-rooted celery, this plant has been developed for the root instead of the top. See Fig. 1. Its culture is the same as that of celery, and the enlarged roots can be used anytime after they become sufficiently large. The late-summer crop of celeriac may be stored for winter use. In areas having mild winters, the roots may be left in the ground and covered with a mulch of several inches (centimeters) of straw or leaves, or they may be lifted, packed in moist sand, and stored in a cool cellar.

Fig. 1. Celeriac. (*USDA photo.*)

CELESTIAL MECHANICS. The term celestial mechanics is applied to that field of astronomical study and research which deals with the motions of two or more bodies in space under the influence of their mutual gravitational attractions. The fundamental elements of the subject are found in the Newtonian law of universal gravitation, the laws of motion, and Kepler's laws of planetary motion. In the classical theory, we find space of three dimensions treated, with time considered as an independent variable. Within recent years, some slight modifications of the classical theory, particularly when the time interval is very long or velocities and accelerations are very high, have become necessary on account of the theory of relativity. Under the general heading of celestial mechanics, we find such problems discussed as the development of the various methods for orbit computation, methods for computing perturbations, and solutions of the three-body problem.

See also **Kepler's Laws of Planetary Motion**; **Three-Body Problem (Astronomy)**; and **Two-Body Problem (Astronomy)**.

CELESTIAL SPHERE AND ASTRONOMICAL TRIANGLE. Although the celestial sphere may be represented as shown in the accompanying figure, or by a globe, it is considered to be infinitely large. Hence, the axis of the Earth and all the lines parallel to it, including the one through the observer (O), appear to pierce the celestial sphere at two points — the *celestial poles*. Thus, only the angle between two stars and not their true distance apart is depicted on the sphere. For an observer on the Earth, the celestial sphere, with its stars, planets, sun, and moon, appears to rotate once a day about two pivotal points — the north and south celestial poles. Some coordinate systems are fixed on the celestial sphere and rotate with it, for example, galactic coordinates defined by the plane of the Milky Way, and the ecliptic system defined by the sun's path; others are fixed with the observer, for example, the horizon system, made up of the zenith, nadir, meridian, horizon, and the cardinal points.

The transformation between coordinate systems involves the formulae of spherical trigonometry. The *astronomical triangle* appears in nautical astronomy and surveying. It is formed on the celestial sphere by great circles: the observer's meridian, the hour angle through the object, and the vertical circle through the object. In Fig. 1, drawn for an observer on the Earth, at latitude φ sighting on a star at declination δ whose hour angle past the meridian is t, spherical trigonometry gives the relations between these quantities and the star's azimuth A and its altitude h:

$$\sin\delta = \sin h \sin\varphi - \cos h \cos\varphi \cos A$$

$$\cos\delta \cos t = \sin h \cos\varphi + \cos h \sin\varphi \cos A$$

$$\cos\delta \sin t = \cos h \sin A$$

If any three elements of the triangle are known, the others may be found. For the navigator, a small hand-held calculator makes this transformation in milliseconds. Definitions are given in Fig. 1.

A.K. PIERCE, Kitt National Laboratory, Tucson, AZ

CELESTITE. The mineral celestite (also known as celestine) is composed of strontium sulfate, $SrSO_4$, occasionally with calcium and barium. It crystallizes in the orthorhombic system in tabular or prismatic crystals. More rarely it may be pyramidal or simply fibrous or granular. Two essentially perfect cleavages may be observed, one parallel to the base, the other parallel to the prism. Its fracture is uneven; hardness, 3–3.5; specific gravity, 3.97; luster, vitreous; color, white, but may be slightly reddish or bluish; transparent to translucent.

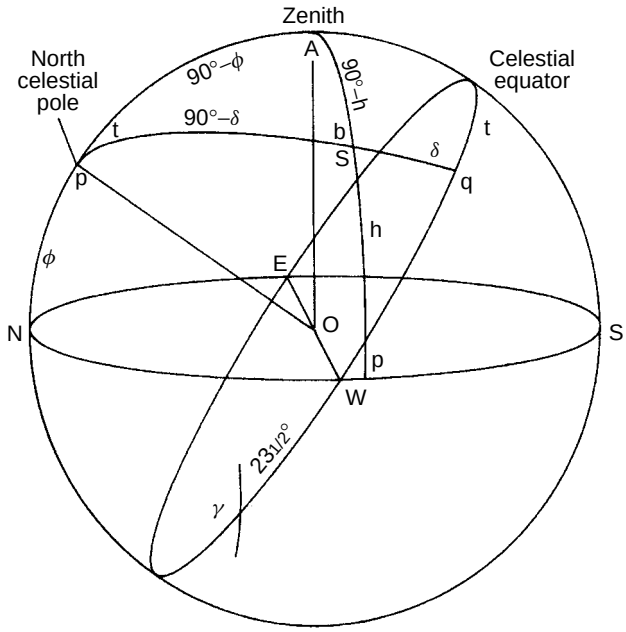

Fig. 1. Diagram showing celestial sphere and astronomical triangle. The important features include:

- *The Horizon* is the great circle formed on the celestial sphere by the plane passing through the eye of the observer (O) and perpendicular to the plumb line.
- *The Celestial Equator* is the great circle formed on the celestial sphere by the plane perpendicular to the Earth's axis, 90° from the celestial poles.
- *The Zenith and Nadir* are the points above and below the horizon on the celestial sphere pierced by a plumb line.
- *The Hour Angle* of a celestial body is the angle at either pole between the meridian and the hour circle through the body measured positive west and negative east of the meridian.
- *The Ecliptic System* is defined by the path of the sun on the celestial sphere and is inclined to the equator by $23\frac{1}{2}^\circ$. Its origin is taken to be the vernal equinox. To avoid confusion, the great circle representing the ecliptic (path of the sun) is not shown in the figure except for its intersection with the equator at an angle of $23\frac{1}{2}^\circ$ at the vernal equinox.
- *Right Ascension* is measured eastward from γ to q.
- *Declination* is measured north and south along the great circle through the pole and q and S.

Celestite may occur with gypsum and salt associated with beds of limestone, or by itself in large, commercially important veins. It sometimes occurs with sulfur in volcanic localities and is often a gangue mineral in veins of galena, sphalerite and similar metallic minerals. In Europe there are many localities for fine crystals, especially in England. In the United States celestite is found in New York, Pennsylvania, West Virginia, Tennessee, Kansas, Colorado, and California. The first celestite described was the delicate blue material from Blair County, Pennsylvania. Its "celestial" tints suggested the name. Celestite resembles barite.

CELL (Biology). All animals and plants are made up of cells. Some lower forms of life, such as bacteria, (the *prokaryotes*) may be nothing more than a small single cell which is circumscribed by a double membrane and has none of the internal structures of the larger animal or plant cells (*eukaryotes*). In the prokaryote, the genome is many orders of magnitude smaller than that of the eukaryote, but both translate genetic information into proteins according to the same genetic code. In the prokaryote group of unicellular organisms, however, this genetic development has been shown not to be equivalent in a group of *archaebacteria* epitomized by the methanogens and the extreme halophile and thermo-acidophile bacteria. See also **Bacteria**; and **Methanogens**. The methanogens are found in stagnant water and in the rumen of cattle, among other places; the halophiles require a high concentration of salt to survive, can give a red color to salt evaporation ponds, and can discolor and spoil salted fish; the thermo-acidophiles are found in hot sulfur springs and in smouldering piles

of coal tailings. These organisms have no cell wall, but simply the limiting cell membrane.

On the basis of these three groups of living cells, Woese has proposed the evolution of three primary cell kingdoms as shown in Fig. 1(a) and (b). However, the more biologists learn about trees of development, the less it appears that organisms are assembled by neat, sequential processes.

Very little information is forthcoming about the cellular biology of these archaebacteria and very little more is known about the biology and development of prokaryotes (Fig. 2) except for their methods of asexual reproduction. The eukaryotes are, however, much more complex (Fig. 3) and more is known of their biological processes. The larger plants and animals are built up by gluing together many of these cells into a larger mass. The human body itself begins as a single cell. This cell divides to

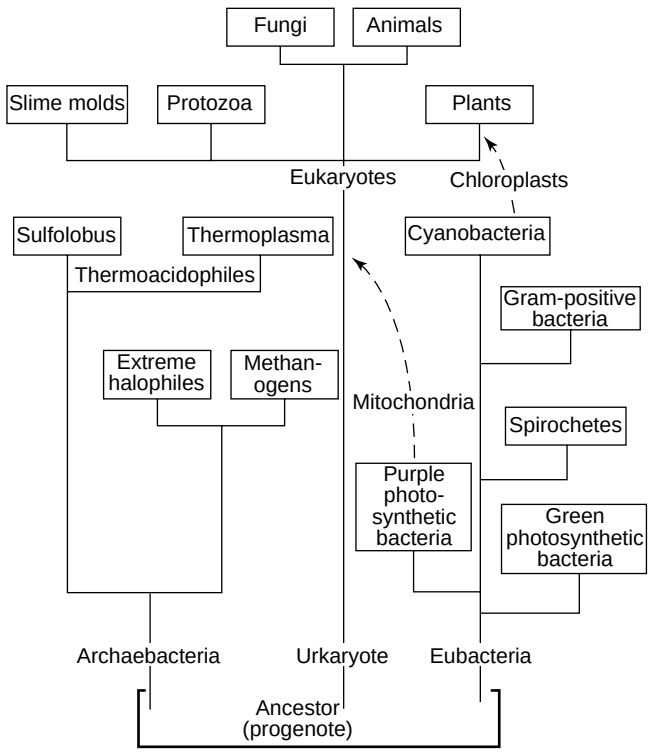

Fig. 1(**a**). Chart showing developmental organization proposed by Woese (1981) for all fundamental forms of cells. It will be noted that both eubacteria and archebacteria are composed of prokaryotic cells. Woese suggests that the archaebacteria, the eubacteria, and an *unkaryote* (designated as the original eukaryotic cell) developed from a common ancestor (designated the *progenote*). It is envisioned that the urkaryote and progenote were much simpler than present prokaryotes as they are understood today. It is further envisioned that once the urkaryote became a "host" for bacterial endosymbionts that developed into mitochondrion and chloroplast, the eukaryotes evolved.

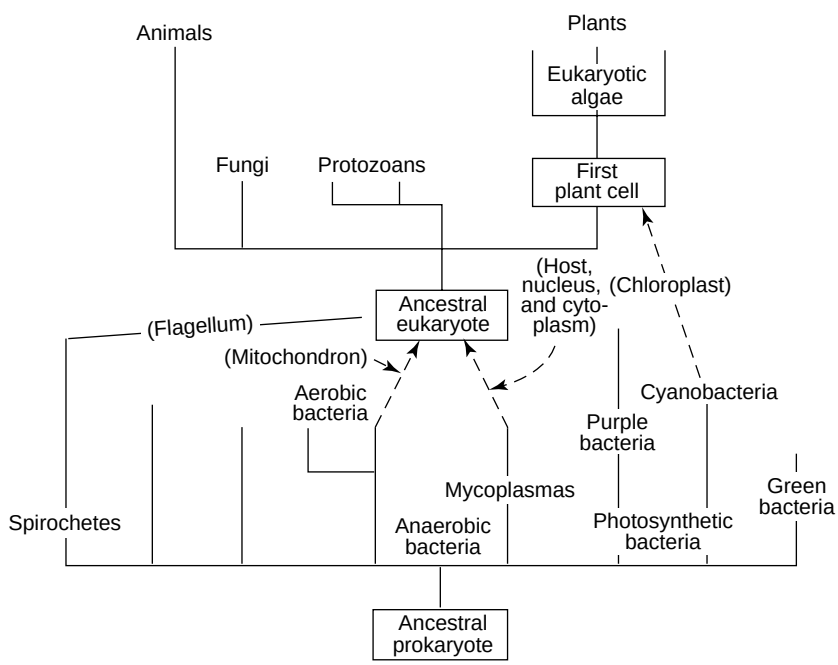

Fig. 1(**b**). Before discovery of archebacteria, traditional cell development organization charts (trees), two principal lines of descent were shown — with the eukaryote derived from the prokaryote. It was assumed that the first cells were prokaryotes (anaerobic bacteria) whose energy was derived from fermentation.

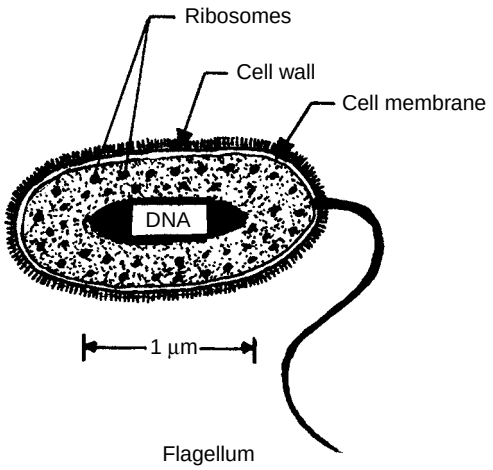

Fig. 2. Schematic diagram of representative prokaryotic cell. Even under the electron microscope, little subcellular structure is seen. A single, circular strand of DNA (genetic material) is loosely contained in the cytoplasm. The prokaryotic cell is considerably smaller than the eukaryotic cell and displays several subcellular structures.

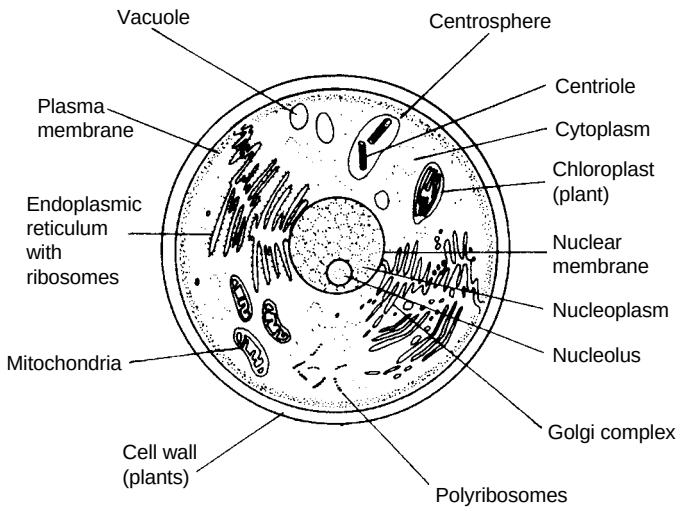

Fig. 3. Schematic of typical cell showing major parts of internal structure. In the cytoplasm, *mitochondria* are organelles in which energy is produced. Ribosomes associated with endoplasmic reticulum or as polyribosomes are active in protein manufacture. *Vacuoles* are storage regions while the *Golgi complex* functions in secretion. The *centrosphere*, containing *centrioles*, functions in normal cell division. Nuclear materials composed of *chromatin* are suspended in the nucleoplasm. Plant cells also possess a rigid cell wall and *chloroplasts* which contain the photosynthetic apparatus.

form two cells, and these divide in turn to form four, and so on, until the complete body, consisting of billions of cells, results. As the human embryo forms, like cells organize the body according to the genetic "blueprint" each cell carries within itself. The size of cells varies greatly, but most of them are so small that a million of them would not be much larger than the head of an ordinary pin. Each cell may be thought of having a life of its own. After a human being dies, it may require hours, even days, before all the cells of the body are dead. When a large number of cells with the same special function work together, they are called a *tissue*. A body tissue is made up of billions of cells which look more or less alike and all of which contribute the same general type of special service to the body. The five different tissue types are: (1) *epithelial tissue* (surface of the body and linings of various internal tubes and cavities); (2) *connective or supporting tissue* (bones and cartilage); (3) *muscle tissue*; (4) *nerve tissue*; and (5) the *blood* and *lymph*. When several kinds of tissue are grouped together, they are called an *organ*; and when a number of organs work together as a unit in the body, they are referred to as a *system*.

The Cell Cycle. Much recent research has been directed to a better understanding of the life cycle of cells. Since the early refinement phases of the gene sciences during the past quarter century, bioscientists have developed a form of shorthand for identifying the phases of cell development and ultimate death, such as G_1 (before DNA synthesis), S (DNA synthesis), G_2 (after DNA synthesis), and M (cell division). An outstanding grouping of papers was presented in the November 3, 1989 issue of *Science*. For those readers who wish to pursue this subject in considerable detail, refer to the following papers, listed under "Additional Reading" at the end of article: Articles by Garza, D.; Hartwell, L.H.; Laskey, R.A.; McIntosh, J.R.; Murray, A.W.; and Pardee, A.B.

The major activity of all cells is to transform energy. A typical cell is shown in Fig. 3. Cells gather energy from the breakdown of food at the molecular level. Cells use energy to grow, to eliminate waste material, to reproduce by splitting in two (*mitosis*), to move about the body, and to perform their specialized tasks. From the single-celled fertilized egg comes specialized cells that make up the complex body. As the body grows, cells increasingly specialize. The cells have differentiated to a point where, in the adult, certain kinds of cells no longer reproduce. Reproduction is left to the eggs and spermatozoa. See also **Gamete**. The specialized cells perform the work of muscles, arteries, lungs, kidneys, and so on. See also **Carcinogens**.

As indicated by Fig. 3, all cells contain a *nucleus* that is a center for reproduction and carries the *genetic code*. The nucleus contains deoxyribonucleic acid (DNA) which produces ribonucleic acid (RNA). The RNA organizes the essential amino acids into the proteins necessary for life. The nucleus is made up of protoplasm, termed *nucleoplasm*. Outside of the nucleus, the remainder of the cell is composed of large, complex molecules and membrane. It contains protoplasm, termed *cytoplasm*. Within this network are lysosomes, pockets of digestive enzymes that break up big molecules of fat and protein. The food is passed on to the *mitochondria* where further digestion occurs leading to production of energy in the form of ATP. Ribosomes consisting of RNA and protein are associated either with the endoplasmic reticulum, or in clusters referred to as polyribosomes, are sites of protein synthesis in the cell cytoplasm.

Although the cells of the body may resemble each other in some respects, their appearance may vary greatly if they come from parts of the body that perform vastly different tasks. Some nerve cells that transmit messages from one part of the body to another may have specialized projections as much as a yard long. They are so fine and threadlike, however, that they are invisible to the unaided eye. Some of the white blood cells behave like independent little animals, frequently leaving the blood and traveling throughout other areas of the body. These cells are very important in bodily defense against invading microorganisms, especially at sites of inflammation.

In the course of a normal lifetime, the ability of the cells of the tissues (in most cases) to replace themselves as they become worn out continues without interruption. A red blood cell normally survives in the blood stream for about 3 or 4 months before it becomes worn out or is destroyed and must be replaced. Over a period of many years, however, the restorative ability of the body generally falls behind. This is part of the aging process. Occasionally, a small area of the body may lose control over its normally systematic and careful replacement of cells and start making new cells at an uncontrolled and rapid rate. Usually, such an occurrence subsides after a short time and no harm is done, but if this process continues, the result is called a *cancer*.

Cell Division

The division of one living cell into two is one of the most important of biological phenomena. By this process, continuity of a species is ensured and mutation of a species is made possible. Moreover, cell division plays an important role in the growth and differentiation of tissues in embryonic forms, in wound healing, in the formation of tumors, and in the normal replacement of old cells in certain tissues, such as the skin of humans. As previously mentioned, a living cell consists of cytoplasm and a body within the cytoplasm, the nucleus. The division of a cell involves not only cleavage of cytoplasm, but also a complex nuclear reorganization in which replicated genetic material, chromatin, of the mother nucleus is distributed to each daughter nucleus.

Interphase. After cell cleavage, and prior to visible nuclear changes of the next division, a cell is said to be in *interphase*. In this condition, the nucleus is bounded by a thin double-layered structure, the nuclear membrane. In the interphase nucleus, chromatin is present in the form of very fine, extended threads, and present also is at least one spherical

body known as the nucleolus. See also **Chromatin**. The chromatin and the nucleolus are immersed in a clear, homogeneous liquid, the nuclear sap, which has a viscosity only a few times greater than that of water. Within the cytoplasm of a cell in interphase are a number of components, such as mitochondria, lysosomes, plastids, vacuoles, endoplasmic reticulum with associated ribosomes and Golgi body, and centrioles (see Fig. 4). Centrioles are always present in animal cells, but they have not been detected in the cells of higher plants.

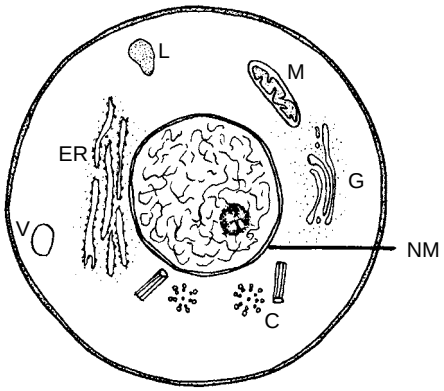

Fig. 4. Structures of interphase cell. C, centriole; ER, endoplasmic reticulum; G, Golgi complex; L, lyosome; M. mitochondrion; NM, nuclear membrane surrounding chromatin threads and nucleolus; V, vacuole.

During interphase, a cell prepares for the ensuing division. During this period, replication of the chromatin threads occurs, forming sister threads. Chromatin consists essentially of two substances, a basic protein *histone*, and DNA. It should be pointed out that the latter is a substance of great molecular weight made up of many units of nucleotides. A nucleotide consists of phosphoric acid, a 5-carbon sugar, and an organic base, either a purine or a pyrimidine. In the case of DNA, the 5-carbon sugar is deoxyribose, the purine bases are adenine and guanine, and the pyrimidine bases are cytosine and thymine.

The synthesis of new DNA within an interphase nucleus can be marked by adding to the environment of a cell a precursor of DNA, thymidine, labeled with radioactive hydrogen (tritium). Radioactive thymidine passes into the cells and can be detected by autoradiography. In a cell not destined to divide, DNA synthesis does not occur, and in a cell in which DNA synthesis does occur, division typically takes place. If DNA synthesis is blocked by treatment of cells with deuterium oxide, division is inhibited; when the block is removed, DNA synthesis proceeds and division occurs.

Toward the end of interphase, the adjacent two pairs of centrioles begin to move in opposite directions. When they come to rest, they will form the poles of a structure known as the spindle. The centrioles are by no means simple structures. From studies with the electron microscope, it is known that a centriole is a cylindrical body made up of parallel, tubule-like structures. Often the centrioles of a pair lie at right angles to each other. Radiating from the region around a centriole pair is a system of fibers, the *aster*. The chemistry of centrioles requires much further investigation. There is some evidence that they contain ribonucleic acid (RNA). RNA differs from DNA in that the 5-carbon sugar is ribose rather than deoxyribose and the pyrimidine base, thymine, is replaced by the base, *uracil*.

Prophase. About the time the centrioles begin to move, other events are initiated, including the dissolution of the nuclear membrane, disappearance of the nucleolus, condensation of the chromatin threads by coiling, and spindle formation. This stage of the division process is called *prophase* (see Fig. 5). Presumably, the nuclear membrane is a lipoprotein similar to that of the cell membrane. Dissolution of the nuclear membrane apparently is brought about by a calcium-ion-activated proteolytic enzyme.

The nucleolus contains protein and ribonucleic acid. RNA is not synthesized in the nucleolus, but accumulates here after being synthesized by DNA. During prophase, RNA accumulates on the coiling chromatin threads, the chromosomes, and it has been suggested that the accumulation of RNA on the chromosomes is the result of blockage of the transfer of RNA from the chromosomes to the nucleolus. Late in prophase, the nucleolus disappears and its RNA passes into the cytoplasm.

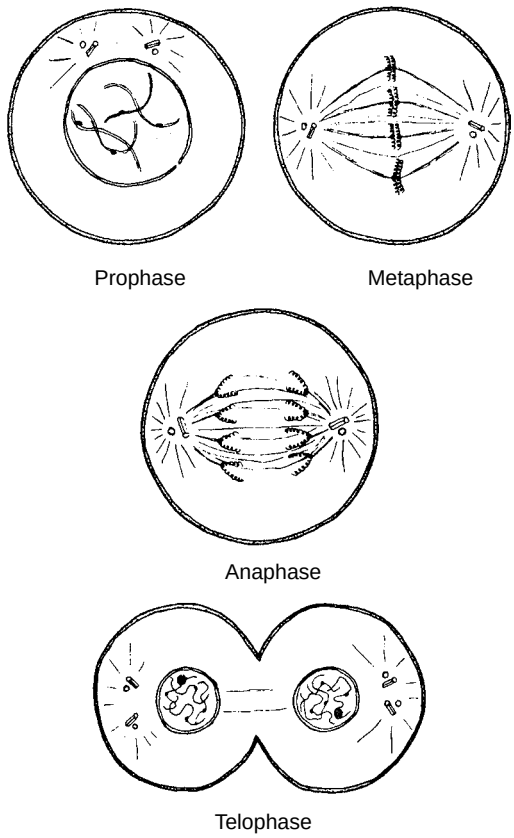

Fig. 5. Stages of cell division.

During the prophase, a dual system of fibers forms between the two poles from protein synthesized during interphase. One system, the primary spindle, consists of fibers extending from pole to pole; the other system, the chromosomal spindle, consists of fibers extending from the poles to the equatorial region between the poles.

Metaphase. Later in prophase, the tightly coiled chromosomes begin a movement that will culminate in alignment of the chromosomes in a narrow band in the equatorial plane of the spindle. When the chromosomes reach this position on the equatorial plate, the cell is said to be in *metaphase*. Each of the sister chromosomes of a pair is connected to a chromosomal spindle fiber of its pole by means of a body on the chromosome called the *kinetochore*. By this time, chromosomes, spindle fibers, centrioles, and asters are surrounded by a gelatinous matrix. This whole structure, known as the *mitotic apparatus*, differs physically from the remainder of the cytoplasm. For example, the mitotic apparatus can be dislodged from its normal position and moved about the cell by means of ultrasonic vibration applied to the cell surface.

Anaphase. The end of metaphase and the beginning of *anaphase* is marked by the separation of sister chromosomes and the beginning of movement of the sister chromosomes toward opposite poles. During anaphase, RNA is lost from the chromosomes, and toward the end of anaphase, there is an accumulation of ribonucleoprotein in the equatorial region between the two chromosome groups. The source of this equatorial RNA is under investigation. It may represent RNA lost from the chromosomes; it may originate from other sources.

Telophase. During the final stage of the division process, *telophase*, the cell body divides into two, a process called *cytokinesis*, and each daughter cell completes processes that restore it to an interphase cell. The mitotic apparatus disappears, the chromosomes become attenuated, the centrioles duplicate and split, the nuclear membrane becomes reconstituted, and the nucleolus reappears.

During anaphase, nucleolar material can be detected among the chromosomes, and by the end of telophase, this material has been accumulated in the body known as the nucleolus. Under investigation is what fraction of RNA in the telophase nucleolus represents RNA lost to the cytoplasm

from the prophase nucleolus. At least part of the RNA in the telophase nucleolus would appear to be newly synthesized.

Although the centriole has the usual capability of reproducing itself, much remains to be found concerning its chemical makeup. Some evidence indicates that centrioles contain RNA.

Various schemes have been proposed to explain the furrowing or cleavage of the cell body. According to one hypothesis, cleavage is brought about by synthesis of new material in the region of the furrow. Another hypothesis proposes that there is a contraction or constriction of cytoplasmic substance in the equatorial region of the cell. The "expanding membrane" hypothesis maintains that furrowing is caused by the expansion of folded protein molecules in the cortical region of the cell.

The events occurring at the furrowing cell surface and those preceding them in the interior of the cell are related. Furrowing always occurs in the equatorial plane between the poles of the spindle. Presumably the interior-to-surface messenger is a chemical substance(s), but the nature and source remain to be determined.

Although the division process requires energy, the active phases of the mitotic cycles are not marked by great metabolic or respiratory activity. On the contrary, the period between active phases, interphase, is the time of high metabolic and respiratory activity. Thus, many investigators believe that the energy required for division is obtained from a "reservoir" prepared during interphase. The nature of the "reservoir" remains to be studied further. Conceivably, a high-energy compound such as adenosine triphosphate may be involved, but evidence for this is not strong.

As a result of cell division, each daughter cell has a full complement of chromosomes (diploid) just as the mother cell. In reproductive organs during the production of germ cells (sperm and eggs of animals and spores of plants), the cells undergo two divisions, called meiotic divisions, which result in gametes each having only half the chromosome complement (haploid) of a somatic cell.

Chromosomes. Each plant or animal species possesses a characteristic although somewhat variable chromosome number, which can easily be visualized in the form of a *karyotype*, the number and form of chromosomes present at metaphase. Originally, chromosome was a term used by microscopists to describe the type of cellular organelles which could be observed microscopically during cell division processes and which had strong affinity toward basic dyes. As genetic studies advanced, it was recognized that these cellular components represented the vehicles which carried the hereditary determinants (*genes*). In more recent years, the term chromosomes has been used to describe the "gene carrier" of any cell, whether it is microscopically visible or not. Thus, the term has lost its morphological connotation, because the chromosomes of most microorganisms, such as bacteria, and viruses, are not always detectable by standard microscopes. The chemical composition of these two types of chromosomes is also quite different. In the following description, chromosome refers to the classic definition, namely, the chromosome of higher organisms.

Investigations into the chemistry of chromosomes have been impeded, because: (1) a chromosome is not composed of a single type of compound, but is a composite of several species of complex macromolecules whose interrelationships have not been well established; (2) no satisfactory method is readily available to isolate chromosomes in quantities to facilitate chemical analysis; and (3) chromosomes can be observed microscopically only when a cell enters division stages (mitosis or meiosis), which represent a small fraction of the life span of a cell. During the rest of the time, the cell is in interphase when the chromosomes are invisible. The chromosomes are "decondensed" and are enclosed in a nuclear envelope. Isolation of chemical constituents, therefore, can be done only from isolated nuclei. Further, it is not fully established that the deoxyribonucleoprotein so isolated equates to the chromosomes.

Some information on the chemical composition of chromosomes has been obtained by cytochemical analysis. The Feulgen reaction has demonstrated that DNA is the major component of chromosomes. Alkaline fast green staining shows that there is also a basic protein component (histone) is the chromosomes. In some viruses, the genetic determinants are in the form of RNA rather than DNA. However, DNA appears to be the hereditary material of the overwhelming majority of life forms, including numerous viruses and bacteria, protozoa, and all higher plants and animals.

In bacteria, and viruses, each "organism" possesses one chromosome, and each chromosome is a single, circular molecule. There is no evidence of proteins closely associated with DNA, such as nucleoproteins in the case of higher life forms. A possibility exists, however, that amino acids or small peptides may be present to interrupt the continuity of the long DNA molecule. Bendich and collaborators have postulated that amino acids may serve as punctuation points for the genetic messages. In the chromosomes of higher forms, more than one DNA molecule per chromosome is probable.

Replication and RNA Synthesis. DNA molecules have two functions: (1) replicating themselves; and (2) providing a template for RNA synthesis. Ample evidence has been accumulated to show that DNA replicates itself in a semiconservative manner. That is to say, each of the complementary strands of the double-helical structure synthesizes its complementary strand, resulting in two double helices each containing one old and one new strand. Apparently, the chromosomes replicate the same way.

The bacterial chromosome replicates itself from a predetermined point and proceeds around the circular chromosome with an apparent constant rate until the entire ring is duplicated. At the time, the two rings separate and each may begin another generation of replication. In higher plants and animals, the chromosomal replication may begin at multiple sites and is asynchronous among different chromosomes of the same cell. The asynchrony is not lost even after an artificial arrest of the DNA synthesis by analogues or inhibitors. Under the influence of arresting agents, the DNA synthesis process ceases. When thymidine is later introduced to the arrested cells, DNA replication resumes at the point where it was stopped. The asynchronous pattern is not altered. This asynchrony of chromosome replication has much genetic significance.

As important as self-replication, the second function of DNA is to serve as template for RNA synthesis. The biosynthesized messenger, mRNA, copies the base sequence of the DNA so that it transcribes the information carried in the original genetic code. The function of mRNA is to carry the genetic message from DNA to the cytoplasm for translation of the message into protein. In *eukaryotic cells*, each mRNA strand codes for one protein, whereas in some bacteria and viruses, mRNA forms polycystronic strands, which code for more than one protein. Chromosomes synthesize DNA only when they are not condensed, i.e., when they are in the interphase stage.

Control of Genetic Expression. All cells of an organism find their lineage from a single fertilized cell, the *zygote*. The original zygote thus contains all the genetic information required for the development and maintenance of this organism. A great deal of genetic information for a specific function necessary for one type of cell will be useless in other cells. In other words, not all the DNA molecules should actively synthesize RNA at one time. In fact, a specialized cell should have many inactivated DNAs whose information belongs to other cell types. Otherwise development cannot proceed in an orderly manner. Thus, some mechanisms must be operative to control the RNA synthetic activity of the chromosomes.

See also **Genetics and Gene Science (Classical)**.

In the chromosomes of higher forms, a considerable quantity of protein is present. One group of proteins, the histones, are basic, because of their high content of arginine and lysine. It has been suggested (Stedman and Stedman) that histones may be the agents that regulate the activity of the genes. It also has been found (Huang and Bonner) that histones inhibit the *in vitro* synthesis of DNA- DNA-dependent RNA. Other studies indicate that various fractions of histones differ in their affinity to DNA.

Genes. These may be defined as segments of genetic material which determine the sequence of amino acids in specific polypeptides, such that there is a one-to-one relation between gene and polypeptide. This definition applies at least to those genes called *stucturalr* genes because they determine the primary structure of proteins. More generally, genes are the physical units of heredity. Structural genes in all organisms appear to be composed of nucleic acids. In the RNA viruses, the genes are RNA only, but in all other organisms, the DNA viruses and the cellular forms which all possess both DNA and RNA, the gene material is either known to be DNA or assumed to be DNA.

See also **Genetics and Gene Science (Classical)**; and **Industrial Biotechnology**.

The genes of viruses and bacteria appear to consist of nucleic acid unaccompanied by closely-bound protein. Ordinarily, this naked nucleic acid is in the two-stranded condition; exceptions are known among both the RNA and DNA viruses, some of which possess single-stranded genetic material. In those organisms with true nuclei, the genetic material is always double-stranded DNA associated with protein ordinarily of the histone type. The function of the protein is not considered to be genetic. It probably controls

DNA in its role of determining protein structure. Also, it may serve to hold genes together and attached to the chromosomes of which they are a part.

Structural genes carry out their role of dictating protein structure by producing a messenger RNA (mRNA) which is a single strand of RNA containing nucleotide bases complementary to one of the strands of the double-stranded DNA of the gene from which it is copied or "transcribed." The evidence is that the same DNA strand of a gene is always transcribed into mRNA. In this way, only one kind of mRNA is made for each gene. In the transcription process, the C, T, A, and G bases of the DNA determine G, A, U, and C, respectively, in the mRNA strand. Transcription effectively constitutes *gene action*. By definition, if a gene is not actively forming mRNA, it is inactive or "turned off."

Each kind of gene is different from every other gene in its DNA sequence. Hence, as many different kinds of mRNA are formed as there are different genes in the organism.

After their formation to the gene level, the mRNA strands attach to ribosomes in the cytoplasm. The process of protein biosynthesis then commences. The significant point is that the sequence of nucleotide bases (the "genetic code") in a particular gene is reflected in a specific sequence of amino acids in the polypeptide produced through the protein synthetic mechanism.

The one-to-one relation between gene and polypeptide is a more accurate statement of the situation than the earlier *one gene-one enzyme* hypothesis. It has been established that a number of proteins are constituted in their functional state of subunits which are polypeptides. When subunits are all identical, the *one gene-one protein* statement holds with certain exceptions. However, proteins such as vertebrate lactic acid dehydrogenase (LDH) and hemoglobin are made up of different subunits.

The term *cistron* also is sometimes used as the name for a structural gene.

Mutation of Genes. Mutation takes place in all types of organisms and is the origin of hereditary variations. A change in the base sequence of the DNA constituting a gene results in an inherited alteration in the code and is called a gene mutation. Changes in base sequence may conceivably result from: (1) the deletion or addition of one or more nucleotide pairs in the DNA chain; (2) changes in one or more bases along the chain; or (3) inversion of a segment of the chain. When the mutation involves the chromosome structure, it is considered a chromosomal mutation or aberration. Somatic mutations are not transmitted from generation to generation, but may produce severe changes in the organism depending upon the type of cell affected and the time at which mutation occurs, i.e., during embryonic development.

Active Transport in Cells

Common to certain of the organelles and to the cell itself are structures referred to as *unit membranes*. Cellular membranes are generally composed of lipid and protein molecules, spatially oriented so that the inner part of the membrane is an area of interdigitated phospholipid and cholesterol ester molecules and the inside and outside coatings of the membrane are largely protein. According to the generally accepted fluid mosaic model, the lipid layers of the membrane are fluid in which (and sometimes through which) float protein molecules. These proteins serve many functions, but perhaps most important of these are their function as cell surface receptors for such various agents as hormones, viruses, and antibodies. The thickness of biomembranes varies, but many membranes appear microscopically as two dark lines of approximately 10 micrometers thickness, separated by a lighter band of about 50 micrometers. Myelin, the covering of nerve axons, is a repeating structure of lipid-protein layers of 140–170 micrometers. The molecules making up these thin structures serve to isolate the cell contents from the environment. They do not fit tightly together as a solid wall or surface, but have areas in which there are pores. These pores or spaces through biomembranes are limited in size (0.7 nanometer) and serve to effectively prevent the passage of a variety of large molecules, thus giving to most biomembranes the property of semipermeability. See also **Molecular Biology**.

Most cells contain considerably more protein than is present in the fluids bathing the cells. The presence of a high concentration of cellular protein, together with the high concentration of salts associated with the charged protein structure, causes an osmotic gradient to exist and results in the flow of solvent into the cell in an attempt to compensate for the osmotic pressure difference. Plant cell walls have rigid structural features that prevent cell wall rupture and cell death when osmotic or hydrostatic pressures are imposed. Animal cells, on the other hand, lack supportive wall structures and must depend upon other mechanisms to restore water and solute balance (and thus osmotic balance). The cell membrane then becomes a dynamic focal point of fluid and solute flow rather than just a static barrier unassociated with the life process.

Diffusion is that motion which is imparted to solutes by the random molecular movements of materials in solution. The diffusion movement of solute is increased with increasing temperature and is directly dependent upon its concentration. In dilute solutions, the diffusion of one species or particle is independent of the diffusion of another species, provided there is not interaction between the species. For a small solute molecule (or the solvent itself), the movement through the small distance involved in the thickness of biomembranes may be of a similar magnitude to the movement in free solution. Water moves rather quickly across many cell membranes. A solute may cross a cell membrane at a rate greater than it would by simple diffusion in water if, in the process of flowing rapidly through the membrane, water "drags" solute with it. This process is known as "solvent drag."

The movement of certain molecules through cell membranes may be restricted or aided because of the lipid layers in the membrane. If a material is not small enough to diffuse through the solvent phase of the membrane, or is hydrophobic in nature, then it may still pass through the membrane phase, later leaving this phase and entering the cell. Since diffusion is related directly to concentration, high solubility of a solute in the membrane should lead to a high probability of its crossing the membrane.

Charged solutes (cations and anions) may be subjected to additional forces in their movements. If one side of the membrane, i.e., the outside of the cell, has a positive charge on it and the inside of the cell has a negative charge, a potential difference exists. Thus, a charged solute in the vicinity of the inner or outer environment of the cell will move with greater or less speed, depending upon the nature of its own charge. An area of opposite charge then can be an attracting force and cause the solute to move at a speed greater than that expected by simple diffusion. Conversely, the electrical field may serve as a barrier to an ion of the same charge as the field.

The net movement of material across a biomembrane against a concentration gradient at a rate greater than that predicted by simple diffusion or by electrical gradients is considered to be *facilitated diffusion* or *active transport*. Facilitated diffusion does not directly involve cell metabolism and does not require energy. Active transport is metabolically coupled and requires expenditure of energy in the form of ATP. Both types of processes appear to involve membrane protein carrier molecules. The descriptive term "uphill transport" has been used synonymously with active transport.

Cation Transport. Plasma membranes have in common the ability to transport alkali metal ions in the face of osmotic, electrical, and concentration gradients. By means of mechanisms not fully explained, cells may maintain a high internal concentration of K^+ and a low concentration of Na^+, while existing in an environment that has a low K^+ and a high Na^+ concentration. This unlikely distribution is not due to a lack of movement or passage across the cell membranes, but rather to selective processes that extruded ("pumped") ions from an area of low to an area of high concentration. Data supports the concept that the driving force of the "pump" is closely linked to reactions involving the use of ATP (adenosine triphosphate). This prime energy source is supplied by the catabolism of foodstuffs and the union of food hydrogen with environmental oxygen.

Sugar Transport. A variety of mechanisms operate for the movement of sugar into cells. Sugars may enter by simple diffusion, but this is a slow process without great structural specificity. This movement is always away from the region of highest concentration. Transport from a high to a low concentration is often called "downhill" transport. In the case of many cells, the movement of certain sugars appears to be much more rapid than expected from simple diffusion. In those instances where there is rapid movement, but where the movement is still "downhill," the transport is called *facilitated transport*. Facilitation of solute movement is presumed to result from the interaction of the sugar with a carrier substance in the membrane. The complex moves across the membrane, the sugar is discharged on the far side, and the carrier returns for another cycle. In the case of glucose uptake by human red cells, the exchange is up to 100 times faster than that predicted by simple diffusion. Although this facilitated transport shows specificity for structures and demonstrates saturation phenomena, the process does not seem to directly require metabolic energy.

CELL-MEDIATED IMMUNITY. See **Immune System and Immunology**.

CELLULITIS. A spreading inflammation of fatty or areolar subcutaneous tissues with progression usually extending along the interfascial spaces giving rise to hyperthermia, edema, and leucocytic infiltration. The condition is dangerous because it may spread locally to important structures, such as tendon sheaths, bones of joints, or more distantly, causing lymphangitis and septicemia, the latter inducing abscess formation with suppuration, sloughing, or necrosis.

The organisms most commonly responsible for the infection are staphylococcus and streptococcus species, but many others may cause cellulitis, such as those anaerobes responsible for gas gangrene.

The symptoms produced depend upon the tissue area invaded. For example, Ludwig's angina is the resultant of an infected mandibular molar and leads to swelling of the floor of the mouth and cellulitis of the submaxillary tissue spaces. The condition demands immediate chemotherapy and immobilization of the affected part to prevent local and general complications. See also **Fascia**.

CELLULOSE. The formula for cellulose is sometimes given as $(C_6H_{10}O_5)_n$. This is an oversimplification inasmuch as the cellulose present in natural substances, such as wood and cotton fibers, usually is combined with other constituents, such as fats and gums. Cellulose is found almost exclusively in plants and accounts for about 30% of all vegetable matter. Cellulose is the principal substance of which the walls of vegetable cells are constructed. The term *cellulose* is derived from the Latin *cellula*, meaning little cell. Relatively pure cellulose can be obtained from cotton fibers (90% cellulose) and flax fibers. Very small amounts of cellulose are found in insects and not in other animal tissues. Digestive juices and enzymes present in animal systems do not appear to attack cellulose and thus ingestion by humans is relatively limited. By means of other biological processes, such as those involving amoeboid protozoa present in the digestive tract, herbivora and insects digest and absorb some cellulose.

Cellulose is a polysaccharide of glucose. See Fig. 1. Cellulose is a white solid, odorless and tasteless, insoluble in cold or hot water, and chemically nonreactive except when treated with strongly corrosive materials. If heated with water at 260 °C and under rather high pressure, however, cellulose dissolves, but with decomposition. Concentrated sulfuric acid dissolves cellulose, the solution upon dilution and boiling yielding glucose. When treated with sodium hydroxide (15 to 25% NaOH) cellulose fibers swell up and upon washing and drying possess a lustrous appearance. This is the mechanism of *mercerization*. With iodine in potassium iodide solution plus zinc chloride (Schulze's solution), cellulose produces a dark blue color. When treated with an 80% sulfuric acid solution and rapidly washed and dried, cellulose yields a parchment-like surface.

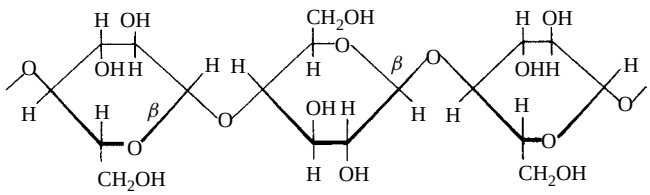

Fig. 1. A segment of the cellulose molecule.

In biochemical terms, cellulose is the name given both to a specific polysaccharide, consisting of βD-glucose residues joined end-to-end by linkage through $-O-$ of C_1 of one residue to C_4 of the next (see Fig. 2); and to a resistant family of polysaccharides (containing cellulose in the strict sense) isolated from plants by specific chemical treatment. Cellulose appears to be always associated in plants with other polysaccharides and polysaccharide derivatives, such as mannan, xylan, araban, galactan, polygalacturonic acid, and, in woody plants, with lignin.

The mechanism of cellulose synthesis and microfibril orientation is not fully understood. Synthesis probably occurs from a glucose/phosphate precursor, which may be guanosine diphosphate glucose. The enzyme system involved can be extracted from the plant (e.g., from *Acetobacter xylinum*) and synthesis by cell-free extracts has been achieved. The synthetic mechanism in organisms higher than bacteria is thought to be located on the cell surface, and both granular aggregates and microtubules seen in the electron microscope are considered as possible sites.

The "brown rots" (e.g., *Coniphora casebella*, *Poria monticola*) and the "white rots" (e.g., *Polystictus versicola*) are both basidiomycetes. Both attack cellulose, but only the latter takes lignin to any large extent. "Soft rot fungi," recognized relatively recently as important in this regard are members of the *Ascomycetes* and *Fungi imperfecti* (e.g., *Chaetomium globosum*). They all attack the cellulose of wood, producing characteristic angular cavities. The evidence is that all of these fungi attack the

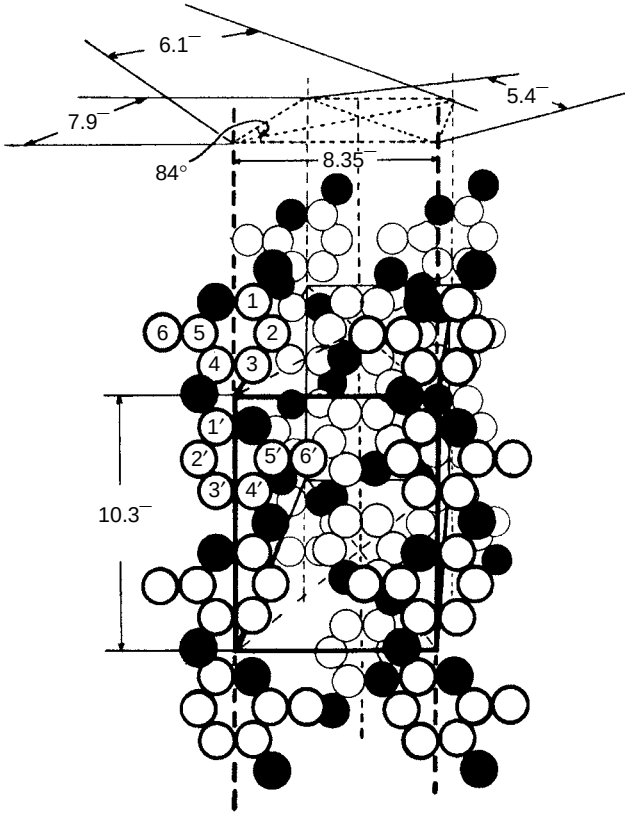

Fig. 2. Diagrammatic representation of the unit cell of cellulose. The monoclinic cell, dimensions 10.3 Å × 8.35 Å = 84°, is delineated by solid lines with one cellulose chain at each vertical edge and one (antiparallel) in the center. Open circles = carbon atoms; solid circles = oxygen atoms. For clearness of the diagram, the hydroxyl groups on carbons 2, 3, and 6 are omitted; and hydrogen atoms are omitted. Two spacing at 6.1 Å and 5.4 Å are included, inasmuch as these are strongly represented in the x-ray diffraction diagram.

paracrystalline component of cellulose more rapidly than the crystalline component.

Compound celluloses are widely distributed in plants, the two principal types being:

(a) Lignocelluloses, of woods, cereal straws, jute. These cellulose materials yield lignin by treatment (1) with 43% hydrochloric acid, cold, for 12 hours, (2) with 8 to 12% sodium hydroxide at 140 to 160 °C for 6 to 10 hours, (3) with 72% sulfuric acid at ordinary temperature for 18 hours (the common method). Wood yields about 25% of lignin by the last treatment.

(b) Pectocelluloses, of flax, hemp, ramine. These cellulose materials yield pectic substances by treatment with oxalic acid or ammonium oxalate at 85 °C for 24 hours, followed by carefully defined treatment with alcohol, acetic acid and calcium chloride. Pectic substances are most abundant in leaves, e.g., ivy, sycamore, and in apples or oranges, especially the white peel of the latter.

Cellulose dissolves in Schweitzer's reagent, an ammoniacal solution of cupric oxide. After treatment with an alkali, the addition of carbon disulfide causes formation of sodium xanthate, a process used in the production of rayon. See also **Fiber**. The action of acetic anhydride in the presence of sulfuric acid produces cellulose acetates, the basis for a line of synthetic materials. See also **Cellulose Ester Plastics (Organic)**. Nitrocelluloses are produced by the action of nitric acid and sulfuric acid on cellulose, yielding compounds that are highly flammable and explosive. See also **Explosive**.

On a heavy tonnage basis, cellulose is important as a raw material in the production of wood pulp and paper. See also **Papermaking and Finishing**; and **Pulp (Wood) Production and Processing**.

Dietary aspects of cellulose are given in the entries on **Digestive System (Human)**; and **Digestive System (Ruminants)**.

CELLULOSE ESTER PLASTICS (Organic). The cellulosics are unique among the plastics in that the basic materials used in their manufacture are not synthetic polymers. Rather, they are derivatives of a natural polymer, *cellulose*. See also **Cellulose**. The preparation of an organic cellulose ester plastic involves the formation of a suitable cellulose derivative, followed by processing steps that convert the cellulose derivative into a plastic.

Cellulose, with its many hydroxyl groups, can react with organic reagents such as acids, anhydrides, and acid chlorides to form organic esters. The first reported organic ester of cellulose was cellulose acetate, prepared by Schützenberger in 1865 by heating cotton and acetic anhydride to about 180 °C in a sealed tube until the cotton dissolved. Franchimont, in 1879, accomplished this reaction at a lower temperature with the aid of sulfuric acid as a catalyst. The product in both cases was very nearly the triester. Miles, in 1903, first described partially hydrolyzed (generally called "secondary") cellulose acetate and distinguished it from the triacetate by its acetone solubility. The solubility of secondary cellulose acetate in such inexpensive and relatively nontoxic solvents as acetone contributed greatly to the development and commercialization of this material.

Cellulose esters of the 2-, 3-, and 4-carbon acids are readily prepared by the cellulose-anhydride reaction; the acetate ester and the mixed acetate butyrate and acetate propionate esters are manufactured and used in large amounts. Esters of higher acids require different synthesis techniques and tend to be prohibitively expensive except as specialty products. Some are in commercial production, however. Cellulose acetate phthalate, for example, is manufactured for use as an enteric coating on pills.

Most commercial preparations of cellulose esters still follow, basically, the methods described by Franchimont and Miles — esterification with sulfuric acid catalyst followed by hydrolysis. The principal steps in this process are shown in Fig. 1.

Esterification. The nature of cellulose is such that its esterification does not occur randomly. Even when the DS (degree of substitution — the average number of hydroxyl groups replaced per anhydroglucose unit in the cellulose chain) is approaching 3 (complete reaction), many anhydroglucose units have a DS of zero. If the ester is recovered before the reaction is complete, the product will not be homogeneous and it will be hazy. Regardless of the desired DS of the final product, therefore, the reaction must be allowed to proceed to virtual completion if a homogeneous material is to be produced. In most processes, the ester dissolves in the reaction mixture as the reaction approaches completion.

The cellulose used to manufacture cellulose esters is highly purified cotton linters or wood pulp. It is generally treated to reduce its crystallinity and make it more reactive, then agitated at somewhat elevated temperatures with the appropriate acids, anhydrides, and catalyst until it dissolves. Some of the polymeric chains of the cellulose are broken during the reaction, and consequently the molecular weight decreases; thus, the catalyst concentration, reaction temperature, and reaction time must be controlled very carefully to give a product of the desired molecular weight.

Some acetate ester is recovered at the completion of reaction and marketed as commercial cellulose triacetate; it has a DS very close to 3. Other triesters have found no commercial applications.

Hydrolysis. The compatibility of a cellulose ester with other materials is influenced by the acid or acids used in its preparation, but it is controlled primarily by the hydroxyl content of the ester, which varies reciprocally with the degree of substitution. Cellulose triacetate, for example, does not dissolve in acetone; its solution requires very strong solvents such as methylene chloride. Plasticizers can be added to the triacetate in solution and will remain in the ester if the solvent is removed. Plasticizer added in this manner will affect some of the properties of the triester, but they will not appreciably reduce its softening temperature, which is higher than its

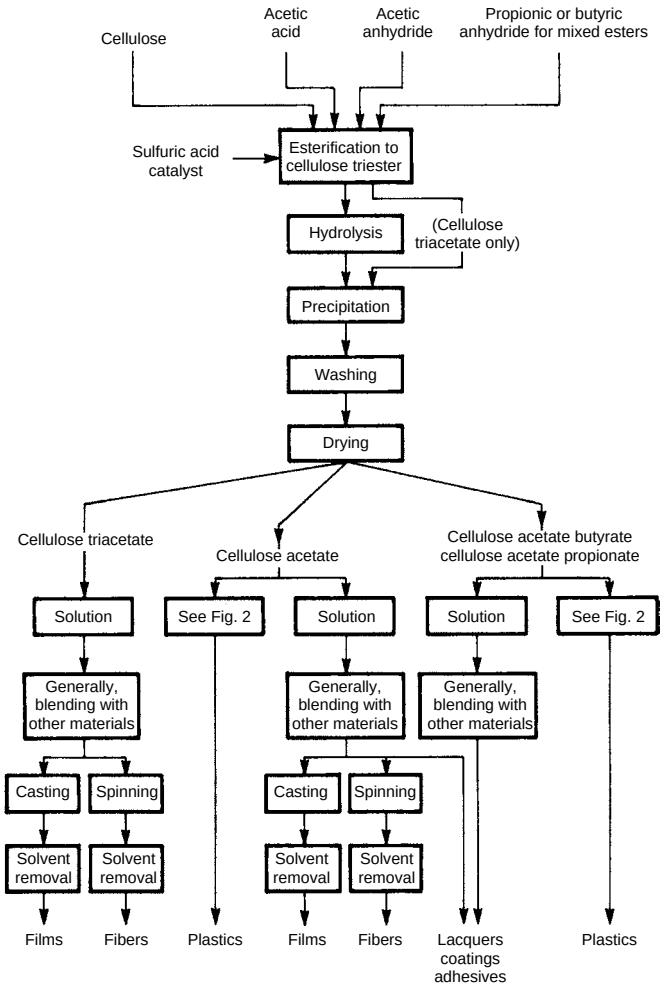

Fig. 1. Production and end-uses of organic cellulose ester.

decomposition temperature. The hydroxyl groups in secondary cellulose acetate, however, have for other polar materials an affinity that is lacking in the triacetate. The ester will dissolve in acetone, and plasticizers will both affect its mechanical properties and reduce its softening temperature sufficiently for the mixture to be processed as a thermoplastic. It is necessary, then, that cellulose esters to be used for plastics contain a significant number of hydroxyl groups, and these are produced by partial hydrolysis of the triester formed in the reaction step. Since the triester is in solution, hydrolysis is random and produces a homogeneous product.

Hydrolysis is initiated by the addition of water and stopped at the desired point by neutralization of the catalyst.

Precipitation, Washing, and Drying. The cellulose ester in solution in the reaction mixture is precipitated by the addition of water. Some precipitation processes produce a flake precipitate; some produce a powder. The precipitate is removed from the slurry, washed with water until it is free of acids, and dried.

Cellulose Esters

The cellulose esters that result from the process described are chemical raw materials and are used by many branches of the chemical industry. They are generally characterized by acyl content in weight percent and viscosity in seconds, the viscosity being obtained by timing the fall of a steel ball through a solution of the cellulose ester in accordance with ASTM Method D 1343. Low-viscosity esters are generally used in solution processes; high-viscosity esters are used in the production of plastics.

Cellulose Triacetate. It has already been implied that cellulose triacetate will not produce a thermoplastic, as its softening point cannot be reduced appreciably by plasticizers. It is used in solution processes, however, to produce films and fibers. Triacetate films absorb less water than films of secondary cellulose acetate, and they are therefore more dimensionally stable in environments where the humidity is not controlled. Triacetate fibers, with a similar resistance to water, impart to fabrics wrinkle resistance, dimensional stability, and the ability to dry rapidly. Under United States federal regulations, a fiber must be made from a cellulose acetate having at least 92% of its hydroxyl groups acetylated if it is to be called "triacetate."

Cellulose Acetate. Like the triacetate, secondary cellulose acetate (CA) is used in solution processes to produce fibers and films. CA fibers were originally called "rayon," the name that was already in use for regenerated cellulose fibers. In 1951, however, the regulatory authorities formally acknowledged the chemical distinction between CA and cellulose, and the term "rayon" was reserved for fibers of regenerated cellulose. CA fibers are officially called "acetate," and they are used in a wide variety of fabrics. They also are used for cigarette filters. However, the majority of CA produced is used for manufacture of plastics.

Cellulose Acetate Butyrate and Cellulose Acetate Propionate. These two cellulose esters are somewhat similar in properties and applications. Cellulose acetate butyrate is commonly referred to in the chemical industry as CAB, while cellulose acetate propionate is simply termed "cellulose propionate" and referred to as CAP or as CP.

The major usage of CAB and CP is in plastics. Additionally, CAB and CP are mixed with a variety of synthetic polymers to produce lacquers for wood, metal, and plastics. CAB finds relatively small usage in hot-metal coatings and in optical-grade cast film used in the manufacture of sunglass lenses.

Organic Cellulose Ester Plastics

Although the first cellulose plastic (cellulose nitrate plastic-based on an *inorganic* ester of cellulose) was developed in 1865, the first *organic* cellulose ester plastic was not offered commercially until 1927. In that year, cellulose acetate plastic became available as sheets, rods, and tubes. Two years later, in 1929, it was offered in the form of granules for molding. It was the first thermoplastic sufficiently stable to be melted without excessive decomposition, and it was the first thermoplastic to be injection molded. Cellulose acetate butyrate plastic became a commercial product in 1938 and cellulose propionate plastic followed in 1945. The latter material was withdrawn after a short time because of manufacturing difficulties, but it reappeared and became firmly established in 1955.

Since the cellulose esters CA, CAB, and CP are chemical raw materials, the word "plastic" was used in the preceding paragraph to differentiate the product from the raw material. The cellulose ester plastics are commonly called simply "acetate," "butyrate," and "propionate," and these names will be used in the text that follows.

Commercial Production. In the manufacture of cellulose ester plastic, the appropriate ester is blended with plasticizer and other additives, such as stabilizers, ultraviolet inhibitors, dyes, and pigments, commonly in a large sigma-blade mixer. The mixture thus obtained is heated to its softening temperature and kneaded until it is homogeneous. This is done on hot milling rolls, in a compounding extruder, or in a Banbury mixer. The molten mass of plastic that results is formed into small rods or strips that are then cut into cylindrical or cubical pellets, which ordinarily have dimensions of about $\frac{1}{8}$ inch (3 millimeters). See Fig. 2.

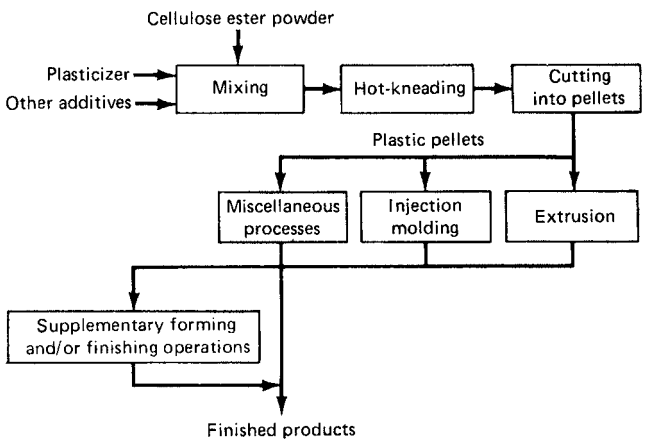

Fig. 2. Manufacture of cellulose ester plastics.

Properties. The concentration of plasticizer in a cellulose ester plastic determines its "flow temperature," which in turn determines its "flow designation," as defined by ASTM Method D 569. Flow designations range from various degrees of hardness (H4, H3, H2, H) through medium-hard (MH), medium (M), and medium-soft (MS) to various degrees of softness (S, S2, S3, S4, etc.). At any given flow designation, the characteristics of the plastic will vary somewhat with the identity of the plasticizer used. Some plasticizers, for example, give very hard materials, some give very low water absorption, and some permit unusual ease of processing. The flow temperature is used for quality control and the corresponding flow designation is a part of the purchase specification when material is ordered.

Depending upon plasticizer content, cellulose ester plastics range from soft, extremely tough materials to hard, strong, stiff compositions that still retain a considerable degree of toughness over a wide range of temperatures. They are basically transparent and virtually colorless, which makes it possible for them to be manufactured in almost any desired transparent, translucent, or opaque color. They are resistant to water and aqueous salt solutions, but they are attacked by aqueous solutions that are strongly acidic or basic. They resist several types of organic solvents, such as ethers and aliphatic hydrocarbons, but they are dissolved or swollen by strongly polar liquid organic compounds such as aromatic hydrocarbons, chlorinated hydrocarbons, ketones, and esters. The susceptibility of the plastics to attack decreases as the molecular weight of the attacking compound increases.

All three cellulose ester plastics are available in formulations that meet the regulatory requirements for use in contact with food.

Butyrate and propionate are available in special formulations for continuous use outdoors, where they generally remain useful for several years. Formulations other than the special outdoor-type materials should not be used in this manner. Acetate formulations are not suggested for outdoor use, as CA does not respond well to the addition of protective compounds.

Although acetate, butyrate, and propionate resemble each other in many ways, there are a number of significant differences among them. Butyrate and propionate are generally easier to process than acetate, and this factor, also, subtracts from the price advantage of acetate. Acetate is available in very hard flows, so it can be obtained with higher stiffness, hardness, and tensile strength than can the other two cellulose ester plastics. Butyrate is available in the softest flows, so it can be obtained in the toughest and easiest-processing formulations. Butyrate and propionate are generally considered to be tougher than acetate, even though in some instances the measured impact strengths may be similar. Butyrate retains its toughness better than does propionate at low temperatures. Butyrate and propionate use higher-boiling, less-water-soluble plasticizers than does acetate, which leads to better retention of plasticizer by butyrate and propionate when exposed to elevated temperatures or to the leaching action of water. Better plasticizer retention, in turn, leads to better permanence characteristics in the plastic — i.e., smaller changes in dimensions and properties with time.

Processing. The organic cellulose ester plastics are versatile materials and can be processed by almost any hot-processing technique used for thermoplastics. The principal techniques for all three plastics are injection molding and extrusion. Blow molding is also possible. Butyrate and propionate powder are used in fluidized-bed and electrostatic coating processes, as well as in the rotational molding process.

The toughness of cellulosics nearly always enters into the selection of one of these plastics for a particular application, but if the potential toughness of cellulosics is to be realized, the materials must be processed correctly. Correct processing involves heating the plastic sufficiently for it to flow freely (*not* forcing half-melted plastic through a die or into a mold) and cooling it slowly. Fast cooling causes the outside of the finished product to harden while the inside is still molten. When the inside cools and contracts, powerful stresses form within the plastic, and these frozen-in stresses can detract very significantly from the toughness of the plastic. Sprues, runners, trim, and other scrap from molding and extrusion operations, if kept clean, can be reground, mixed with new feed stock, and reused. Butyrate and propionate are sometimes compatible with each other, but acetate is not compatible with either of the others and must not be allowed to contaminate them. Synthetic polymers must be rigorously excluded from all cellulosics.

CELLULOSICS (Applications). The cellulose ester plastics described in the prior article are suitable for a wide range of uses because of their exceptional balance of properties. Cellulose acetate and cellulose acetate butyrate are widely used for making tool handles because of their toughness, torque strength, and machinability for obtaining a good grip. Tool parts can be solvent vapor-polished to a smooth finish.

Acetate and propionate are widely used in eyeglass frames because their properties are well adapted to the post-finishing operations needed. Cellulosics are frequently used for a variety of home furnishing products, such as table edging and venetian blind wands, and fixtures. The clarity of the finished plastic is desirable for such applications.

Increasing numbers of retail goods, such as small hardware pieces, electronic parts, and some apparel, including T-shirts, underwear, and pantyhose, are packaged in cellulosic tubes. Because of their clarity and toughness, butyrate and propionate are commonly used. Tooth and hair brushes are commonly made of butyrate, again where clarity and toughness are required. Other major uses for cellulosics include extruded tape, audio tape, pressure-sensitive tape, gold-stamped foils, and face shields. Printed signs for interior use frequently are made from butyrate sheet. When coated with a weather-resistant formulation, butyrate is often used for heavy-gage outdoor signs.

In the automotive industry, propionate and butyrate find many over-foil uses, where the plastics are coated over foil strips for vehicle trim.

CELP (Code Excited Linear Predication). See **Data Compression**.

CELSIUS. Temperature scale proposed by Swedish astronomer Anders Celsius in 1742. A mixture of ice and water is zero on the scale; boiling water is designated as 100 degrees. A degree is defined as one hundredth of the difference between the two reference points, resulting in the original term, "centigrade" (100th part). To convert Celsius to Fahrenheit: multiply the Celsius temperature by 1.8 and add 32 degrees. $F = 9/5\ C + 32$. To convert Fahrenheit to Celsius: subtract 32 degrees from the Fahrenheit temperature and divide the quantity by 1.8. $C = (F - 32)/1.8$. See also **Units and Standards**.

CELSIUS, ANDER (1701–1744). Celsius was a Swedish astronomer, mathematician, and physicist. He is best known for his development of a temperature scale based on the decimal system with fixed points separated by one hundred degrees. He proposed all scientific measurements of temperature should be based on the boiling point and the freezing point of water.

Celsius was a professor of astronomy at Uppsala University. He is noted for trying to determine the magnitude of the stars in the constellation Aries. He published 316 of his observations on the aurora borealis.

See also **Celsius**; and **Heat**.

CELSIUS DEGREE. See **Units and Standards**.

CEMENT. Cement is a finely powdered substance that possesses strong adhesive powers when combined with water. Gypsum plaster (see also **Calcium**), common lime, hydraulic limes, Puzzolan, natural and Portland cements are a few of the materials which are used for cementing purposes.

Portland cement, which is the most important of these materials since it is a basic ingredient of concrete, was first manufactured in England in the early part of the nineteenth century. It derived its name from the fact that this newly discovered cement resembled a building stone that was quarried near Portland, England.

There are three fundamental stages in the process of manufacture of Portland cement, namely, (1) preparation of the raw mixture, (2) production of the clinker, (3) preparation of the cement. Whether the process used is wet or dry, the raw materials are selected, analyzed, and mixed so that, after treatment, the product, or clinker, has a desired, narrowly specified composition. A factory analysis of slurry, where the wet process is

in use, is as follows: calcium oxide 44%, aluminum oxide 3.5%, silicon oxide 14.5%, ferric oxide 3%, magnesium oxide 1.6%, loss on ignition about 33% (largely carbon dioxide), showing that the composition of the resulting burned clinker is essentially a calcium aluminosilicate. The system calcium oxide-aluminum oxide-silicon oxide has been determined by Rankin and co-workers. In some places the composition of the rock is practically of the desired composition, and in other places clay and limestone are mixed in the desired proportions.

The raw mixture is heated in a continuously operated, long, almost horizontal, slowly rotated furnace or kiln at a high temperature. The temperature is regulated so that the product consists of sintered but not fused lumps. This is clinker. Too low a temperature causes insufficient sintering, and too high a temperature results in a molten mass or glass, the product in either of these cases being valueless for cement purposes. Clinker is unaffected by water, and may be stored indefinitely without detriment. In 1824, Joseph Aspin, an English bricklayer, took out a patent for the manufacture of an improved cement, which he called Portland cement. The cement thus produced was not what is known now as Portland cement as the temperature of burning was not sufficiently high. The value of burning at a temperature sufficiently high to cause incipient fusion was soon afterwards discovered.

In order to obtain the desired setting qualities in the finished cement, there is added to the clinker about 2% of gypsum (calcium sulfate, $CaSO_4 \cdot 2H_2O$), and the mixture is pulverized very finely. For every ton of Portland cement shipped, over two and one-half tons of raw materials *and* cement clinker must be ground very finely. See Table 1.

The wet process for making cement is shown in the flowsheet in Fig. 1. Selective quarry of raw materials for specific cement requirements is based upon chemical data. A television receiver, mounted on the quarry control panel, oversees these operations. Rocks sent to the crushing plant are reduced to pieces smaller than 2 inches. These are dropped onto a reversible shuttle conveyor that stockpiles the materials according to chemical composition in the raw materials storage located above a reclaiming tunnel. From the stockpiles, vibrating feeders then withdraw specified amounts of raw materials and discharge them over a 1230-foot (375-meter) belt conveyor that passes through the reclaiming tunnel. A television camera at the tunnel entrance observes the materials on their way to the next crushing stage. A second television camera supervises the screening operation, and a third camera observes the unloading of crushed material into the storage silos.

Raw materials, withdrawn from the silos, are conveyed to the raw-grinding mill, and water is added. A sonic system which "listens" to the sound of steel balls impacting the inside of the mill indicates the amount and fineness of the material being ground. Feedback from this system controls the feed rate to the mill. Raw-mill discharge (a slurry of about two-thirds solids content) is screened over a 50-mesh screen cloth and pumped to two slurry basins where it is homogenized. Each basin (44 feet high $\times$ 85 feet diameter) (13.2 meters high $\times$ 25.5 meters diameter) holds about a 3-day supply for the kiln.

The rotary kiln is 510 feet (153 meters) long and is fired by oil. Maximum daily output of the kiln is 1,760 tons (1,584 metric tons) of clinker, equivalent to 9,700 barrels of cement. Operations are automatically controlled, and two television cameras, one at each end of the kiln, observe all material flow.

In its downward path through the kiln, the slurry passes first into a 91-foot long drying zone (maintained at 2,000 °F) (1,093 °C) and then into a hotter (above 2,800 °F) (1,538 °C) calcining and burning section. The drying zone is fitted with steel chains to improve fuel efficiency through better heat transfer. Feed rate of the oil is controlled by the gas temperature in the calcining zone. Thermocouples placed at intervals inside the kiln measure the temperature of solid particles and kiln gases. The critical parameters are relayed to the plant central control room.

The initial quarrying, primary, and secondary crushing and screening of raw materials are not shown in the flowsheet. See also **Gypsum**.

When Portland cement is mixed with water, the product sets in a few hours and hardens over a period of weeks. The initial setting is caused by the interaction of water and tricalcium aluminate $3CaO \cdot Al_2O_3$, present in the cement, accompanied by the separation of gelatinous hydrated product. The later hardening and the development of cohesive strength are due to the interaction of water and tricalcium silicate $3CaO \cdot SiO_2$, also present in the cement, accompanied by the separation of gelatinous hydrated product. In each case the gelatinous material surrounds and cements together the individual grains. The hydration of dicalcium silicate $2CaO \cdot SiO_2$, also present in the cement, proceeds still more slowly than that of the above compounds. The ultimate cement agent is probably gelatinous hydrated silica SiO_2. See also **Concrete**. The analyses of some typical Portland cements are given in Table 2.

Deductions regarding the mechanism of setting and hardening, and the identity of the substances concerned are the results of extensive studies, involving the use of the microscope in the examination of thin sections, on the individual compounds, the clinker, and the resulting concrete. Elaborate researches have also been conducted to determine the best way of incorporating the ingredients of concrete, the nature of the aggregate (sand, gravel, crushed rock) to be used, and the proportions of cement, water, and aggregate, in order that the resulting concrete, really an artificial rock, shall possess the greatest possible strength.

Special applications of cements and lutes are frequently demanded, as for example in floor covering, in tank lining, and in the closure of joints. The difference between a cement and a lute is that the former sets to a rigid solid mass whereas the latter retains some plasticity so that some movement of the lute is possible without cracking. A lute must have support in order that it be retained in position.

A somewhat crude though convenient classification can be made on the basis of the principal ingredients, thus, (1) Portland cement, (2) high alumina cement, (3) sodium silicate, (4) magnesium oxychloride plus copper powder, (5) litharge or red lead plus glycerol, (6) rubber latex, and (7) synthetic resins. Supplementary materials to be considered are asbestos, white lead, plaster of Paris, sulfur, graphite, sand, pitch, tar, rosin, and boiled linseed oil.

The choice to be made depends upon the kind of material to which the cement or lute must adhere; what it must withstand in the way of acid, base, sulfate, or organic liquid; also what temperature is involved; and finally the matter of resistance to vibration and shock.

Portland and high alumina cements do not withstand acids but are resistant to bases. High alumina cement attains its maximum strength more quickly than Portland, and has the extra advantage that it withstands solutions of sulfates.

[a] From Meade's "Portland cement."
[b] White Portland cement.
[c] Seawater cement.

Sodium silicate cement does not withstand bases, but is resistant to acids except hydrofluoric. This cement sets to a very rigid solid, so that when subjected to mechanical shock or to temperature change it is liable to crack.

A cement containing 90% magnesium oxychloride and 10% copper powder is strong, resistant to abrasion, and can be bonded to Portland cement.

Rubber latex cement withstands dilute acids and dilute bases, and adheres well to ceramic materials such as stoneware. This cement remains somewhat pliable, thus resisting mechanical shock and temperature change. Organic liquids in general attack this cement.

Synthetic resin cements withstand hydrochloric acid, dilute nitric acid, dilute sulfuric acid, and dilute bases, and are frequently more resistant to organic liquids than is rubber latex cement. The adherence to ceramic materials is good, and the liability to cracking less than for sodium silicate cement.

As for the miscellaneous ingredients mentioned, some are used as fillers or extenders as in the case of sand, and some are used in their own right as when pitch, tar, rosin, molten sulfur, or packed asbestos can be used. See also **Adhesives**.

CEMENTATION. In geology, cementation is the process of deposition from solution of mineral matter in the interstices of rocks, and is an important factor in the consolidation of coarse-grained elastic rocks such as sandstones and conglomerates or breccias. This action is continually going on in the groundwater zone, so much so that the term zone of cementation has come into common use.

Cementation may occur in fissures or other openings of the rocks and in time all such spaces will be closed to further deposition or entrance of groundwater.

In metallurgy, cementation is the process by which one substance is caused to penetrate and change the character of another, by the action of heat, at temperatures below the melting points.

CEMENTITE. Iron carbide, Fe_3C, is a compound present at room temperature in nearly all iron-carbon alloys such as steel and cast iron. It is very hard and brittle and weakly magnetic and has an orthorhombic *crystal* structure. In commercial steels, the chemical composition of cementite is usually changed by the presence of manganese and similar carbide forming elements in the steels, which replace iron atoms in the compound. Cementite is a metastable phase and, under the proper conditions, decomposes to form carbon (graphite) and iron. In ordinary steels, this decomposition rarely occurs. Most cast iron, however, contains graphite. This is because the higher silicon content of the cast iron makes cementite less stable. See also **Iron Metals, Alloys, and Steels**.

CENOPHYTIC. A paleobotanic division of geologic time. This term signifies the time that has passed since the development of the angiosperms in the middle or late Cretaceous. See also **Paleobotany**.

CENOZOIC. An era of geologic time, from the Tertiary period to the present. Considered to have begun about 70 million years ago, the Cenozoic is characterized paleontologically by the evolution and abundance of mammals, advanced mollusks, and birds. Paleobotanically, it is characterized by angiosperms. Informally, the Cenozoic era is sometimes referred to as the *age of mammals*. See also **Geologic Time Scale**.

CENTAURUS (the centaur). A large and brilliant constellation of the southern sky, which is invisible to observers in North America and Europe. Centaurus has two bright stars, frequently spoken of as the "southern pointers," since the line through them passes through the Southern Cross (the constellation Crux). The brighter of these stars (a Centauri) is not only the third brightest star in the entire sky, but also the nearest bright star to earth, at a distance of 4.3 lightyears. The only star known to be closer to the earth is a faint star known as Proxima Centauri. Alpha Centauri is a double star, and its brighter component is interesting in that it is almost a duplicate of our sun in size, temperature, and other physical characteristics. (See map accompanying entry on **Constellations**.)

CENTER GAGE. A small gage used for checking lathe center point angles and threading tool points; also used for setting single-point threading tools on a lathe.

CENTER (Instantaneous). The point about which a body having general motion may be considered to be in pure rotation (i.e., without translation) for any instant. The instantaneous center is not necessarily on the body; in fact, it can be, in the case of rectilinear motion, infinitely distant.

CENTER OF ACTION. 1. Any one of the semi-permanent highs and lows that appear on mean charts of sea level pressure. As originally used by L. Teissenenc de Bort in 1881, this term was applied to maxima and minima of pressure on daily charts. The main centers of action in the Northern Hemisphere are the *Icelandic low*, the *Aleutian low*, the *Azores high* and/or *Bermuda high*, the *Pacific high*, the *Siberian high* (in winter), and the Asiatic low (in summer). Other less intense or less consistent mean systems may be considered. Fluctuations in the nature of these centers are intimately associated with relatively widespread and long-term weather changes.

2. As used by Sir Gilbert Walker, any region in which the variation of any meteorological element is related to weather of the following season in other regions.

AMS

CENTER OF GRAVITY. For an extended body or collection of particles subject to the earth's gravitation, the point through which the resultant force of gravity acts (i.e., the weight of the body or collection) no matter how the body is oriented. In a uniform gravitational field in which the ratio of gravitational force to mass is always the same, the center of gravity is the same as the center of mass. See also **Centroid**.

The mathematical definition of center of gravity is

$$\mathbf{x}_e = \left(\int \mathbf{x}\rho dV\right) \Big/ \left(\int \rho dV\right)$$

where vector $\mathbf{x}$ describes the position of the object in a given coordinate system, $\rho = \rho(\mathbf{x})$ is the density, and V is the volume of the object.

CENTER OF MASS. Imagine a body divided into infinitesimal particles or elements of mass. If each of these elements is acted upon in the same direction, chosen at random, by a force proportional to its mass, it is easily shown that, whatever the direction of this set of parallel forces, their resultant mean always passes through a certain point, which is the center of mass of the body. Since the weights of the particles of a small body constitute approximately such a system of forces, it has become customary to call this point the center of gravity, though it is in general not strictly correct to do so.

If the body is given a linear acceleration in any direction without rotation, since the inertia of each particle is proportional to its mass and acts in direct opposition to the acceleration, the resultant inertia of the whole body acts in a line through the center of mass; which is therefore properly called also the center of inertia.

If any plane is passed through the center of mass of a body, it divides the body into two parts which have the property that their mass moments with respect to the plane are equal but of opposite sign. This means that if the mass of each particle is multiplied by its distance from the plane, and the products added, the sum is numerically the same for both parts of the body. This principle may be put into mathematical form and the position of the center of mass calculated therefrom. It may be shown, for example, that the center of mass of a homogeneous right circular cone is on its axis at a distance from the apex equal to 2/3 of the altitude. For a continuous body of homogeneous material, the center of mass coincides with the centroid. See also **Centroid**.

CENTER-OF-MASS SYSTEM. In general, any frame of reference that moves with the center of mass of a system. Calculations in the center-of-mass system are often simpler than in other coordinate systems because the total momentum in the former is always zero.

CENTER OF OSCILLATION. The frequency of oscillation of a physical pendulum is given by

$$f = \frac{1}{2\pi}\sqrt{\frac{gl}{k^2 + l^2}}$$

where l is the distance from the point of suspension to the center of mass, and k is the radius of gyration. A simple pendulum having the same frequency will be of length

$$l_1 = \frac{k^2 + l^2}{l}$$

The point that lies at a distance l_1 from the point of suspension on the line through the point of suspension and center of mass is called the center of oscillation. If the physical pendulum were to be suspended from this point, its frequency would be the same as for the original point of suspension. See also **Pendulum**.

CENTER OF PERCUSSION. That point (with respect to a given point of suspension) on a rigid rod, like a tennis racket or baseball bat, such that an impulse applied perpendicular to the rod at the point produces no impulsive reaction at the original point of suspension. The center of percussion coincides with the center of oscillation.

CENTER OF PRESSURE (Hydrostatic). The point of application of the resultant of all the pressure forces acting upon an exposed area is called the center of pressure. Water and air create pressures that are of importance in phases of engineering. The center of pressure on a horizontal plane immersed in water to a depth h is the center of the area, that is, the point corresponding to the center of mass of a flat, uniform plate coinciding with the area.

More generally, if a plane surface is completely immersed in a liquid at an angle θ with the horizontal, the center of pressure upon that surface lies at a depth below the top of the liquid, given by the equation $d = \sin\theta \cdot I/M$; in which I is the moment of inertia of the surface with respect to the line of intersection of its plane with the plane of the top of the liquid, and M is the moment of the surface with respect to the same intersection. For a vertical surface ($\theta = 90°$), $d = I/M$. Thus, in the case of a vertical rectangle whose upper and lower edges are horizontal and at depths h_1 and h_2, and whose width is b, we have $I = b/3(h_2^3 - h_1^3)$, while $M = b/2(h_2^2 - h_1^2)$; hence the depth of the center of pressure is

$$= \frac{2}{3}\frac{h_1^2 + h_1h_2 + h_2^2}{h_1 + h_2}$$

In particular, if the upper edge is at the top of the liquid, and if the altitude of the rectangle is a, so that $h_1 = 0$ and $h_2 = a$, $d = \frac{2}{3}a$.

See **Hydrostatics**.

CENTER OF SYMMETRY. A point within a body or within a set of points, having such location that for every point there is a similar point on a line passing through the first point and the center of symmetry, the distance of the two points from the center being identical. If the center of symmetry is located at the origin of a Cartesian coordinate system, then for every point with coordinates x, y, z there will be an identical point with coordinates $-x, -y, -z$.

CENTER PUNCH. A hand tool with a sharp conical point, used for layout work and locating centers for drilling.

CENTIPEDE *(Insecta, Arthropoda, Chilopoda).* Worm-like land-living tracheate animals with segmented bodies, a distinct head bearing a pair of antennae and three pairs of jaws, and a pair of jointed legs on most segments of the body. The first pair of legs is modified as poison claws for the capture of prey.

The centipedes differ from the nearly related millipedes (*Diplopoda*) in the presence of poison claws, in having only one pair of legs to a segment and in the more flattened body. Each segment has a dorsal and a ventral plate connected by softer tissue and has the legs joined to the sides of the body.

The house centipede (Fig. 1) is not to be confused with the garden centipede or symphylid. The latter is damaging to vegetable plants, whereas the house centipede consumes numerous insects, including roaches, flies, and other small species, and thus is considered a beneficial insect.

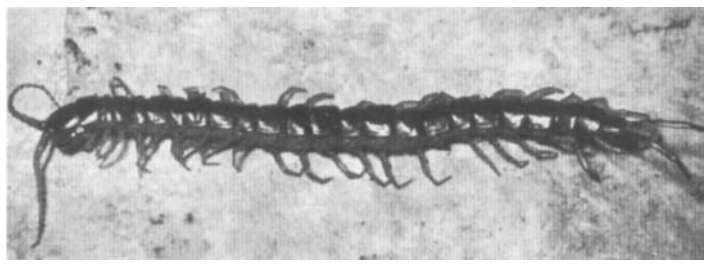

Fig. 1. Centipede. (*A.M. Winchester*.)

CENTRAL AND PERIPHERAL NERVOUS SYSTEMS. At the end of the twentieth century, the neurosciences were intensely active, but they had not achieved a semblance of maturity. Although some knowledge of the human nervous system dates back nearly two centuries, numerous uncertainties pertaining to the fundamental principles of neuroscience remain to be clarified. Just within the relatively past few years have molecular and genetic science, as examples, been applied to this multifaceted and very intricate field. A flood of recent literature and the lively interchanges

of viewpoints among the experts are indicative of a science that still is searching for agreement on various fundamentals. Only in the recent past have techniques, such as *patch-clamp* experimentation, been available to increase the resolution of research measurements. Progress is being made to expand and to meld the many disciplines that participate in the area of neuroscience. Unifying principles for the field remain to be established.

Although not unique in its awareness, the U.S. Congress designated the 1990s as the "Decade of the Brain." But it is interesting to note that the National Institute of Neurological Disorders and Stroke, which required over $700 million for the first year, of the decade, was awarded a smaller increase of less than $500 million.

Organization for Research. The manner in which neuroscience programs are organized depends, of course, on specific interests and whether these be private or governmental. The National Institute for Mental Health (U.S. Public Health Service) has several research branches: behavioral and cognitive sciences; prevention and behavioral medicine; neuroimaging and applied neuroscience; personality and social processes; psychopharmacology; and molecular and cellular neuroscience.

The categorization of the neurosciences has been the subject of debate that reflects similar debates in other fields of scientific endeavor. On the one hand, there is a trend to create macrosciences made up of numerous micro- or minisciences, a situation that has prevailed in the areas of physics and chemistry. Conversely, there is a trend to create classifications that unite all sciences under one umbrella for a given topical field. Thus, several years ago, one commenced to hear of neuroscience used as a unifying term and that continues to persist. Thus created are such areas example, as neuroanatomy, neurochemistry, neuropharmacology and neurology. A relatively recent term used is neurocomputing. The list of specialties is expanding. In a recent countertrend, some of the neurosciences are being treated on a less specialized basis, such as placing cellular neurobiology in with other cell biology programs, and including developmental neurobiology in with developmental biology. Some researchers prefer more a specialized grouping of the neurosciences based upon the observation that brain has unique problems not shared by other systems.

Research Highlights. Major accomplishments in the neurosciences since the mid-1980s include the following. (1) The discovery of scores of neurotransmitters (only four were known in the 1970s). (2) The discovery that the brain, among its many other purposes, also functions as an endocrine gland by synthesizing and releasing several hormonelike peptides. It has been qualitatively established that these substances affect behavior, appetite, reproductive activity, and alleviate pain under certain circumstances. (3) Treatment of brain and nervous system illnesses and disorders, including Parkinson's disease, myasthenia gravis, Huntington's disease, depression, schizophrenia, and Alzheimer's disease, among several others. Advances have occurred, not because there is a full understanding of causation, but through the use of qualitative and clinical observations and experiments. (4) Initial studies that are attempting to relate brain and nervous system function with specific genes, such investigations assisted by probing involved chemicals and their reactions at the molecular level. (5) Neurosurgeons have dealt successfully with nerve transplantation and brain grafts. (6) Considerable research has been directed to describing and isolating specific nerve growth factors and relating these findings to general developmental physiology. (7) An encouraging start has been made in computerized brain mapping. (8) Laboratory research tools and instrumentation have undergone gross improvements, including the development of the patch-clamp technique and refinements of imaging methods. (9) Reviews of the literature reveal much increased activity in developing postulations and theories of neural functions at the neuron and total system level.

Several of the foregoing topics, particularly pertaining to nervous system disease and mental illness and to the function of the human visual and audio perceptive systems, are described elsewhere in this Encyclopedia. Consult alphabetical index.

The Nervous System Complex

Like any other tissue of the body, the brain and nervous system are made up of cells. These cells function in accordance with the same fundamentals that apply to other cells, even though the cells of the complex interwoven brain tissue and the highly specialized cells of the central and peripheral nervous systems engage in unique operations. On a comparatively large scale, investigations of the brain and of the central nervous system can be conducted much as other organs are studied. Maps have been drawn of the interconnections of the brain on a relatively massive, regional basis, but remain severely lacking in terms of the huge numbers (millions or even billions) of interconnections among extremely tiny elements that constitute the infrastructure of the brain. Both the neuroanatomy and neurophysiology of the brain can be described as in a very early stage of understanding. Most scientists will agree that this statement holds even in view of the very impressive progress that has been made in brain and nervous system research over the last several years. Up to a point, the electrical and chemical signaling apparatus of the brain and nervous system can be measured and interpreted, but beyond a general understanding of the brain, the problem of comprehending brain function in depth is of a staggering nature for several reasons.

(*1*) *The sheer numbers* of individual elements of the brain system that exist within an organ whose mass in the average adult human is about 45 ounces (1.3 kilograms), representing an information processing system unparalleled in the universe as it is known today. It is conservatively estimated that there are on the order of 10^{11} (a hundred billion) nerve cells (neurons) in the human brain. This number approximates that of the number of stars in our galaxy. Some neuroscientists consider this figure woefully small. If the 10^{11} figure is assumed, it suggests that neurons in the embryonic and fetal stages, originating as a flat sheet of cells on the dorsal surface (*neural plate*) of the developing embryo, must develop at an average rate of more than 250,000 per minute. Once the production of neurons is completed, there is no further replication during the remainder of life, but as life progresses, large numbers of neurons are destroyed.

How can researchers "get a handle" on so many components? By comparison, the number of components in the most capable of modern computers pales. The number of synapses (*connections*) in the brain is estimated at 10^{14} (100 trillion).

(*2*) *The extremely small size* of the nerve cells is another problem. Research has confirmed that so many "components" are perforce extremely tiny to fit in such a relatively small volume. The typical neuron (cell) is estimated to range from 5 to 100 micrometers (thousandths of a millimeter) in diameter. There are even much tinier subelements which make up these cells. Very important nerve actions occur in which the amount of substance involved is expressed in terms of a few hundreds of molecules.

(*3*) *The variations of form and function of neurons* make generalizations difficult. The neuron is not a conventionally shaped cell. It takes the form of a trunk of a tree with a well-developed root system, where the trunk may be as short as 10–12 micrometers (thousandths of a millimeter) in diameter, and yet the entire cell may have a length ranging from as short as 0.1 millimeter to as long as 1 meter or more. Because neurons are tightly packed in many regions of the brain, they tend to occur in "thickets," much as the intertwining roots of closely planted trees. But, despite the high-density packing, a very effective insulation between the intertwining fibers provides full chemical and electrical integrity of each neuron except at specific designated points (*synapses*) of connection. The fluid film that provides this protection of nerve fibers is only about 0.02 micrometer in thickness.

As will be evident from later descriptions, there are many variations in the physical and electrical and chemical characteristics among individual neurons and, to date, these variations have not been easy to classify in terms of a relatively few categories. An important aspect of progress in neuroscience during recent years has been that of identifying previously unknown neuron forms and characteristics and developing a series of generalizations that provides pathways toward a better understanding of specific information. Although from a systems standpoint, there appears to be a high degree of specificity represented by the neurons and their synapses, the tight packing of these elements into such a small volume (skull) creates a type of geometry that tends to defy the neatness desired by the human analytical mind. It is as though millions of very neatly arranged computer circuit boards or silicon chips were tightly squeezed into a plastic ball, but with the integrity of these elements still maintained. Although the analogy is not very apt, the intricacies of the brain resemble the "spaghetti" of wiring encountered in an old-fashioned radio chassis as contrasted with the extreme neatness and geometry of modern electronic equipment.

(*4*) *The dynamics of the brain system* can only be partially studied by examining dead brain tissue. It will be recalled that death itself is defined in terms of "brain death." It is the living, functioning brain that yields a

full comprehension of brain function. Lower animals and some primates have provided leads to understanding the human brain function. Much of what has been learned concerning the nerve impulse has been gleaned from studies of the squid.

Research Breakthroughs of the Past. Because of the very high-density packing of neurons in brain tissue, a discovery by the Italian anatomist Camillo Golgi, as early as 1875, was of great note. Although the phenomenon of Golgi's brain tissue staining technique remains unexplained, the technique makes it possible to stain only small numbers of brain cells at any one time. This technique has proved invaluable to neuroanatomy and neurophysiology because the method allows specific identification and study of a few components that otherwise would be lost in a morass of thousands upon thousands of similar components. A Spanish contemporary of Golgi, Ramón y Cajal, applied Golgi's technique over a lifetime and in 1904 published "*Histologie du système nerveux de l'homme et des vertébrés*." This publication is still regarded as the greatest single work in neurobiology. In the time of Golgi and Cajal, the research tools were confined to the staining technique and the light microscope. One of Cajal's sketches of Golgi-stained nerve tissue is shown in Fig. 1. Within these limitations, Cajal proposed two important concepts: (1) Patterns do not suggest a network (particularly as suggested by a modern computer network), but rather a system comprised of specific cells which communicate with each other only at certain points (connection points or synapses). (2) Interconnections do not suggest a random arrangement, but rather a highly structured, quite specific arrangement. One might suggest that perhaps the organization of the brain may provide new concepts in computer engineering that can be reduced to practice only after a great deal more is learned of brain function and organization. Based upon present knowledge, the often suggested brain-computer analogy is of little value.

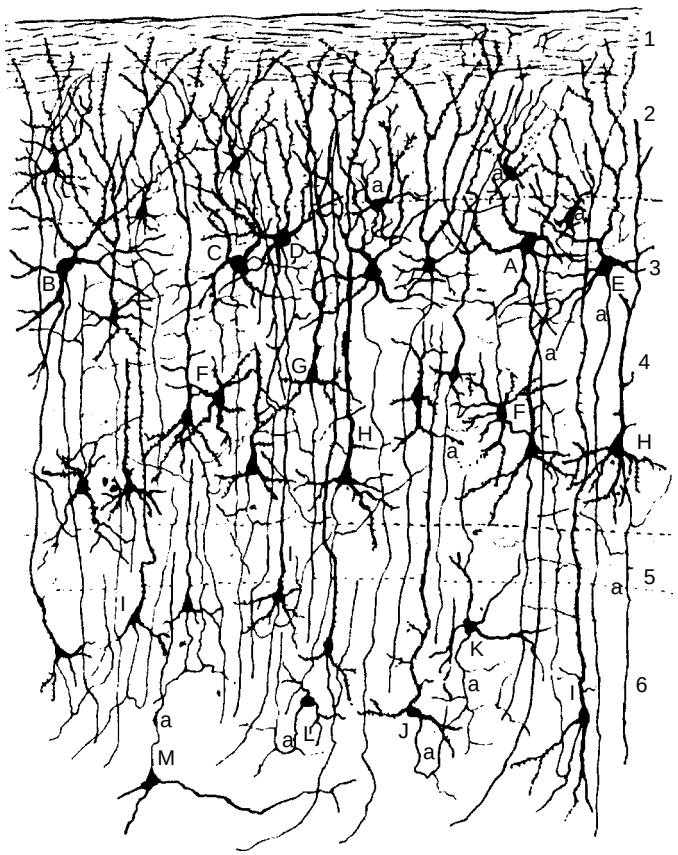

Fig. 1. Sketch from "Histologie du système nerveux de l'homme et des vertébrés," published by Ramón y Cajal in Spain in 1904. Cellular layers are identified by numerals at right-hand edge of diagram. Neurons are indicated by capital letters.

It was not until the early 1950s that a scientist in the Netherlands, Walle J.H. Nauta, developed an improved staining method. Nauta found that there is a short period of the time during which the nerve fiber degenerates when the fiber can be stained to differentiate it from living fibers. Thus, it is possible to trace that fiber to a specific neuron that may be remotely located in some other region of the brain. This technique has greatly expanded the researcher's ability to trace interconnections, and thus, add many details to the maps of the brain.

Since the mid-1960s, other advanced techniques have contributed in a major way to developing a better understanding of the anatomy of the brain. One of these is the injection of radioactive substances into brain tissue. Some of these substances are absorbed by cell bodies and transported to terminals; other substances are absorbed by the terminals and transported by axons to the cells. In a technique developed by Louis Sokoloff (National Institute of Mental Health), radioactively labeled deoxyglucose is used. This substance collects in nerve cells and the degree of accumulation is an indicator of a cell's activity. This technique is used in conjunction with known laboratory stimulation of various areas of the brain and thus permits brain research in real time as contrasted with examining dead tissue. For example, if the stimulation is aural, those cells involved in the process of hearing will be active and can be revealed by later microscopic examination. In a more recently developed technique, positron-emitting radioactive isotopes are combined with tomography, which makes it possible to conduct these studies entirely outside the skull, and thus, makes it possible to expand the research to living animals. In the diagnosis of mental problems, the technique may be refined to include observations of the living human brain.

The decades of the 1970s and 1980s were marked by numerous discoveries pertaining to the biochemistry of the brain. For example, the known chemical transmitters have been expanded from a list of just a few to several. Much has been learned concerning the production of chemical substances within the brain, once considered a function in the exclusive province of the glands. Research commenced by neuroscientists at McGill University in the mid-1950s led to the discovery of "pleasure centers" within the brain that play a role in learning and memory. As pointed out by Routtenberg (1978), the so-called reward system can be localized in particular nerve cells and their fibers. The system is affected by drugs that interact with the substances secreted by these nerve cells. The fact that only certain nerve-fiber pathways are implicated in brain reward suggests that these pathways have a specific function. This parallels what is known of the brain's visual and movement systems, each of which has a specified set of component pathways. This research led to many new insights on the functioning of various psychoactive drugs. Neuroscientists at several institutions have found many new substances, generally referred to as neuropeptides, in brain tissue. These substances include the heavily publicized enkephalins and endorphins. Researchers have found that neuropeptides differ from previously identified transmitters in that they appear to orchestrate complex phenomena, such as thirst, memory, and sexual behavior. See also Table 1.

Broad, Traditional Concepts of the Central Nervous System

The large, soft mass of nerve tissue making up the brain is contained within the cranium (*encephalon*). The brain consists of four major parts: the *cerebrum*; the *thalamus*; the *brain stem*; and the *cerebellum.* The brain and spinal cord together constitute the *central nervous system.*

By way of generalization, the brain is the control station for nerve impulses. The brain is composed chiefly of nerve cells with their fibers interwoven in a complex relay system. At birth, the human brain weighs between 11 and 13 ounces (312 and 369 grams) and, as previously mentioned, attains a weight of about 45 ounces (1.3 kilogram) in the adult. The brain increases in weight until about the twentieth year, after which there is gradual loss of weight for the remainder of life. The volume of the human adult brain is 2000 cubic centimeters or greater. By comparison with other animals, the human brain is very large. See Fig. 2.

In 1990, paleoanthropologist Dean Falk postulated that the hominid brain required a special cooling system before the brain could expand to its present size. The scientist proposed that the brain size, like an engine, is restricted by the capacity of the cooling system if it is to continue "running" within a given temperature range. Simply called the "radiator theory," Falk's proposal has garnered both positive and negative reactions from professionals in the field. Pro and con details are covered by A. Gibbons in the listed references.

In an excellent paper, P.H. Harvey and J.R. Krebs (University of Oxford, Department of Zoology) point out, "Some animals have larger

TABLE 1. VERY ABRIDGED LIST 0F IMPORTANT NERVOUS SYSTEM AND BRAIN RESEARCH EVENTS

- In 1870, G.T. Fritsch and E. Hitzig first suggested functional compartmentalization in the cerebral cortex.
- In 1872, Francisci Gennari (Parma, Italy) discovered the visual cortex.
- In 1875, Golgi developed a brain tissue staining technique which enables the staining of a comparatively few neurons and neuronal systems at one time, thus making it possible to study a few out of many thousands of adjacent systems.
- In 1885, P. Ehrlich discovered the blood-brain barrier, finding that many blood-borne solutes do not penetrate into central nervous system tissue as rapidly as they penetrate into most other tissues. The functional significance of the blood-brain barrier mechanism is to buffer the neuronal microenvironment against changes in plasma concentrations of various important solutes and to regulate the composition of the neuronal "atmosphere" for optimum performance. See also **Blood-Brain Barrier**.
- In 1904, Cajal published the findings of a lifetime of study of brain tissue and neuronal systems as the result of combining the Golgi staining technique with light microscopy.
- In 1904, Ivan Pavlov, Russian physiologist, was awarded the Nobel prize in medicine for pioneering studies of the nervous system and demonstrating the conditioned reflex in dogs.
- In the first third of the present century, numerous investigators, among them Sir Henry Dale, Otto Loewi, A.L. Hodgkin, A.F. Huxley, B. Katz, Sir John Eccles, and S.W. Kuffler, made major contributions to an understanding of how individual neurons work. One finding was that all neurons, regardless of size and shape, appear to utilize the same two kinds of electric signals (graded potentials and action potentials). Dale initially proposed the concept that a neuron released only one transmitter chemical from all its terminals, an observation that was considered inviolable until recently. It is now suspected that some neuropeptides can coexist in the same neurons as certain transmitters, such as norepinephrine and serotonin.
- In 1949, Donald O. Hebb published "The Organization of Behavior," which became a keystone of modern neuroscience. The tome described cell assembly theory and foreshadowed neural network theory.
- In the 1950s, E.J. Furshpan and D.D. Potter (University College London) discovered that some synapses are profoundly different from the usual chemical type, depending on the flow of current rather than diffusion of a transmitter.
- In the early 1950s, W.J.H. Nauta (then in the Netherlands) developed an improved brain tissue staining technique which differentiated degraded nerve fibers from living fibers, making it possible to identify specific fibers with remotely located neurons. This expanded the ability of researchers to provide greater detail in brain mapping.
- In the early 1950s, A.L. Hodgkin, A.F. Huxley, and B. Katz (British scientists), as the result of studying the nerve-impulse transmission in the giant axon of the squid, demonstrated that the propagation of the nerve impulse coincides with sudden changes in the permeability of the axon membrane to sodium and potassium ions.
- In the early 1950s, P.A. Weiss and colleagues (University of Chicago) discovered the phenomenon of axonal transport.
- In the mid-1950s, Sutherland and his associates (Case Western Reserve University) demonstrated that dopamine and norepinephrine, among other transmitters, increase or decrease the concentration of a second messenger substance in target cells, the latter mediating the electric or biochemical effects of the transmitter in the first messenger. (See later reference to Sutherland.)
- In the mid-1950s, neuroscientists at McGill University (Montreal) discovered pleasure centers within the brain that play a role in learning and memory.
- In the 1960s, methods for selectively staining neurons containing a particular transmitter were developed and utilized by a number of investigators. The natural transmitter substance can be converted into a fluorescent derivative that glows under ultraviolet radiation. Another method was developed that takes advantage of the high specificity of antibodies. A specific enzyme involved in the synthesis of a particular transmitter is purified from brain tissue and then injected into an experimental animal, whereupon the enzyme induces the manufacture of antibodies which, in turn, specifically combine with the enzyme. The antibodies are then purified and labeled with a fluorescent dye. Then they can be used to selectively stain neurons containing the relevant enzyme. Such techniques have greatly expanded the researcher's ability to map detailed anatomical distribution of individual transmitters. Falck (University of Lund) and Hillarp (Karolinska Institute, Sweden) first demonstrated that neurons containing monoamines fluoresce green or yellow when the transmitters are first converted into fluorescent derivatives. The best mapped transmitters are the monoamines norepinephrine, dopamine, and serotonin.
- In the early 1960s, V.P. Whittaker (University of Cambridge) and E. De Robertis (University of Buenos Aires) found that when brain tissue is gently disrupted when homogenized in a sugar solution, many nerve terminals break away from their axons. These terminals form intact, closed particles called *synaptosomes* which contain the means for synthesis, storage, release, and transmitter inactivation associated with the nerve terminal. The synaptosomes can be purified by spinning in a centrifuge. The availability of these substances made it possible for neuroscientists to study the mechanisms of synaptic transmission in vitro.
- In 1962, F.H.C. Crick was awarded the Nobel prize in physiology or medicine for contributions to the understanding of how the human brain works.
- In the 1970s, L.L. Iversen (Cambridge), T.J. Crow (London), and P. Seeman (University of Toronto), among others, revealed abnormally high concentrations of dopamine and dopamine receptors in the brains of deceased schizophrenics.
- In the 1970s, Perry (University of British Columbia) discovered that a specific deficit of gamma-aminobutyric acid (GABA) occurs in the inherited neurological syndrome known as Huntington's chorea. See **Chorea (Huntington's)**.
- In the 1970s, pioneering research efforts revealed that opiate receptors are located in those regions of the brain and spinal cord which are known to be associated with pain. S.H. Snyder and C.B. Pert (Johns Hopkins University School of Medicine), E.J. Simon (New York University School of Medicine), and L. Terenius (University of Uppsala), among others, used radioactively labeled opiate compounds to reveal these sites. This research paved the way for discovery of the enkephalins and endorphins, among other neuropeptides.
- In 1971, Bloom and co-workers (National Institute of Mental Health) demonstrated that cyclic AMP can affect signaling in neurons. A bit later, Greengard and associates (Yale University School of Medicine) showed that cyclic AMP is involved in the synaptic actions of several brain transmitters (norepinephrine, dopamine, serotonin, histamine). Greengard et al. suggested a unifying process to the effect that cyclic AMP activates specific enzymes in the target cell called *protein kinases* and, through a complex process, changes the level of excitability of the target cell.
- In 1971, Sutherland (see previous mention in this list) received the Nobel prize in physiology and medicine for identifying the second messenger substance as cyclic adenosine monophosphate (cyclic **AMP**).
- In the early 1970s, L.E. Eng and A. Bignami (Stanford University) isolated glial fibrillary acidic protein (GFAP) as a component of astrocytes.
- In 1975, J. Hughes and H.W. Kosterlitz (University of Aberdeen) first isolated the enkephalins. Shortly thereafter, the endorphins, also morphine-like compounds, were isolated from the pituitary gland.
- In the late 1970s, researchers found "substance P," associated with spinal neurons involved in pain stimuli.
- In 1979, Rita Levi-Montalcini and Pietro Calissano were awarded the Nobel prize for physiology or medicine for their identification of the nerve-growth factor (NGF).
- In the early 1980s, research on trophic substances, such as nerve-growth factor (NGF), accelerated into a major effort.
- In 1991, Bert Sakmann and Erwin Neher shared the Nobel prize in physiology or medicine for their invention of the patch-clamp technique used in cell membrane and ion channel research.

brains than others, but it is not yet known why. Specific differences in life-style, including dietary habits and patterns of development of the young, are associated with variation in brain weight, independently of the effects of body weight and evolutionary history. Taken together with behavioral and neuroanatomical analyses, these studies begin to suggest the evolutionary pressures that favor different sized brains and brain

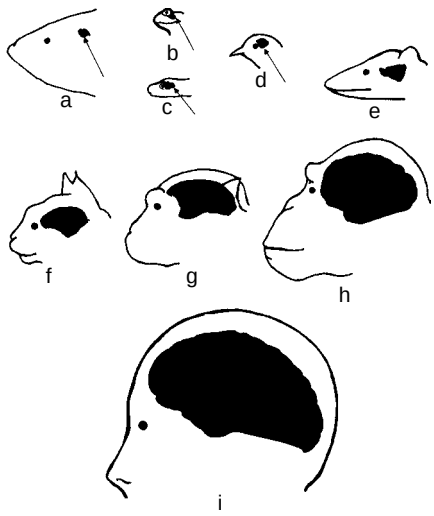

Fig. 2. Comparative sizes of the cerebrums of various animals: (**a**) bass, (**b**) leopard frog; (**c**) grass snake; (**d**) pigeon; (**e**) opossum; (**f**) cat; (**g**) macaque monkey; (**h**) chimpanzee; (**i**) human. (After Hubel.)

components." In their paper, the investigators compare brain size and functionality against numerous other body features in numerous animals as well as in humans. It is pointed out that it has not been unusual for researchers to seek associations between encephalization and more than 20 variables that summarize the life-styles of various species. Among specific animal groups, a significant association at the 5% probability level includes diet in mammals and the pattern of development in birds.

In any investigation of encephalization, it is evident that, when one brain region is enlarged, the whole brain is not. The authors conclude their paper with an observation of Mark Twain: "I never could keep a promise. I do not blame myself for this weakness, because the fault must lie in my physical organization. It is likely that such a liberal amount of space was given to the organ which enables me to make promises that the organ which should enable me to keep them was crowded out."

Medulla Oblongata. This organ is approximately 3/4 of an inch to 1 inch (19 to 25 millimeters) in length. Externally, it appears like an expanded part of the spinal cord. See Figs. 3 and 4.

Internally, its structure is quite complex and consists of nerve tracts passing into the brain. From some of the nuclei come fibers that eventually emerge to form the VIIIth, IXth, Xth, XIth, and XIIth cranial nerves. Cell centers in this area also are concerned with swallowing, vomiting, breathing, speech, digestion, metabolism, and the beating of the heart. In the medulla oblongata, the large bundles of fibers, which originated in the two halves of the cerebrum and which transmit the impulses of voluntary movement, cross to the opposite sides. Thus, movement in the right arm, for example, is controlled by centers in the left half of the cerebrum.

Pons. Lying above the medulla oblongata and continuous with it is the pons. It is made up of massive bundles of fibers that start in the cerebrum and sweep backward to the cerebellum. This connection makes possible many skilled acts that require coordination of sight, hearing, muscular movement, and various other sensations. The playing of a musical instrument is an example of such an act. The pons contains a space called the *fourth ventricle*. In the floor of this ventricle is the nucleus of the VIth cranial nerve. This nerve, inside the skull of all the cranial nerves, is concerned with turning the eyeball outward.

Cerebellum. The second largest part of the brain is in back of the pons and termed the cerebellum. It lies in the back of the skull. The cerebellum is made up of many narrow, leaflike folds arranged into two large masses and of a middle portion. Rich in cells, it has many complex connections with the brain above it and with the spinal cord below. The chief function of the cerebellum is to coordinate relatively complex movements into special

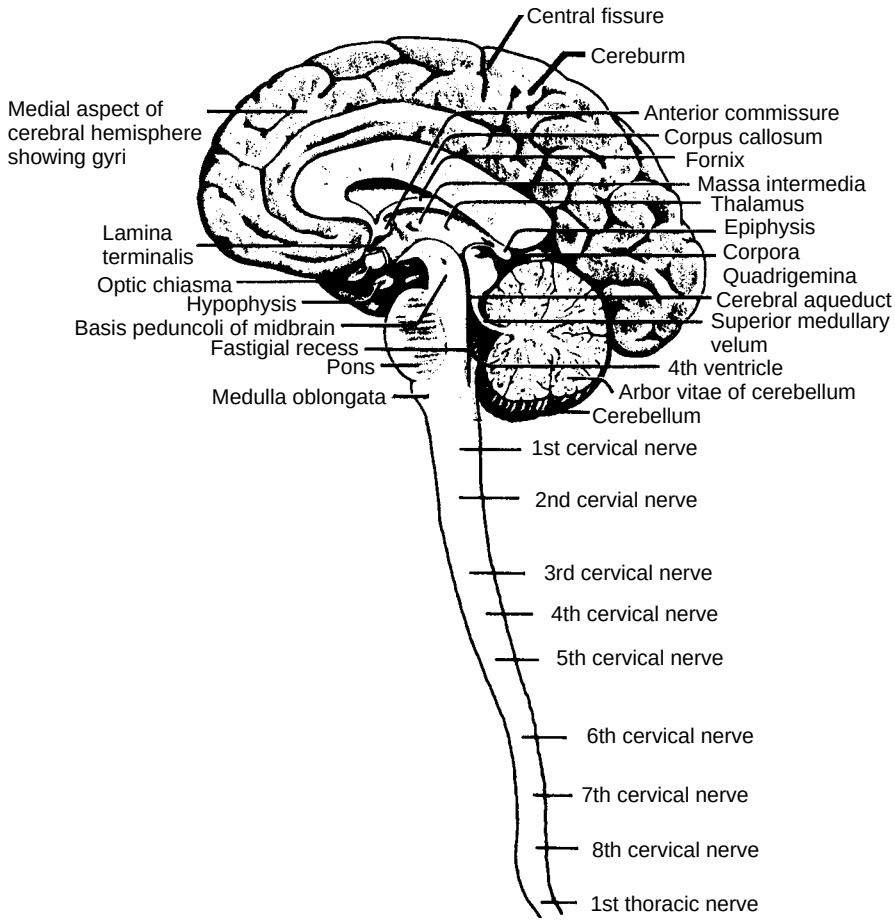

Fig. 3. Traditional diagram of median sagittal section of the human brain.

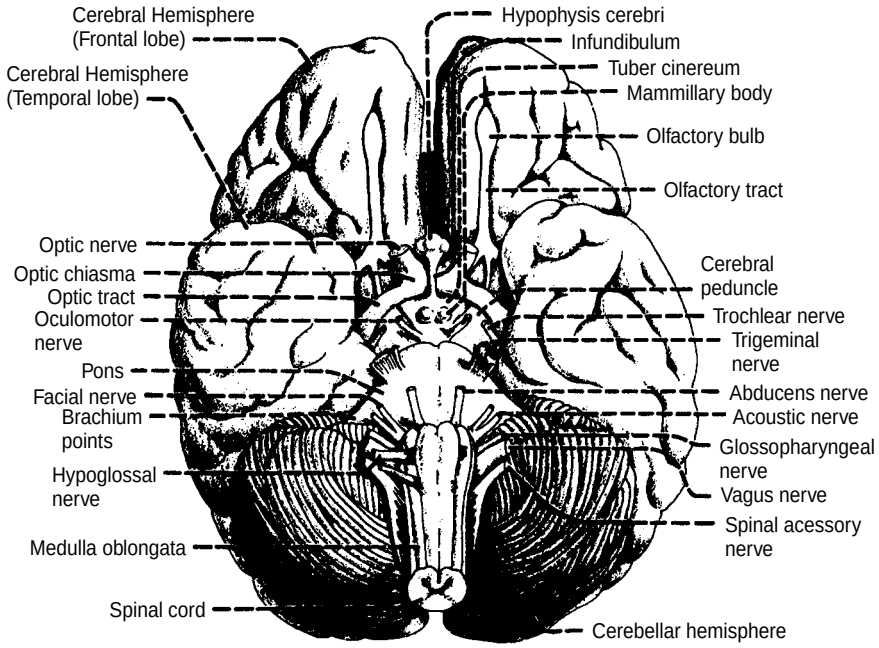

Fig. 4. Traditional diagram of the base of the human brain and cranial nerve roots.

acts. This may be movement in different parts of the same limb; combined action of the head, limbs, and body. For example, picking up a pencil, writing with it, and laying it down again requires smooth interaction of many muscle groups. The cerebellum correlates the actions of the various groups. To do this, range, direction, rate, and force of movement must be synchronized and maintained with the movement of the eye. Disease in the cerebellum does not cause paralysis, but it does produce disturbance of muscular coordination. Tremors, staggering gait, and excessive relaxation of the muscles result from disease in this part of the brain, as well as disturbances in components of muscular activity.

Midbrain. This is a small area between the pons and the cerebrum. It is an important relay station for the sensory impulses. The midbrain also governs some muscle activity of a reflex nature. Many of the involuntary acts of the eye, such as narrowing of the pupil in bright light, originate in this area. The IIIrd, IVth, and Vth cranial nerves originate from cell collections in this area of the brain.

Hypothalamus. Just above the midbrain, an important group of nuclei comprise the hypothalamus. Beneath it, the two large nerves from the eyes meet and part of their fibers cross to the opposite sides. Other cells of this region are concerned with such vital functions as regulation of body temperature, metabolism, and heart rate. Sexual development, sleep, and the body's use of fat and water are influenced by this region in the brain. There is an essential relationship between the hypothalamus and the nervous system and the endocrine system.

Thalamus. The thalamus is found next to the foregoing group of cells and contains another group of nuclei, which integrates sensations of many sorts. Also, the thalamus is the site of a crude form of consciousness and plays a role in the production of emotion. When this part of the brain is diseased, spontaneous laughter or crying may occur. The crude emotional responses that arise are further elaborated and controlled by the cerebral cortex.

Hippocampus and Amygdala. Both of these structures are anchored to the inner surface of the temporal lobe in both hemispheres of the brain. Because of its shape, hippocampus is named from the Greek for *seahorse*. Similarly, because of its shape, the amygdala is named from the Greek for almond. From experience with amnesia patients and experimentation with laboratory animals, it has been noted that memory loss occurs after surgery or damage to the hippocampus. Neuroanatomical studies of the circuitry linking the structures indicate similar, but not identical participation of these two structures. Mishkin reported in 1987 that although the hippocampus and the amygdala can substitute for each other in learning to recognize an object, the hippocampus seems to be particularly important for learning spatial relations. Further research has shown that the amygdala (amygdaloid complex), which consists of several nuclei, has direct and extensive connections with all the sensory systems in the cortex. The amygdala also communicates with the thalamus, along a path that is a segment of the memory system. Mishkin further observes that the same parts of the amygdala on which sensory inputs converge send fibers deeper into the brain to the hypothalamus (believed to be the source of emotional response). The amygdala, with so many connections, is now believed to mediate the association of memories formed through the different senses.

Contribution of the hippocampus to the memory system has been studied in monkeys by L.R. Squire and S. Zola-Morgan (Veteran Affairs Medical Center, San Diego, California) and reported in 1991. See reference listed. The paper concludes with, "Cumulative and systematic research with monkeys and related research with humans has identified the components of the medial temporal lobe memory system: the hippocampus, together with adjacent anatomically related cortex (entorhinal, perirhinal, and parahippocampal cortex). This system is fast, has limited capacity, and performs a crucial function at the time of learning in establishing long-term declarative memory. Its role continues after learning during a lengthy period of reorganization and consolidation, whereby memories stored in the neocortex eventually become independent of the medial temporal lobe memory system. This process, by which the burden of long-term (permanent) memory storage is gradually assumed by the neocortex, assures that the medial temporal lobe system is always available for the acquisition of new information. The anatomy and function of the system and its relation to the neocortex are becoming well enough understood that computational modeling should provide a fruitful way to make these ideas more formal and quantitative."

Cerebral Hemispheres. The two cerebral hemispheres represent 70% of the entire nervous system. This is the area of the nervous system in which all the sensory experiences are mixed and blended. Specific sensory impulses thus become associated with many others and expand the experience and consciousness. The individual's capacity for many and varied activities, and memory, emotions, and ideas is dependent upon the action of this part of the nervous system.

The surfaces of the hemispheres are marked by large, rounded folds and deep grooves. Partly on the axis of the main grooves and partly on imaginary lines, the cerebrum is divided into four lobes: *frontal*, *parietal*, *temporal*, and *occipital*. Each lobe has special functions, but these functions are only partly understood. More recently, emphasis on connecting pathways among lobes has resurfaced as an important perspective on cognitive function. This view was largely resurrected by Norman Geschwind, a behavioral neurologist, who, in his treatise "Disconnexion Syndromes in

Animals and Man (1965)," discussed dramatic behavioral consequences of disrupting specific pathways in the brain. See reference listed.

The occipital lobes at the back of the skull are the site where visual impressions are made. Color, size, form, movement, and distance are evaluated in this portion of the brain, leading to the identification of a particular object. Also, the differences between similar objects are discerned. For example, two objects high in the air can be recognized as a bird and an airplane on the basis of past experience. Injury to this area may cause blindness.

The temporal lobes receive the fibers concerned with hearing, speech, balance, and smell. Diseases related to these lobes cause loss of smell, or they may be responsible for imaginary smells.

The parietal lobes are concerned with taste sensations and some other sensations, such as the ability to judge weight, shape, and textures. By the action of this area, one is able to tell what various objects are by feeling, rather than seeing them.

The frontal lobes are concerned with some of the most complex abilities of the mind. Reason, emotions, and judgment have their site here. Additionally, there is a group of large cells in the posterior region of the frontal lobes, which are involved with complex voluntary movements. The speech center is located here. It is found to predominate on the left side in right-handed individuals and *vice versa*. If the speech function is lost because of injury to only one side of the brain, it can sometimes be reacquired by reeducation. The area responsible for these complex voluntary movements is called the *motor cortex*. The muscles of the body are controlled by various areas of the motor cortex. Irritation of the cells in these zones will cause spasms of the muscles they supply. Destruction of the cells will produce complete loss of voluntary movement of the muscles. These cells also function to keep the muscles in balance between relaxation and contraction. If this region of the brain is seriously damaged or destroyed, this inhibiting power is lost. Consequently, the muscles become contracted and stiff (*spastic paralysis*).

The frontal lobes have many connections with the thalamus as well as with the other lobes of the brain. In the frontal lobes, feelings or emotions are added to the other associations. The combination of feeling and knowing determines most voluntary action of the body. Thinking, reasoning, judgment, and imagination result as the sensory and emotional associations become more complex. Disease in the frontal lobes of the cerebrum causes personality changes, errors in judgment and insight, and poor emotional control.

Twelve pairs of nerves arise from the brain proper. The 1st is associated with the sense of smell; the IInd with sight: the IIIrd and IVth with the eye muscles that move the eyeball or the muscles of the pupil; and the Vth causes the muscles of the jaw to move. The VIth is concerned with the movement of the eye to the side. The VIIth carries impulses to all the muscles of the face. The VIIIth conducts impulses having to do with hearing and with balance; the IXth transmits taste sensations from the posterior third of the tongue, and other sensations from the throat and mucous membranes; and also aids in swallowing. The Xth is an exceedingly long nerve that extends down the neck and into the chest and abdomen; it is concerned with swallowing and talking; its action also slows the rate of the heart and regulates the movement of the stomach. It is a large part of the parasympathetic system in the upper part of the body, including the esophagus, stomach, intestines, liver, bronchi, lungs, heart, and blood vessels. The XIth supplies some of the muscles that turn the head and some of those in the neck. The XIIth is responsible for the movement of the tongue.

Spinal Cord. The nerve tracts passing to and from the brain are contained in the spinal cord, which is continuous with the lower part of the brain. It is about 18 inches (46 centimeters) long and is rounded in shape. This nerve tract is larger in the regions that give rise to the nerves to the arms and legs, since these parts have many complex functions, thus requiring a large nerve supply. From the neck to the lowest parts of the vertebral column, 31 pairs of nerves emerge from the spinal cord. Each nerve is attached to the cord by two roots. Because the spinal cord is not as long as the vertebral column, the roots of the nerves must gradually increase in length before they can emerge from between the vertebrae. These longer nerve roots collect in a mass that fills the lower end of the vertebral canal. The structure resembles a horse's tail and is called the *cauda equina*.

A cross section of the spinal cord reveals a gray figure, roughly shaped like an "H," imposed on a white background. The nerve cells make up the gray matter, while the nerve bundles form the white matter. Bundles with specific functions occupy specific areas of the spinal cord. Thus, injury to the cord results in certain abnormal reactions, which are evident upon neurological examination. The abnormal findings suggest where the diseased part is located.

Impulses that arise in the brain and are concerned with voluntary muscular movements, are received by specific cells in the spinal cord. They relay these impulses to the nerves that control the various muscles. These cells have connections with other cells in the nervous system that act together to bring about *reflex activity*. Reflexes control the position of the head so that it automatically assumes the normal position. Withdrawal or *flexion* reflexes pull limbs away from painful or disagreeable stimuli. *Extensor* reflexes straighten out the limbs and work with the flexor reflexes. Bladder and bowel actions result from reflex action over which there is some voluntary control. In injury to the spinal cord, the tracts allowing voluntary control may be interrupted, so that action is then reflex in origin.

The cells on the front and anterior side of the spinal cord connect with cells in the cerebellum to control the direction and precision of normal muscular movement. From still another part of the brain, connecting fibers come to these cells to bring about certain automatic, associated muscular movements, as in the instance of swinging of the arms as one walks. Another function of these cells is the maintenance of the proper amount of constant contraction or *tone* of the muscles. If the muscles are too contracted, they move too slowly and rigidly. If they are too relaxed, too much stimulation is needed to make them respond.

The cells along the side of the cord send out fibers that unite with others to form the *sympathetic chain*. These cells are concerned with the action of involuntary muscles in the intestines, arteries, and other internal structures. Various glands receive fibers from these cells. Cells on the back or posterior side of the spinal cord receive the sensations of touch, pain, vibration, temperature, pressure, and position. They then transmit these various sensations to other cells in the brain. Thus, impulses of many sorts travel down the paths in the spinal cord, while others enter it and travel upward to the brain. Still others enter and travel only part of the way up and set off the spinal reflexes.

The Peripheral Nervous System

The peripheral nervous system is composed of the cranial nerves, the spinal nerves, and the autonomic nervous system. The autonomic system supplies nerves to most of the "automatic" organs of the body, i.e., the glands, heart, blood vessels, and the involuntary muscles in the internal organs. One part of the autonomic nervous system prepares the individual for emergency situations, shifting circulating blood to skeletal and heart muscles, increasing heart and lung function, dilating the pupils of the eyes, and moistening the skin with perspiration. The other division is concerned with conserving and restoring bodily resources. Thus, it protects the eyes by causing the pupils to constrict in bright light, and prevents the heart from overexerting itself. All of the digestive processes are promoted by this division. See also **Autonomic Nervous System**.

Nerve Definition and Function. A nerve is a slender cord made up of nerve fibers (neurons). In the vertebrates the nerve is surrounded by loose connective tissue called the epineurium. Each small bundle of fibers within the epineurium is surrounded by a thin, compact perineurium, and from this layer thin septa, the endoneurium, run between the irregular groups of fibers within the bundle.

Nerves form the communicating paths between the central nervous system and the various parts of the body, as well as the connections between ganglia. They have been given special names according to their anatomical distribution, and a few functional properties have been indicated by descriptive terms. Thus sensory or afferent nerves carry impulses from sense organs to the central nervous system and motor or efferent nerves lead out to muscles and other effectors. Most nerves of the body contain fibers of each kind and so are mixed nerves. Nerves arising from the brain in the vertebrates are called cranial nerves and those connected with the spinal cord are spinal nerves. Typically, all of these main nerves of the vertebrate are supposed to be based on the form of the spinal nerves, which connect with the cord by two roots. The dorsal root bears a spinal ganglion and carries all the sensory fibers and the ventral root lacks a ganglion and is motor. All sensory nerves bear a ganglion or arise from a sensory layer such as the retina of the eye and no purely motor nerves have ganglia.

The motor components of these nerves grow out from cells in the central nervous system and the sensory components grow into the central system

from ganglia or from sensory cells and also out from the ganglia toward the periphery of the body.

A nerve impulse is a progressive transfer of a condition of excitation along a nerve fiber, initiated by a stimulus acting upon a sensory organ, by a cell within the nervous system, or experimentally by direct stimulation of the nerve fiber. The nerve impulse involves measurable chemical changes and energy consumption accompanied by changes in electrical potential associated with membrane depolarization. The electrical changes have been used extensively in investigation of nerve physiology and of the brain. The passage of the nerve impulse over the synapse is accompanied by the action of acetylcholine in cases that have been studied. Terminal nerve fibers may form either acetylcholine or sympathine, the latter being closely related to adrenaline. The impulse activates some organ of the body or enters the nervous system, where it is relayed to other parts. These mechanisms are further described later.

The attainment of harmonious action of all component parts of the animal and the adjustment of its behavior to environmental conditions is by way of communication and regulation through the nervous system. Coordinative processes of this type are aided by the secretion and distribution of hormones. The latter process is termed *chemical coordination*. Coordination by way of the nervous system occurs, of course, with much greater speed than actual materials can be transported from one part of the body to the next. The nervous system is responsible for the immediate adjustment of the animal to fluctuating conditions, while chemical coordination is extensively involved in the maintenance of the normal organic processes, which are a more uniform part of the animal's activity. Coordination, in general, is due to close interaction of the two types; neither is wholly independent of the other.

The process of coordination through the nervous system is based on the general sensitiveness of protoplasm known as irritability and on the property of conductivity by which some result of stimulation passes rapidly through the adjacent substance. All living cells are irritable to some extent. They respond to some stimulus with characteristic activity. Sensory organs possess this property to a high degree and in addition are specialized to receive a certain kind of stimulus. Nervous tissue is specialized for ready activation and for the rapid conduction of the impulse generated within it.

The organs that receive stimuli as a special function for the benefit of the animal, whether relatively simple cells or extremely complex organs like the human eye, are known as receptors. They have special nerve endings, often associated with other structures, and are connected by afferent or sensory nerves with other parts of the nervous system or, in very simple animals, with some organ capable of acting in response to the condition from which the stimulus arose. Organs of the latter category are muscles, glands, electric organs, light organs, and some pigment cells, and are known collectively as effectors. Usually one or more cells of the nervous system intervene between the sensory cell associated with the receptor and the motor cell which communicates directly with the effector. The more complex this nervous chain, the more intricately may nerve impulses be relayed through different paths in the body, but in all cases the net result is the same. All adjustments are due to the reception of stimuli by sense organs, both internal and external, followed by appropriate reaction of other parts of the body.

The most common type of nervous system among invertebrates consists of a small brain lying above the alimentary tract near the anterior end of the body. See Fig. 5. It is connected by cords passing down around the sides of the gut with a ventral nerve cord. In the annelid worms this cord is a chain of ganglia, one lying in each segment. Conclusive evidence from embryology and minute anatomy shows that the primitive cord was a paired structure and that each segment contained a pair of ganglia connected by transverse nerves as well. In most existent species the adult shows no visible evidence of the paired condition.

In all of the more complex nervous systems, a major center, the brain, is present as a part of the central nervous system, and supplementary centers called ganglia, each containing a small number of nerve cells, are scattered through the outlying parts of the system. All of these parts are connected by nerve cords or nerves and are joined in the same way with other structures of the body.

In the arthropods a concentration of ganglia in some species has resulted in one large ganglionic mass near the anterior end of the ventral cord.

Many mollusks have a number of ganglia of about equal size as nerve centers, although the cephalopods have a concentrated brain equal to any other invertebrates.

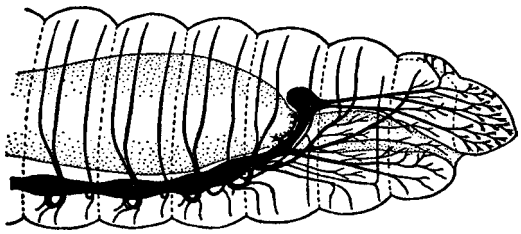

Fig. 5. Nervous system of earthworm. This is a lateral view of the arrangement of the larger nerve trunk in the left side of the anterior segments of the earthworm.

In the vertebrates the entire central nervous system lies above the alimentary tract. The brain is large and complex in most classes. From it a spinal cord runs back along the axis of the body. Both brain and spinal cord bear nerves that extend throughout the animal. See Fig. 6. Below the spinal cord two chains of ganglia connected by slender nerves with each other and with the spinal nerves constitute the sympathetic chains of the autonomic nervous system. Nerves of this system supply the viscera and are widely distributed elsewhere in the body. In cooperation with the parasympathetic fibers of the cranial and sacral nerves, they control the functions that cannot be deliberately regulated by individual desire, such as the movements of the alimentary tract.

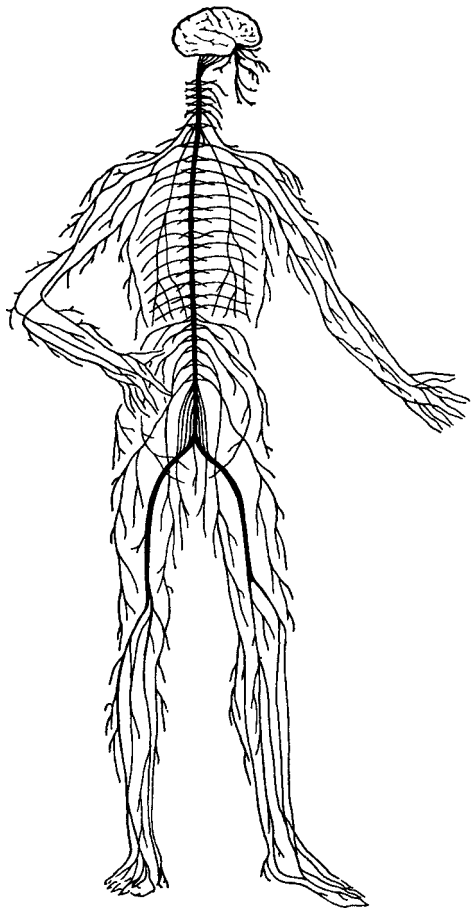

Fig. 6. Human nervous system.

Early Nerve Development in the Brain. Although poorly understood, the brain appears to undergo at least two developmental (constructional) phases. Sometimes referred to by scientists as "temporary scaffolding" (comparable to construction aids for mechanical structures, such as a building), researchers suggest that these *subplate* neurons serve as a temporary linkage for the forthcoming permanent adult brain structure. The early brain is quite different from the mature brain. The analogy has been suggested that in some instances a group of short-lived cells may serve as intermediate targets and "tour guides" for incoming axons. (See Holloway reference listed.)

Synapses and Neuromuscular Junctions. The area of functional contact between two nerve cells (*synapse*) and between an axon terminal and a muscle fiber (*neuromuscular junction*) are regions of unique anatomical, physiological, and biochemical specializations that are concerned with information transfer. Since there is a wide variety of types of synapses and neuromuscular junctions, to date investigations have been relatively limited to mammalian, amphibian, and invertebrate species of select categories.

Synapses and neuromuscular junctions have been classified on a variety of morphological, functional, and biochemical bases. Anatomically, synapses have been classified as being either central (brain and spinal cord); or peripheral (autonomic ganglia, peripheral sensory ganglia and effector junctions) in position and/or axo-dendritic, axo-somatic or axo-axonic in contact relationships. Physiologically, synapses have been classified as either excitatory or inhibitory in action and/or as chemically or electrically mediated. Biochemically, synapses have been classified as either releasing acetylcholine, epinephrine, norepinephrine, or other substances that are currently being researched. Neuromuscular junctions are classified anatomically as within the peripheral nervous system; functionally as excitatory, inhibitory or sensory; and biochemically as releasing acetylcholine.

When synapses and neuromuscular junctions are observed with the electron microscope, their fine structures are seen to be basically similar. The similarities include increased electron density of the presynaptic and postsynaptic membranes, the presence presynaptically of large numbers of mitochondria and synaptic vesicles, and an intersynaptic cleft space of 200–300 Å. Synaptic vesicles are 300–600 Å in diameter in synapses where acetylcholine is the mediator; and 600–1000 Å in diameter in synapses where epinephrine or norepinephrine are the mediators. The accumulation of mitochondria and synaptic vesicles on the presynaptic side occurs as a result of the distal migration of materials from the cell body into the axon. Differences in the morphology of central nervous system synapses have been reported and various functional attributes have been alluded to. These include differences in presynaptic and postsynaptic interspace distances, postsynaptic membrane electron densities, and amounts and electron density of interspace substance.

Synapses transmit either electrically or chemically, and they may be either excitatory or inhibitory in action. Most synapses and neuromuscular junctions are chemically mediated and excitatory in action. Types of chemically mediated synapses include those from the mammalian and amphibian central nervous system, sympathetic and parasympathetic ganglia, and sympathetic innervation of the adrenal chromaffin cells. As previously mentioned, the three most widely known transmitter substances are acetylcholine, epinephrine, and norepinephrine.

Operation of the central nervous system depends upon two substances: the *gray matter* (Nerve cells), and the *white matter* (nerve fibers given off-by the cells). The function of the gray matter is the generating and dispatching of nerve impulses. The function of the white matter is the conduction of these impulses to and from the cells in the gray matter. Other cells in the nervous system have no nervous function, but instead are concerned with the support and nourishment of nerve cells.

Nerve tissue proper consists of cells giving off threadlike processes (*axons*) some of which are extremely long. The axons connect with other cells in the brain or spinal cord. These cells constantly generate, receive, or store up energy. Unlike most body tissues, nerve cells are not replaced once they are destroyed. If the cells are destroyed, their axons degenerate. Some cells concerned with generating or receiving similar impulses may be collected into definite groups called nuclei. The axons from these cells unite and form bundles of nerves which then transmit the impulses. The nerve cells are not collected into nuclei in the cerebral hemispheres, but form a uniform layer (*cortex*) of gray matter over the surfaces.

A series of highly specialized organs, called *receptors*, detect changes in and about the body. They rapidly transmit this information to definite stations within the nervous system. This is called *sensory* activity. Receptors, called *exteroceptors*, gather information from a distance, such as seeing, hearing, and smelling. *Interoceptors* detect things in contact with the body, as pain, temperature, and touch. *Proprioceptors* pick up information from within the body, giving a sense of bodily position. Fibers from the receptor organs pass into the spinal cord as a part of the nerve. Within the cord, they unite to form ascending tracts which connect with other spinal cells or enter the brain. Fibers from some special receptors, such as the eye, form nerves that enter the brain directly.

It is postulated that when a sensory impression reaches the brain, it stimulates a nerve cell, which, in turn, stimulates another cell. A third cell is then stimulated and so on, until a circle has been completed, and the last cell restimulates the first one. The circuit continues to *reverberate*, thus retaining the impression that set it off. It is further postulated that these reverberating circuits hold the impressions so that they can be recalled later, or compared with other impressions. It is believed that a cell may participate in more than one circuit, thus accounting for various associations of sensory and muscular activity.

Synapse Modification. In a 1987 paper, Bear, Cooper, and Ebner (Brown University) reported on a physiological basis for a theory of synapse modification. The researchers point out that the functional organization of the cerebral cortex is modified dramatically by sensory experience during early postnatal life. The basis for these modifications appears to be a type of synaptic plasticity that may also contribute to some forms of adult learning. The question of how synapses modify according to experience has been approached in the reported study by determining theoretically what is required of a modification mechanism to account for the available experimental data in the developing visual cortex. The resulting theory states precisely how certain variables may influence synaptic modifications. This insight has led to the development of a biologically plausible molecular model for synapse modification in the cerebral cortex.

Neurons

No two nerve cells (neurons) are exactly the same, but the majority of neurons as presently understood have three main structural features: (1) The *cell body*; (2) the *dendrites*; and (3) the *axon*. See Fig. 7.

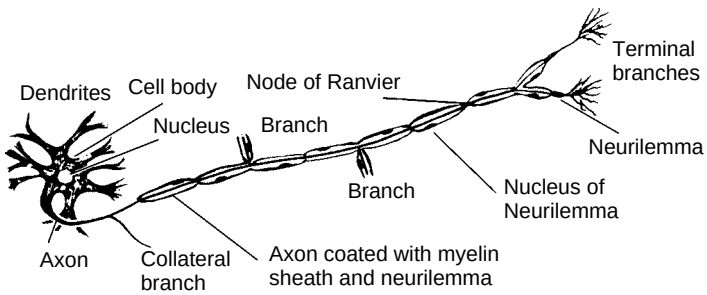

Fig. 7. Simplified presentation of principal elements of a neuron (typical of a motor neuron from ventral column of spinal cord).

Cell bodies may be spherical or pyrimidal in shape. They contain the nucleus of the neuron, that is, the biochemical substances and associated processes required to synthesize enzymes and other substances needed to maintain the life of the cell.

The dendrites (*dendrons*) most often are short and comparatively thick at their points of origin and branch out in a treelike manner. There is a variable number of dendrites with various cell bodies, ranging from a few to many in number. Generally, the dendrites are considered to be the information-receiving channels of the neuron.

The axons are threadlike channels, which connect the cell body and dendrites to remote motor and other cells. In some cases, an axon may be as much as half as long as the entire human body. Generally, the axons are considered to be the information-transmitting channels of the neuron. The axons taper very little as they progress outward from the cell body, but frequently they have multiple branches. These branches are called *collaterals*. The axons are filled with a jellylike fluid called *axoplasm*. This fluid was once thought to be simply an inert mechanical support for the excitable membrane that propagates the nerve impulse. Research commenced by Weiss in the late 1940s led to the modern concept of axoplasm, which likens it to an artery for bidirectional flow of molecules moving between the cell body of the neuron and its axon terminals. A number of different systems apparently are operative within the axoplasm. For example, there is a comparatively slow system (movement of about 1 millimeter day), which accounts for the greatest volumetric flow of substances in the axonal system. These are materials required for the growth and regeneration of the axon. There is a much faster system which transports cellular components, such as enzymes, specifically required for the manufacture of transmitters. The different rates of axonal transport are poorly understood, but in essence appear to be related to rates of demand.

The importance of axonal transport to neuron maintenance is revealed by the fact that once the central nervous system is fully developed, there is no replacement of old cells with new ones as occurs, for example, in the liver. Therefore, it is mandatory that the original cells be well maintained for long life.

While attention is usually concentrated on the neurons when describing the brain and central nervous system, it is important to mention in passing the dense network of blood vessels that furnish oxygen and other nutrients to the nerve cells. Connective tissue is also required, particularly at the surface of the brain. There are also *glial cells*, which take up nearly all the volume in the nervous system that is not required by the neurons. The detailed functions of the glia are not well understood, but it can be safely generalized that the glia provide both structural and metabolic support for the intricate network of neurons.

Returning to the axons — these are jacketed by Schwann cells, a process that commences during embryonic development. A multiple layer of these cells develops and insulates the axon. This material is called *myelin* and the insulating coating is called the *myelin sheath*. It should be mentioned that some neurological disorders arise from disturbances of this sheath. In most axons, the myelin sheath is interrupted at intervals of about 1 millimeter or more. These interruptions are called the *nodes of Ranvier*. It is believed that these interruptions make it possible for extracellular fluid to directly contact the cell membrane and possibly serve as a source of certain membrane proteins, which are described later. Researchers believe that the myelin sheath functions to conserve the metabolic energy of the neuron. Research has shown that nerve fibers with the myelin sheath conduct nerve impulses at a faster rate than unmyelinated fibers. It will be noted from Fig. 7 that some parts of the axon may be protected only by a substance known as *neurilemma* (where the myelin sheath is absent).

The importance of conserving the metabolic energy requirements of the neuron is demonstrated by the fact that, even though the human brain constitutes only about 2% of total body weight, the brain and central nervous system require at least 20% of the body's total oxygen needs when the body is at rest. This represents a use of oxygen at a rate of about 50 milliliters per minute. The brain metabolic rate is essentially constant even when the body is at rest, and some researchers suggest that during certain phases of sleep, the rate of oxygen required may rise. The total energy equivalent of brain metabolism is about 20 watts. Unlike some other cells of the body that can utilize a variety of fuels, such as sugars, fats, and amino acids, neurons require blood glucose exclusively. Since the brain depends entirely upon oxidative metabolism, consciousness is lost within 10 seconds, and brain tissue degeneration commences upon cessation or severe diminution of oxygen supply and blood glucose. Diabetic coma from overdosage of insulin, which greatly lowers blood glucose levels, is exemplary of this dependency. More detail on brain metabolism is given a bit later.

Neuronal Information Exchange. Although the detailed functioning of the neurons remains somewhat vague, it is known that a typical neuron may exchange information with a thousand or more other neurons. These connections (synapses) may arise between: (1) the axon of one neuron and the dendrite of another (apparently this occurs in the majority of cases); (2) the axon of one neuron and the axon of another; (3) the dendrite of one neuron and the dendrite of another; and (4) the axon of one neuron and the cell body of another. These four possible connections are probably not fully representative. It is this great connective potential among millions of neurons that leads to connective networks that are unknown even to the most complex of electronic circuits designed by humans and that, from the standpoint of traditional electronic connective networks appear unworkable. The fact, of course, is that they do work.

Neuroscientists are becoming increasingly interested in the role of NMDA (*N*-methyl-D-aspartate) receptors in the regulation of many normal changes in the brain of an adult or developing animal. Also, there is increased awareness that NMDA may be involved in nerve cell death as encountered in some heart attack and stroke patients. Currently it is believed that NMDA does not exist in the normal brain, but there are NMDA receptors that can be excited by NMDA when used as a tool to probe the activity of this class of receptors. It has been learned, for example, that amino acid neurotransmitters, such as glutamate or aspartate, may stimulate the NMDA receptors.

Charles Stevens (Yale University of Medicine) observes, "Excitotoxicity comes into play if there is too much glutamate and too much calcium. It is not known what the actual mechanism of cell death is, but a current guess is that calcium stimulates protein- and fat-digesting enzymes within the cell that destroy it." Researchers are now seeking a new class of compounds that may block the activity of the receptors and thus prevent nerve cell death. Stuart Lipton (Harvard Medical School) has suggested that, in the brain of a stroke patient, damage to nerve cells increases with the release of more and more excitatory neurotransmitters. The drug MK-801 may be effective in blocking the effects in a patient with escalating levels of excitatory neurotransmitters in the brain. Enrichment of the literature in this area is increasing at a rapid rate.

At a point of connection (synapse), the axon normally enlarges and takes the form of a *terminal button*. This button incorporates tiny chambers (*synaptic vesicles*) which contain a *chemical transmitter*. For many years, the concept that a neuron released only one transmitter chemical from all its terminals as proposed originally by Sir Henry Dale was considered inviolable. Within the past few years, researchers have found that a number of neuropeptides can coexist in the same neurons as norepinephrine or serotonin. The functional significance of such a dual-transmitter system has not been established. The quantity of chemical transmitter released by the terminal button vesicles can aptly be described as vanishingly small. The quantities range from a few hundred to a few thousand molecules. As previously mentioned, transmitter chemicals may be excitatory or inhibitory.

Neuron Membranes. Like other cells of the body, neurons have membranes. In the neuron, the membrane is made up of two layers of lipid molecules. The membrane is about 5 nanometers (∼0.0003 millimeter) thick. The hydrophilic ends of these molecules are oriented toward the water on the inside and outside of the cell. The hydrophobic ends are oriented away from the water and thus these form the interior of the membrane. Lipid materials tend to be relatively uniform for all cells. But membranes do differ, and these differences arise from the specific proteins that are associated with a given membrane. Membrane differences comprise just one more way in which neurons differ from each other, adding to the overall complexity of classifying and understanding them.

When the proteins are embedded in the bilayer of lipids, they are called *intrinsic proteins*. Although essentially bound, in some cells these intrinsic proteins can move about a bit by diffusion, while in other instances they are physically fixed to the membrane at specific sites. Other proteins, equally important, attach themselves to the membrane surfaces, but are not an actual part of the membrane structure.

These membrane proteins fall into at least five categories, based on their function: (1) *Pumping proteins* maintain the needed concentrations of particular molecules within the cell and thus set up the conditions necessary for a nerve impulse. The pumping proteins regulate concentrations by moving ions and molecules against concentration gradients and hence require considerable metabolic energy. (2) *Channel proteins* provide pathways (tiny orifices) through the lipid bilayer membrane and thus regulate the diffusion of specific ions through the membrane because the ions are of discrete size, some larger than others. Without these channels, the membrane would be essentially impervious. (3) *Receptor proteins* provide binding sites to enable the cell membrane to recognize and attach various specific kinds of molecules. The receptor proteins are highly specific, much as a lock is specific to one key. (4) *Enzyme proteins*, located in or on the membrane, participate in chemical reactions at the membrane surface. For example, one of these enzymes, known as adenylate cyclase, regulates the intracellular substance cyclic adenosine monophosphate (cyclic AMP). This substance serves both as a regulator and catalyst. (*5*) *Structural proteins* contribute to the physical support of the system.

Membrane proteins are keys to the function of the neuron because they provide the means for creating and propagating the nerve impulse. The concentrations of sodium and potassium ions on either side of the cell membrane differ markedly. In a resting state, researchers have estimated that this difference in ionic concentrations causes the interior of the axon to be about 70 millivolts negative with respect to the exterior. In terms of the sensitivity of modern instruments, this is a very significant voltage differential. As a nerve impulse propagates along the axon, the permeability of the axon membrane to both sodium and potassium ions is altered. The impulse is usually triggered in the cell body as the result of reaction to dendrite synapses, and the voltage across the membrane just ahead of the traveling impulse is lowered. This adjustment of sodium ion channeling permits sodium ions to flood into the axon. During this process, the internal potential of the membrane is changed from negative to positive.

But the sodium channels remain open for but an instant, after which the potassium channels are opened to permit the outward flow of potassium ions, thus returning the original differential of −70 volts to the interior of the membrane. The sharpness of these actions appears as a spike on an oscilloscope and the phenomenon is generally called *action potential*. See also **Action Current**; and **Action Potential**. In actuality, since the axon is divided into numerous sections (Fig. 7), a wave of voltage propagates along the axon until the terminal button is reached. The action is analogous to a flame traveling along a fuse to an explosive. An explanation of this action in traditional terms is given in Fig. 8.

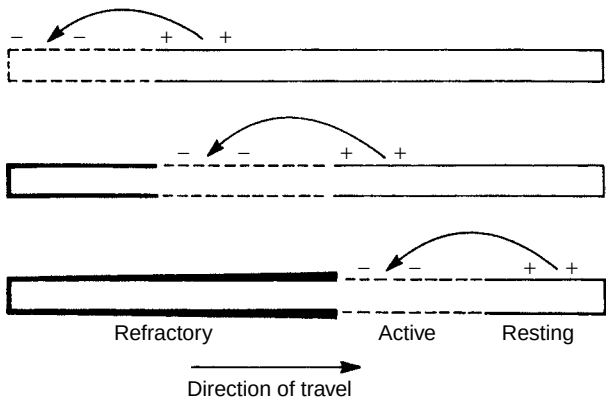

Fig. 8. Simplified representation of nerve impulse conduction.

As previously mentioned, the channel proteins accommodate the sizes of specific ions. The sodium ion is about 30% smaller than the potassium ion. Some channel proteins are relatively undiscriminating, permitting only a slightly reduced number of sodium ions versus potassium ions to pass through the channel. Other channel proteins are highly selective, allowing, for example, fewer than 10 sodium ions to pass for every 100 potassium ions. The diameter of the former type of channel is about 0.8 nanometer and the pore is filled with water. The opening of the second type of channel is considerably smaller and, of course, contains less water. These variations again exemplify the rather extreme degree to which neurons can be tailored to need and thus serve not simply as on-off switches, but provide shading, averaging, and tempering of input and output. The voltage-gated channels just described are traditionally named sodium or potassium channels in accordance with which ion is most readily passable. In other parts of the nervous system, calcium ions also play an important role.

The measured potential (70 millivolts) is less than the equilibrium value calculated by the Nernst equation for the potential that would be developed by a simple concentration battery formed by the unequal distribution of sodium and potassium ions. The reduced potential is probably the result of special back-pumping of the sodium (extruded) ions and the potassium (reabsorbed) ions against their concentration and electrochemical gradients. This pumping action proceeds simultaneously with the diffusion and thus distorts the picture of diffusion as would be determined by membrane permeability alone.

The resulting modified potential is the source of current that eddies into the point of dropped (or even reversed) potential resulting at the site of stimulation, permitting temporary free diffusion of ions and a resulting depolarization. The transient free diffusion of ions across the cell membrane carries the current into the cell. The eddy currents, in turn, act as stimuli to the surrounding membrane, which is then depolarized and draws current from more regions adjacent to the new stimulus sites. These new currents, in turn, stimulate more distant regions, and so on. Meanwhile, the original sites of stimulation and depolarization are repolarizing or recovering.

These events are shown in simplified format in Fig. 8, showing the change of resting, polarized to active, depolarized region, and the influence of the subsequent eddy current in creating a progression of the active region from left to right, tailed by a region of restored membrane. The latter is temporarily more stable than normal and, therefore, resistant to restimulation, that is, it is refractory for a short period. The eddy of current in this way spreads into a self-propagated wave, which is the conducted impulse whose minute electrical accompaniment can, after suitable amplification, be recorded as the action potential.

The channeling characteristics of the membranes of axons vary considerably, depending upon specific function. There are two principal forms. In one type, a nerve impulse opens and closes the channels in response to voltage differences across the cell membrane. Channels of this type are said to be *voltage gated*. In the other type, there is little if any response to voltage changes, but instead they respond to a particular chemical substance, as when a transmitter substance binds to a receptor region on the channel protein. These are called *chemically gated*. It has become traditional to name the chemically gated channels in accordance with the transmitter chemical involved, such as a GABA-activated channel.

In a 1986 paper, J. Dumont and R. Robertson (McGill University) suggested that neuronal circuits be considered from an evolutionary perspective. They point out that to understand neural circuits fully, it is necessary to know not only how they work, but also why they work that way. Answers to the latter questions have been almost teleological in their assumption of optimal design. However, close examination of certain systems has revealed features that apparently lack adaptive value. Their existence can be understood only if the evolution of these circuits is considered and, in particular, how nonadaptive determinants have guided their evolution. In making their proposal, the researchers describe the neuronal circuitry of the locust and the crayfish. Whether a study of arthropods can be translated to human nervous systems is uncertain.

In a scholarly paper (1992), Bert Sakmann (Max Planck Institut für Medizinische Forschung, Heidelberg, Germany) discusses the fundamentals of the plasma membrane of a cell that separates its interior from the extracellular environment and from other cells, and acts both as a diffusional barrier and as an electrical insulator, allowing differentiation of cells with specialized functions. He generally reviews how the nervous system connects cells in a very specific way, including the signal transmission between individual cells that take place at contacts (synapses) and cells that are anatomically and functionally highly specialized. Mention of relatively recent experimental methods, such as the patch-clamp technique, are described in the article. Sakmann was awarded the 1991 Nobel prize in physiology or medicine. Copies of the lecture are obtainable.

Patch-Clamp Technique. This method for separating ion channels in cell membranes was introduced by Sakmann and Erwin Neher in the mid-1970s. Since that time, several hundred research laboratories have adopted the technique. Although quite simple conceptually, several years were required to refine the technique.

Basically, the technique requires a specially contoured, extremely thin glass pipette, which is sealed tightly against a cell membrane. Thus, a small patch of the membrane and the ion channel that it contains can be isolated. Once isolated, the channels can be manipulated chemically or electrically. In some cases, it may be possible for an investigator to construct a window in a living cell for the purpose of altering the cytoplasmic constituents. This provides, in essence, a "hands on" approach to cytology at the microscopic level. The objectives of most patch-clamp technology are to probe how ion channels affect membrane voltage and to observe cell processes, including secretion and contraction.

As early as the late 1960s, researchers showed that, when trace amounts of certain antibodies or proteins are inserted into the cellular membrane, they become electrically conductive. Neher and Sakmann (see reference listed) observe, "The discrete changes in the current passing through the membranes suggest that the proteins created porelike channels that opened and closed individually. Charged ions then can traverse the membrane through the open channels."

The neuromuscular junction of skeletal muscle has been the object of numerous experiments. Here the presynaptic neurons release acetylcholine in discrete multimolecular packets (quanta). Molecules of acetylcholine transiently bind to acetylcholine specialized proteins in the post-synaptic membrane, thus creating a current flow across the end-plate membrane. End-plate current is the sum (aggregate) of elementary currents through several hundred thousand channels. As pointed out by Neher and Sakmann, "To increase these elementary currents individually, one can press the top of a patch pipette onto a muscular fiber at the end-plate membrane. This region of muscle surface contains the acetylcholine receptor channel. When a low concentration of acetylcholine is in the pipette solution, the current recorded with the pipette switches between two levels. At one level, effectively no current flows because all the ion channels in the membrane patch are shut. When one channel molecule flips to the open state, because of a voltage applied to the membrane, a current of about 2.5 picoamperes

abruptly flows through it. After a variable period, the molecule flips back to the shut state, and the current switches off."

The patch-clamp technique, in addition to illuminating molecular details of channel function, also is useful in the study of signaling mechanisms at the molecular level by way of a technique referred to as *voltage clamp analysis*, the development of which is attributed to K.S. Cole (Marine Biological Laboratories, Woods Hole, Massachusetts) as early as 1949.

In summarizing the advantages of their patch-clamp technique, Neher and Sakmann observed in 1992, "The extreme sensitivity of the patch-clamp technique has revealed molecular details of how channels function. The technique has enabled us to study the miniscule cells of mammalian tissue and to trace their signaling pathways by controlling the intracellular environment. Although it is powerful, the technique is also very simple. As more researchers adopt it, we hope and expect that it will continue to help unlock cellular secrets."

It should be mentioned that the thin glass pipette is approximately 1/25,000 the diameter of a human hair.

Chemical Messengers in the Nervous System. These messengers can be placed into three overlapping categories according to their mode of action as suggested by R.H. Scheller, et al. (Stanford University) These messages are (1) *neurotransmitters*, which act quickly and over short distances to alter transiently the excitability of cells; (2) *neuromodulators*, which alter the response of a cell to a distinct chemical input; and (3) *neurohormones*, which act at a distance from their site of release and give rise to neuronal effects that tend to be slow in onset. In studying chemical messengers, Scheller and colleagues have observed the central nervous system of the gastropod mollusk *Aplysia*. The marine organism can reach 30 to 50 cm in length and often weighs up to 1 kilogram. The central nervous system contains some 20,000 neurons clustered into 5 major ganglia, which are interconnected by an intricate network of connective nerve tracks. The research team has applied recombinant DNA techniques to isolate the genes that encode the precursors of peptides expressed in identified neurons of known function. The organization and developmental expression of these genes have been examined in detail. Several of the genes encode precursors of multiple biologically active peptides that are expressed in cells that also contain classical transmitters. These studies, as well as immunohistochemical studies and the use of intracellular recording and voltage clamp techniques may be the first steps toward revealing the mechanisms by which neuropeptides govern simple behaviors.

Some of the better known chemical transmitters, found to be mono-amines or amino acids, are illustrated in Fig. 9. The most common of inhibitory transmitters found in the brain is gamma-aminobutyric acid (GABA). This substance is produced almost exclusively in the brain and spinal cord. Some researchers believe that about one-third of the synapses in the brain involve GABA as a transmitter. It has been reasonably well established that a deficiency in brain GABA is the cause of Huntington's chorea. See also **Chorea (Huntington's)**. To date, it has not been possible to replace deficient GABA in the brain because no GABA analogues thus far developed can penetrate the blood-brain barrier. See also **Blood-Brain Barrier**. Recent research has indicated that the effectiveness of certain anti-anxiety drugs, such as diazepam (Valium®) and other drugs of the benzodiazepine class, may derive their effectiveness as psychoactive drugs because of their ability to increase the effectiveness of GABA at its receptor sites.

Amino acids, such as glycine, GABA, and L-glutamate, are the most prevalent signaling substances for rapid communication. Channels that bind these transmitters open and close randomly. Thus, these receptor channels operate in a manner similar to the acetylcholine channels at the end plate. Neher and Sakmann observe, "Transmitter-gated channels in the central nervous system often show an additional complexity, in that some channels may be only partially open or closed and that different sub-types of channels may occur in various brain regions."

A better understanding of the manner in which chemical transmitters are manufactured and utilized is developing. The greatest progress has taken place during the past decade. Several steps are involved in the production of these substances. One or several enzyme-catalyzed steps may be required to transform precursor molecules (which are stored in readiness for conversion) to the final transmitter chemicals. In the instance of acetylcholine, only one enzyme-catalyzed step is required. In the cases of some others, such as norepinephrine, three such steps are required, commencing the synthesis with tyrosine, which is taken up by the nerve terminal from the bloodstream. Tyrosine is converted

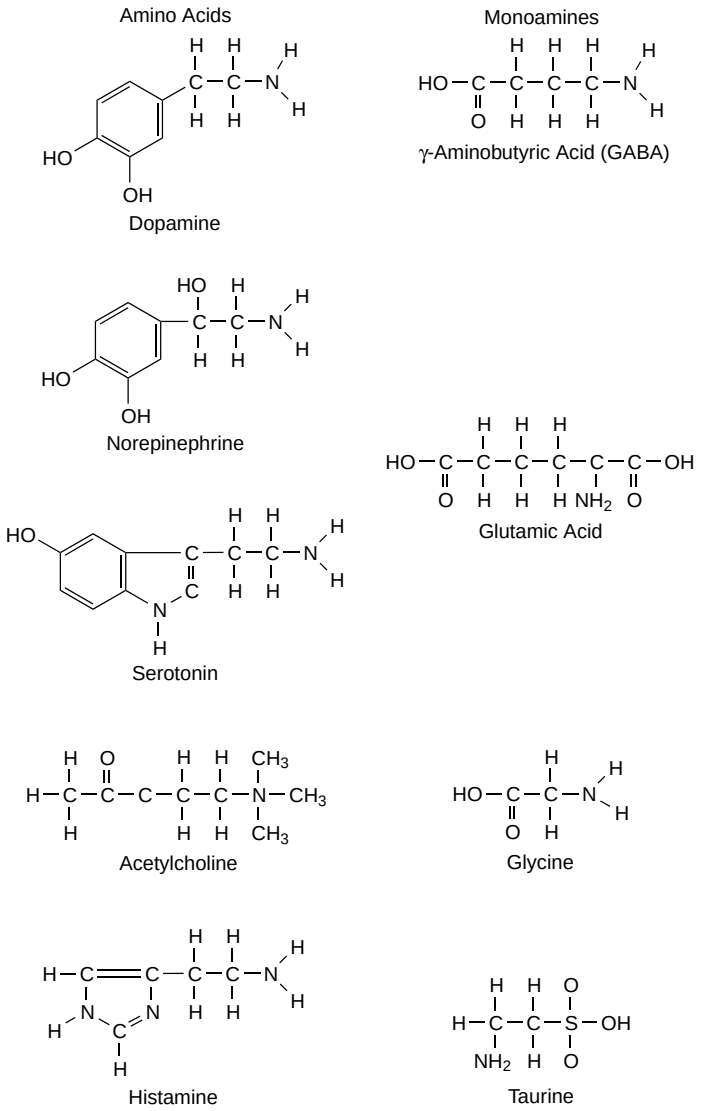

Fig. 9. Neurological system transmitter chemicals. Typically, these substances are small molecules that contain a positively charged nitrogen atom. Usually each substance characteristically inhibits or excites neurons, but in some instances the transmitter substances may play one role in one part of the brain and the other role in another part of the brain. At one time it was believed that all terminals of a given axon will transmit only one substance, but there is growing evidence that this may not always be true.

to L-DOPA. This intermediate is then converted to dopamine and, in another step, dopamine is converted to norepinephrine. Once manufactured, vanishingly small quantities are temporarily stored for a short period (until needed) in the synaptic vesicles. The tiny quantities involve only between 10,000 and 100,000 molecules of transmitter substance. These molecules in the vesicles are protected from enzymes in the terminal that would degrade them. (The mechanism of protection is not fully understood.) A nerve impulse triggers the expulsion of the transmitter substance from the synaptic vesicles into the synaptic space; this transfer in turn activates other neurons. Few details are known concerning the transfer mechanism, but it has been established that an increase in the permeability (to calcium ions) of the nerve terminal serves to engage the release mechanism. Once released, the transmitter molecules seek out specific receptor sites and thus propagate the effects of a single nerve impulse.

Although a minor degree of interaction can take place between the electrical fields of adjacent fibers, the neural impulse conduction system is essentially an adequately well-insulated system, suited to discrete communication. The development of widespread patterns of activity reflects the functioning of interconnections at the synaptic level. It should not be surprising, since transmission is effected by specific chemicals, to find that under special circumstances of great stress, a major depot of

such chemicals (adrenaline and noradrenaline) located in the medulla of the adrenal gland can pour these synaptic inhibitory chemicals into the bloodstream. Distributed in this way to all synapses, the adrenal medullary secretion can supply a cutoff influence limiting the massive discharge of impulses that stress is apt to initiate, and thus prevent it from becoming so excessive that it is detrimental. In this way, the neurohumoral transmission mechanism also affords a means of chemical homeostatic regulation.

The vulnerability of impulse transmission to chemical influences may not always serve homeostasis; for here also is where the action of poisons such as mescaline and lysergic acid diethylamide takes place. They produce in humans a temporary mental derangement or psychosis. Experiments show that these substances inhibit impulse transmission at cerebral synapses and that tranquilizers prevent this effect. Such experiments in disturbed impulse transmission are developing the basis for understanding of chemically induced psychosis and the manner of action of tranquilizers. A sufficient parallelism appears to exist between the experimental laboratory findings and data in clinical psychosis to suggest that the latter may, also, sometimes be a disturbance of impulse transmission in the brain and that tranquilizers tend to restore synaptic equilibrium.

The Neuropeptides. During the past decade, the number of chemical-messenger systems identified has increased dramatically. This advance is highlighted by the discovery of a large family of brain chemicals known as *neuropeptides*. As shown by Fig. 10, these molecules are made up of long chains of amino acids, ranging from a few to as many as 39 amino acids. Research indicates that these substances are resident within the neurons. A few of these substances, such as corticotropin (ACTH) and vasopressin, have been known for many years and identified with the hypothalamus and pituitary gland. Probably of greatest interest to researchers are the *enkephalins* and *endorphins*. These chemicals are strikingly similar to the opiate morphine. Identification of these substances followed the finding that specific regions of the brain possess receptor sites that bind opiates with a high affinity. These sites were revealed through the use of radioactively labeled opiate compounds. Further research showed that opiate receptors are located in those regions of the brain and spinal cord which are known to be associated with pain and emotion. Pioneering research efforts in this field included the work of S.H. Snyder and C.B. Pert (Johns Hopkins University School of Medicine), E.J. Simon (New York University School of Medicine), and L. Terenius (University of Uppsala). The enkephalins (Met- and Leu-), as shown in Fig. 10, were first isolated by J. Hughes and H.W. Kosterlitz (University of Aberdeen) in 1975. Each enkephalin contains five amino acids, one of these being methionine in one case, and leucine in the other case. Shortly after the isolation of these compounds, the endorphins, also morphinelike compounds, were isolated from the pituitary gland. Some researchers have suggested that some of the nontraditional methods used for relieving chronic pain, such as acupuncture, direct electrical stimulation of the brain, and possibly hypnosis, may be effective because these procedures may cause enkephalins or endorphins or both to be released to the brain and spinal cord. The drug naloxone (Narcan®) blocks the binding of morphine and experiments have shown that naloxone also blocks the effects of the aforementioned pain-relieving procedures; hence the tentative hypothesis.

Early research findings indicate that neuropeptides are released from axon terminals through the presence of calcium ions known to be the releasing mechanism in connection with established transmitters. Thus, some investigators believe that the neuropeptides also may be transmitters. This is particularly true of a compound simply identified as *substance P*.

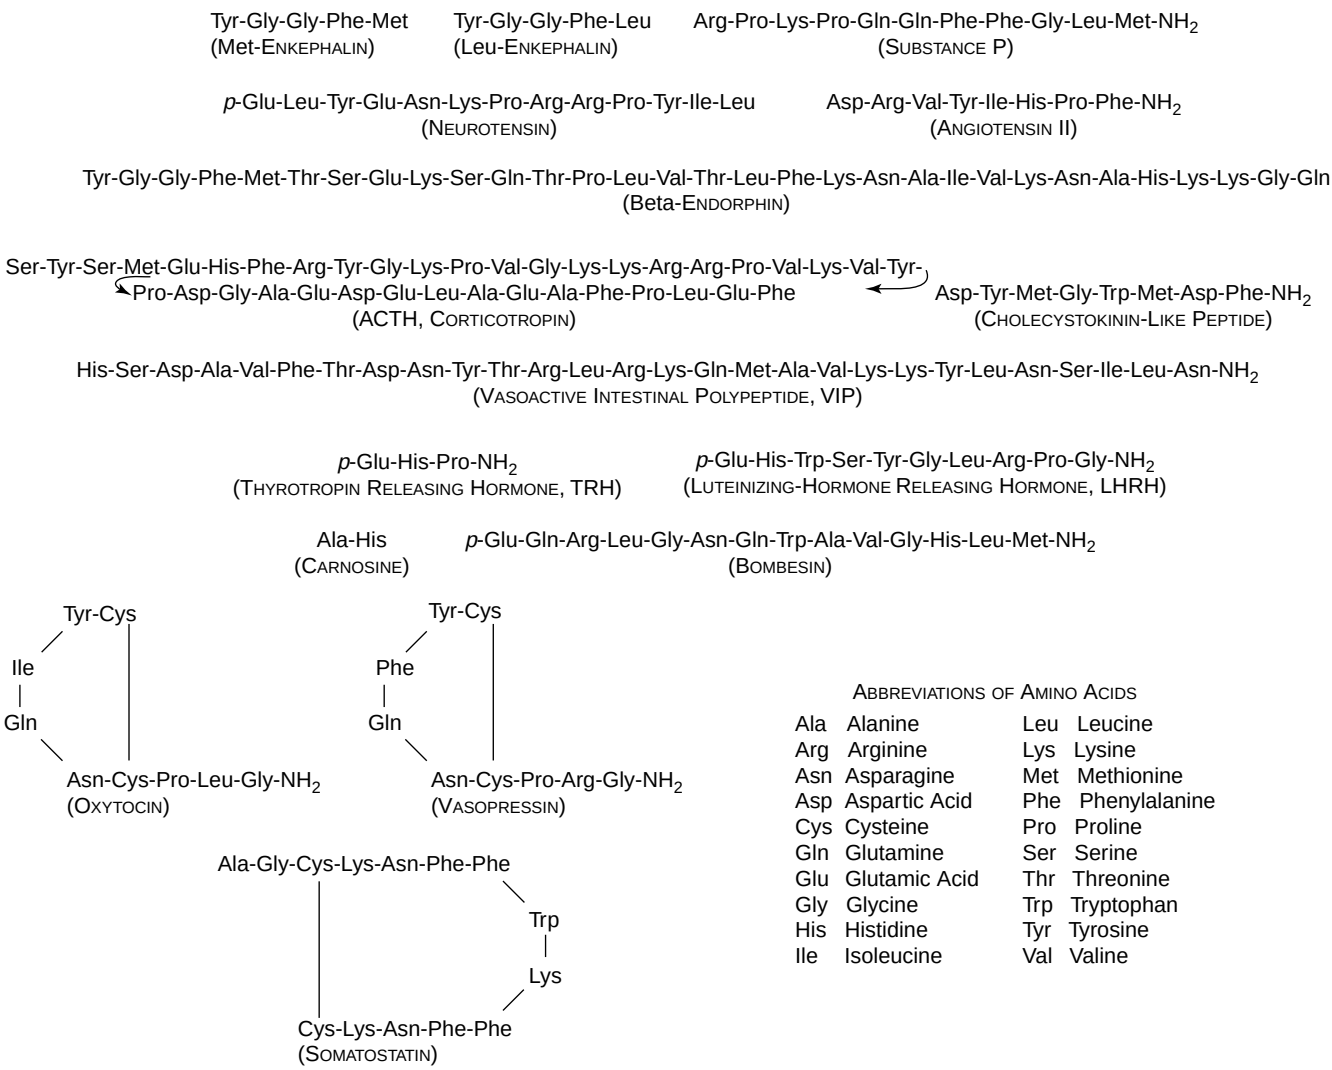

Fig. 10. Now believed to be transmitters, neuropeptides, which are short chains of amino acids found in brain tissue and notably localized in axon terminals, participate in complex mental activity, such as thirst, memory, and sexual behavior.

See Fig. 10. Some investigators have found that *substance P* is associated with spinal neurons involved in pain stimuli. P.T. Jessel and L.L. Iversen (Cambridge) had demonstrated that opiate drugs are able to suppress the release of *substance P* from sensory fibers.

Using experimental animals, researchers have shown that injection of nanogram amounts of a neuropeptide directly into brain tissue (to avoid the blood–brain barrier) causes marked behavioral changes in the subject, such as prolonged drinking behavior (at a time when the animal should not be thirsty), enhancement of sexual behavior, and improvement of memory. Some scientists have suggested, for example, that vasopressin may have beneficial effects on human patients suffering from memory loss.

One of the surprising findings of recent brain and central nervous system research is that chemical substances previously considered to be exclusive to the province of the brain have been found in organs outside the nervous system (examples: somatostatin, neurotensin, and enkephalins found in the gut); and, conversely, that other substances active in other organs, but not previously associated with the central nervous system, have been found in the latter (examples: gastrin, vasoactive intestinal polypeptide (VIP), and cholecystokinin, traditionally associated with the gastrointestinal tract, but now found in the central nervous system).

In an interesting paper (see reference listed), D.I. Gottlieb (Washington University School of Medicine) describes how nerve cells not only excite their neighbors, but also inhibit them. Such inhibitory activity, often mediated by GABA, helps to shape the neural networks that underlie all behavior.

In the early 1980s, some pharmacologists suggested that nitric oxide, gas, may be an important regulator of body activities. Recent research at the Johns Hopkins University has noted a specific connection between nitric oxide and the brain. In low concentrations, the chemical can act as a neurotransmitter for carrying nerve impulses from one cell to another. In high concentrations, the substance can be toxic to neurons. A factor that impedes research in this area is that nitric oxide has a very short life span; it lasts for only a few seconds after its manufacture. Researchers at Johns Hopkins now are attempting to clone the gene that encodes nitric acid synthase, the enzyme that makes nitric oxide in nerve cells and also in the endothelial cells that line blood vessels.

Astrocytes. The importance of excitable neurons to brain processes is fundamental. However, H.K. Kimelberg and M.D. Norenberg (University of Miami School of Medicine) reported (1989) that approximately half of the brain does not contain excitable cells, but rather is made up of nonexcitable cells. The latter are placed in two groups: (1) *neuroglia* (a word first used by a German pathologist in 1846) and sometimes referred to as "nerve glue," and (2) *astroglia*, commonly referred to as *astrocytes*. They are named for their starlike shape. Scientists in the past generally have regarded these cells as passive support elements for the neurons. Improved methods for growing and identifying astrocytes have revealed for the first time the role of these cells in brain physiology, brain development, and nervous system pathology.

Investigators now admit that a better understanding of astrocytes is needed to establish a full picture of the workings of the brain and no longer can be accepted simply as passive in nature.

Once regarded as a cementlike connective tissue, Golgi in the mid-1870s identified *neuroglia* by using staining techniques. A classifying system developed by Santiago Ramón y Cajal (Spanish neuroanatomist) during the same time frame referred to the majority of neuroglia as macroglia, a concept that has persisted over the years. Macroglia are made up of astrocytes and *oligodendrocytes*. The latter are known to form myelin, which protects axons and neurons in the white matter of the brain.

Glial fibrillary acidic protein (GFAP) was discovered in the early 1970s as a component of the cytoplasm of astrocytes and became a convenient marker for identifying the cells. GFAP was isolated by L.E. Eng and A. Bignami (Stanford University) in the 1970s. The ability to work with these cells in samples of tissue and in culture led to a further understanding of the role of astrocytes. Research has implicated astrocytes in neuron damage that is manifested by psychiatric disorders ranging from stupor to coma, an example of which is known as *hepatic encephalopathy*. The mechanisms currently involved are poorly understood. Certain psychoactive drugs adversely interact with astrocyte receptors in some still unexplained way. Astrocytes are believed to participate in Huntington's disease, Parkinson's disease, multiple sclerosis, and Raye's syndrome. Researchers Kimelberg and Noremberg observe, "The time has come to consider astrocytes equal partners with neurons in both the normal and abnormal brain."

Protection of Central Nervous System. The total system is well protected by the rigid *skull* and the flexible backbone (*vertebral* or *spinal column*). The skull consists of a dome of thin, porous, but strong bones. The bones of the forehead contain the sinuses of the nose. The floor of the skull is composed of somewhat thinner bone and contains more sinuses that connect with the nasal passages. The deeper structures of the ear are embedded in the bones forming the base of the skull. The floor of the skull consists of three irregular depressions (*fossae*) that form three descending levels. The fossa in the back of the skull is the largest and deepest. The cranial nerves arise from different parts of the brain and emerge through various bony canals and openings of the skull.

Inside this hard shell, three separate tissues provide additional covering for the brain and spinal cord. The outermost, *dura mater*, consists of layers of dense, fibrous material. The outer layer of the dura adheres tightly to the bones of the skull. The inner covers the brain and spinal cord, forming a tough, saclike structure. Within the skull itself, the dura is folded into partitions that separate and support the various parts of the brain. One such fold is called the *falx cerebri*, which divides the cerebral hemispheres into right and left halves. Another fold, the *tentorium*, separates the back fossa from the vault of the skull. It provides a horizontal support for the back part of the brain and separates that part from the cerebellum. Between the layers of the dura are large blood vessels called *venous sinuses*, which collect blood from the brain and return it to the heart.

The middle of the three covering tissues is a delicate membrane called the *arachnoid* (cobweb-like), a layer that encloses the brain and the spinal cord in a loose-fitting sack. The space below this layer is the *subarachnoid space*.

The third covering is a thin, delicate sheet that follows closely all the irregular surfaces and fissures of the brain and spinal cord. This is called the *pia mater* and is next to the nerve tissue proper.

Between the arachnoid and the pia mater circulates the cerebrospinal fluid, which acts as a shock absorber for the central nervous system. Also, it is postulated that this fluid helps in nourishing the nerve tissue itself. This clear, watery-appearing fluid, formed within certain cavities (*ventricles*) of the brain, flows out from small openings into the brain and spinal cord before it is absorbed back into the bloodstream. When the flow or absorption of the fluid is impaired, it accumulates in large quantities. The head enlarges and "water-head" (*hydrocephalus*) results. The spinal fluid is affected by various disorders and is easily drawn off to be examined for diagnostic purposes.

The findings of D. Cunningham (University of California, Irvine) pertaining to the role of clotting factor *thrombin* in helping to maintain nerve connections in the brain were reported in 1992. Thrombin is best known, of course, for its role in blood coagulation. Proteins of the body's blood clotting system assist in the regulation of normal brain development and in protecting the brain against stroke damage, trauma, and other injuries. Further, research indicates that an imbalance of these proteins may contribute to nerve cell damage, as encountered in Alzheimer's and other neuro-degenerative diseases. After years of earlier research, including that of D. Monard (Friedrich Miescher Institute, Basel, Switzerland) in the early 1970s, Cunningham and associates identified newly found protease nexins (PN-1 and 2) as playing an important role in making and maintaining connections between nerve cells. Investigators have found that the action is not only manifested in culture, but also occurs in intact brain tissue. Apparently the actions are limited by the balance between the protein factors. An imbalance can result in protecting nerve connections or, on the other hand, lead to loss of neuronal connections and nerve cell damage, especially if thrombin predominates. It has been suggested by some investigators that tests for the aforementioned substances may become a basis for diagnosing Alzheimer's.

Trophic Substances. Among the most recent discoveries in brain research concerns so-called *trophic substances*, which are believed to be secreted from nerve terminals. One of these substances is nerve-growth factor (NGF). It has been established that this protein is required for the differentiation and survival of peripheral sensory and sympathetic neurons. Considerable research effort is going forward to better understand the function of trophic substances and to isolate and identify them. Substances that may be generated in the pituitary gland and transported to the brain are mentioned in the entry on **Pituitary Gland**.

Another important area of research that benefits from recent findings such as those just described is directed toward a better understanding of how psychoactive drugs interact with the brain and central nervous system.

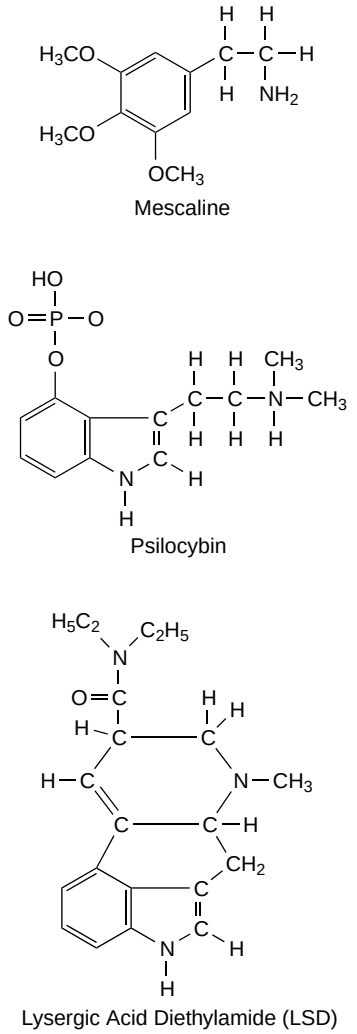

Fig. 11. Representative hallucinogenic drugs which bear structural similarities to some of the monoamine transmitters. It has been hypothesized that these similarities may cause the hallucinogens to mimic natural transmitters at synaptic receptors in the brain. Note presence of benzene-ring structure in these substances, a structure that is present in four out of the five monoamines previously shown. Also note presence of indole ring in psilocybin and lysergic acid diethylamide, a structure that is also present in the monoamines serotonin and histamine.

See Fig. 11. An improved understanding will assist in the treatment of various brain disorders and of countering the effects of hallucinogenic drugs that are willfully, but tragically taken by a small number of very foolish people for "kicks." Research has progressively indicated over the years that tampering with the extremely complex brain and central nervous system is indeed attended by many risks.

Ethnic Disparities in Drug Therapy. As early as 1974, Keh-Ming Lin (University of Washington) noted that, in treating Asian patients with schizophrenic psychoses in Taiwan, they required much smaller dosages of drugs (haloperidol) than proved to be the case of Caucasian patients. To relieve symptoms among the latter ethnic group required about ten times the dosage (2 mg), as was the case in Taiwan. With further investigation, it was found that Asians often require far lower doses of psychotropic drugs than Caucasians. Prior research with the treatment of such diseases as sickle cell anemia and Tay Sachs disease had indicated differences in response related to the ethnic origin of patients. As of 1991, there are several centers that are specializing in this area, one being that headed by Keh-Ming Lin at the Harbor University of Los Angeles, Torrance, California.

Several genetically influenced biological systems may be involved. It is well known, for example, that an enzyme deficiency limits the ability of Orientals to metabolize alcohol. Studies in the late 1970s by British and Indian researchers compared three groups: Caucasians and Sudanese, each in their adopted residency in Britain, and Sudanese in their native villages. Differences in metabolizing certain drugs were noted, but, in such instances, the diet of the patient appeared to be a dominating factor.

Currently, the role of ethnicity in the use of psychotropic drugs is in a very early stage and one that could lead to controversy. One scientist has observed, "We are not looking at the biology of race differences. We are looking at how different ethnic groups respond to treatment for severe mental illnesses known to have biological correlates. What's important is that a center like this will influence practice directly so people will get more appropriate treatment."

Brain Metabolism

The metabolism of the brain usually is measured either in living organisms, or in isolated systems, such as brain slices, brain homogenates, or extracts. In isolated systems, the different metabolic pathways can be closely observed, while measurements under living conditions show which of the possible capacities of the organ observed in isolated systems are operative, and at what rate, in the living brain.

The metabolism of living brain usually is measured by analyzing the arterial blood coming to, and venous blood coming from, this organ. Since cerebral circulation is very rapid (under normal conditions, about 1/6th of the total circulation goes through the brain), this method can only measure those substances that are used or produced rapidly and in significant quantities by the brain. Glucose is the main metabolite of the brain, and the oxidation of this compound accounts for most of the oxygen utilized by the brain. The utilization of oxygen in the brain is surprisingly high, higher than in most other organs, with about one-fifth to one-quarter of the oxygen taken up through the lungs being utilized by the brain, which comprises only 2% of body weight. About 90% of the glucose is oxidized completely to carbon dioxide, the rest mostly to lactic acid, and a small portion to pyruvic acid. The whole brain of a normal young man consumes 46 milliliters of oxygen and 76 milligrams of glucose per minute with a blood flow of 750 milliliters. These figures show that the metabolic rate of the brain is very considerable in the total body economics as far as energy and oxygen utilized, heat produced, and other factors. With physical activity, the oxygen consumption of the whole body changes significantly, but brain metabolism does not. Oxygen uptake and glucose utilization do not change significantly during mental exercise or during sleep, but are altered in extreme circumstances, such as deep anesthesia, which reduces metabolism; or high carbon dioxide content of the air, which increases cerebral blood flow.

The large amount of energy utilized by the brain is somewhat surprising since this organ does not perform work like that done by for example, muscle and kidney. The most plausible explanation is that there is continuous very high activity in the brain. Such activity can be detected by the electroencephalogram. Continuous impulse conduction involves the movement of ions, since conduction by nerve is achieved by temporary change in ion permeability.

Other components metabolized include lipids, nucleic acids, and proteins.

Cerebral metabolic rates change under a number of circumstances. There is a general decrease of oxygen utilization during development. It has been estimated that in the newborn, cerebral respiration can amount to half of that of the whole organism. Metabolism reaches a plateau in adulthood, and further decrease after 50 years of age in humans has been suggested, but not well confirmed. The metabolism of a number of compounds undergoes significant fluctuation under conditions, such as convulsions, hibernation, demyelinating diseases, and other pathological states (multiple sclerosis; myelin). A lot of interest is centered on subtle changes in metabolism which are due to changes in mental activity, such as those shown by comparison of trained versus untrained animals, or animals reared in isolation versus others reared in a complex environment. It is of interest that metabolic changes that were found and which were interpreted as changes in functional metabolism are different in the two types of cells of the brain. In functional metabolism, neurons have preference and glial cells play a supporting role.

The effect of chemical compounds on brain function is well known. Alcohol, antidepressants, hallucinatives all indicate the functional role of metabolism in the brain, particularly of compounds that inhibit cerebral protein metabolism. Compounds that inhibit the latter also inhibit the deposition of short-term memory, while most do not appear to affect already deposited long-term memory.

Traditional Views of Memory Function

As of the early 1990s, even though marked progress had been made in recent years, the manner in which the brain processes information (input signals from the various senses), selectively stores that information over short or very long time spans, and retrieves that information upon command remained relatively poorly understood. It appears that not much will be learned from analogies with modern electronic computers, but that the reverse consequence may occur, namely that of using the human brain, once understood, as a model for industrial, business, and scientific computers. Much is being learned currently about the brain by way of improved imaging techniques and computer mapping, subjects discussed later in this article.

Early Research and Hypotheses. Traditionally, the brain has been described in terms of areas, gross structures, and regions, some of which have been identified with memory functions for a number of years. Most of what has been learned to date concerning the physiology of the brain has been acquired from the study of brain injuries and disorders. Memory research is at a very early stage, in which investigators refer to large subsystems — lobes, areas (Broca's and Wernicke's), and other regions with special names — much as a computer scientist refers to the various storage functions and regions of a data processing machine, except that in the latter case, the manner in which the tiny subelements and components of the larger subsystems are well understood. In a way, the most specialized scientists of today, in terms of understanding the brain's memory function, are about in the same position as the layman who has a fair idea of what computers can do, but no depth of knowledge as to how computers actually work. In making this observation, it is not intended that, beyond the general definition of what the animal and electronic memories do, any parallels be drawn between the two fundamentally different kinds of memory systems.

Just as an expert racing driver can quite accurately evaluate the characteristics and capabilities of an automobile, experimental psychologists have collected a large body of data on human learning and memory. To do this, the racing driver need not necessarily know the details of what is under the hood. Thus, a lot more is known about what the memory can accomplish, i.e., short-term, long-term, etc. than what is known about how these functions are accomplished at the micro or molecular level.

The ability of the human brain to remember in great detail and over long periods of time, thus making language, recognition, music, reading, and writing not only possible, but capable of immense refinement, creativity, and imagination. These are the ingredients of human art, culture, and way of life and this ability is the major distinction of the human being from lower animals.

As early as the 1860s, Broca, a French researcher, showed that damage to a particular region of the cortex will consistently give rise to an aphasia or speech disorder. Now referred to as Broca's area, this is a region on the side of the frontal lobes and is also called the anterior language area. Broca also pointed out over a century ago that damage to this area on the left side of the brain will lead to aphasia, whereas similar damage to the corresponding area on the right side of the brain does not. Over the years, statistics have shown that nearly 100% of all aphasias are caused by brain damage occurring in the left hemisphere of the brain. Frequently, this area is destroyed by a stroke, with at least partial disruption of speech. Somewhat later (1874), Wernicke, a German researcher, discovered another area of the brain associated with aphasia. This area lies between the primary auditory cortex and a structure called the *angular gyrus*. It has been suggested that the angular gyrus mediates between visual and auditory centers of the brain. More recent research also indicates that Wernicke's area and Broca's area are connected by a bundle of nerve fibers known as the *arcuate fasciculus*. These speech centers of the brain obviously must call upon other areas of the brain to bring out all of the stored memory required to recognize, on the one hand, and to formulate on the other hand, the basics of speech and communication.

That the brain functions in what still may be described as mystifying ways is exemplified by a disorder of perception known as *prosopagnosia*. Persons with this disorder cannot identify other people's faces at a glance as is true of the normal individual. In fact, persons so afflicted cannot associate other people with photos or with their real faces, but can process and associate voice information held in memory. Other memory retrieval and processing facilities required to read, write, etc. in such individuals are not impaired. Investigators have identified the location of lesions that cause prosopagnosia. Damage is noted on the underside of both occipital lobes, extending forward to the inner surface of the temporal lobes. The present very qualitative state of understanding of the brain's memory and other specialized functions is exemplified by the 1979 statement of a leading American neuroscientist, "The implication (of the aforementioned findings) is that some neural network within this region is specialized for the rapid and reliable recognition of human faces."

Scientists for many years have made qualitative distinctions between short- and long-term memory. There is asymmetry of the right and left halves of the brain. Certain memory processes appear to be associated with structures on the inner surface of the temporal lobe, such as the hippocampus. Bilateral lesions of these areas have been shown to cause a severe and lasting memory disorder characterized by the inability to learn new information. See also **Amnesia**. Patients with lesions of this type appear to have undiminished powers of perception, but they are largely incapable of incorporating new information into their long-term storage. Acute lesions in this region of a single temporal lobe sometimes result in similar, but less persistent memory disorders that reflect the contrasting specializations of the hemispheres. The type of information that can be learned varies according to the side the lesion is on.

Further qualitative descriptions of memory function have been formulated by experimental psychologists. Qualitative descriptions have been prepared concerning visual analyzers and word detectors. For example, some investigators suggest that a person has a visual feature analyzer and collateral sets of word detectors connected to a semantic memory network. It has been proposed that the feature analyzer receives a row of letters and produces a code representing the letter shapes, based upon their lines, curves, and angles, as well as the spatial relations among them. It has been suggested that the code is sent simultaneously to all of the word detectors, each of which takes time to count how many visual features the letter row has in common with a particular word. Qualitative analogues such as these have been very helpful to teachers for improving the practical utilization of the brain's memory and recognition functions, but do not necessarily lead to an accurate concept of the real physiological basis of these brain functions.

In an excellent paper, A. Baddeley (Medical Research Council, Cambridge, UK) describes the conceptual term, *working* memory. The researcher observes, "The concept of a working memory system that temporarily stores information as part of the performance of complex cognitive tasks is proving to be productive. Studies that have utilized the individual difference approach have linked working memory to performance on a range of important tasks, including language comprehension and reasoning. The more analytic approach has shown that the concept forms a useful conceptual tool in understanding a range of neuropsychological deficits, which in turn have thrown light on normal cognitive functioning. Working memory stands at the crossroads between memory attention and perception."

Endel Tulving (University of Toronto) and D.L. Schacter (Harvard University) define *priming* as a nonconscious form of human memory, which is concerned with perceptual identification of words and objects and which only recently has been recognized as a separate form of memory or memory system. Evidence is converging for the proposition that priming is an expression of a perceptual representation system that operates at a pre-semantic level. It emerges early in development, and access to it lacks the kind of flexibility characteristic of other cognitive memory systems. Conceptual priming, however, seems to be based on the operations of semantic memory.

As pointed out by these researchers, "Memory was traditionally thought to be a unitary faculty of the mind. Recently, however, many researchers have adopted the hypothesis that memory consists of a number of systems and subsystems with different operating characteristics. The problem of what these systems and their properties are, and how they are related to one another, now occupies the center stage in research on memory." The investigators stress the importance of systematic classification of memory systems, both psychological and physiological, as an essential prerequisite for the successful pursuit of the empirical and theoretical understanding of the memory processes and mechanisms. The systems approach, combined with appropriate processing theories, seems to provide the most direct route to the future.

At the 1990 Cold Spring Harbor meeting, debate on the precise cellular basis of memory continued. (See Barinaga reference listed.) For many years, a majority of researchers has contended that long-term memory occurs at the synapses. This is, of course, a generalization that does not satisfy the more curious researchers. Out of further research, the concept

that the postsynaptic (receiving) cell is the site of change is emerging. This phenomenon occurs as the result of a process now referred to as *long-term potentiation* (LTP). R. Tsieu (Stanford University) and C. Stevens (Salk Institute) presented details on the LTP concept and the means for researching the process (*quantal analysis*), the details of which are too complex to present here.

At the 1991 Cold Spring Harbor meeting, T. Tully (Brandeis University) and other scientists described their confidence that *Drosophila*, the fruit fly of genetic research, also can become a good model for investigating memory systems, a proposal that received varying responses at the meeting. (See Stipp reference listed.)

A Return to Pavlov. In recent years, interest has returned to Pavlov's conditioned reflex experimentation in dogs. In 1989, D.L. Alkon (National Institute of Neurological and Communicative Disorders and Stroke) reported on research that indicates that a neuron can alter its structure during the process of *associative* learning. Such structural changes previously had been noted only in embryos and immature animals. Laboratory research was done with the alabaster sea slug (*Hermissenda*), which "instinctively" swims toward light. In a programmed experiment, each time the animal observed a light, it was whirled on a turntable, causing the slug to grip the chamber wall tightly by clenching its foot muscle, thus altering the animals' normal response to light. Careful procedures were followed so that any changes observed in the trained group were related specifically to the learning of a new response. Subsequently, the researchers examined a particular neuron (type B photoreceptor, one of five light-detecting neurons in the slug's eye). The cell from a slug with conditioned response was stained and compared with the similar feature of an unconditioned slug. A significant difference was noted. In the trained animal, the axon spread out in a fanlike shape over a much smaller region (50% or smaller) than the axons taken from two control groups. Animals that learned to respond most strongly had the most tightly focused axon terminals. Researcher Alkon observes, "We see the same biochemical and molecular changes in the rabbit hippocampus as we've seen in *Hermissenda*. We'll be looking for the same structural changes as well."

Imaging the Brain

Since the late 1980s, dramatic progress has been made in imaging the brain, both from the objectives of creating still maps and of observing the brain at work, in connection with research and diagnostic procedures. Principal imaging techniques used have included: (1) X-ray computed tomography (CT); (2) positron-emission tomography (PET); (3) magnetic resonance imaging (MRI); and (4) single-photon-emission computed tomography (SPECT). Although not an imaging technique per se, much nervous system information also is obtained by way of magnetoencephalography (MEG).

Much research in the past has been obtained by using invasive research techniques on animals, notably the macaque monkey. Imaging techniques now are used extensively in animal research. One investigator has developed a chart that reveals 32 areas of the macaque's cerebral cortex associated with vectors of vision, including 300 circuits that connect these areas. The detail is much greater than currently is obtainable in examining the human brain, which is ten times larger than the macaque brain.

Prior to sophisticated imaging processes, human brain research essentially was confined to gleaning information from limited and rather crude methods, such as studying brain lesions and making electrical recordings of neural activity in patients while undergoing brain surgery.

X-Ray CT. These images result from the passage of x rays through the brain or spine in a number of different directions. Intervening tissues attenuate radiation to different degrees, thus producing two-dimensional multiplanar representations of the structures under examination. Detectors in opposition to the series of x-ray sources measure the amount of transmitted radiation. Computer algorithms relate the density of the intracranial or spinal contents to the quantity of attenuation. These are known as tomographic images. By use of iodinated contrast agents given intravenously or intrathecally, tissue attenuation can be increased. The earliest of the imaging techniques, x-ray CT has limitations. Meningiomas and acoustic neuromas are not seen well with CT. MRI is superior to CT in evaluating most cerebral parenchymal lesions. However, since CT requires less time than MRI, it may be the method of choice for some patients. Further, MRI cannot be used with patients who have cardiac pacemakers.

Magnetic Resonance Imaging (MRI). This methodology is based on the responses of protons in a strong magnetic field to the effect of a brief radiofrequency pulse. As described by S. Gilman (University of Michigan Medical Center), "Within the magnetic field, protons of the body align the axis of their nuclear spins with the external magnetic field and are displaced from this alignment by the radiofrequency pulse. When the pulse ends, the protons return to their previous orientation in the magnetic field, and radiofrequency energy is emitted from the tissue. The energy is amplified, recorded, and transformed into a planar or three-dimensional image of the structure. See also Nuclear Magnetic Resonance(NMR) and Magnetic Resonance Imaging (MRI).

Positron-Emission Tomography (PET). Known and used for several years, PET measures gamma rays emitted by radioactive tracer molecules, variously labled, including carbon-11, fluorine-18, and oxygen-15. The method has been useful for clinical diagnosis, but has faced numerous obstacles in developing a reputation as a research tool. PET does not necessarily yield images that correlate directly with brain activity. Although PET scanning can measure blood flow, some investigators observe that blood flow does not always represent an increase in neural activity. Others say that the method simply is not fast enough. Marcus Raichle (Washington University Medical Center) has noted that investigators who got on the PET bandwagon in the early 1980s were not always the most rigorous of investigators, and one can become discouraged when "bad science" is carried out with PET. Nevertheless, improvements are continuing and Raichie observes, "The key issue is to introduce rigor into these experiments, such that people not directly involved will understand that this is a legitimate scientific tool, that this isn't just playing or picture taking." Researchers have developed new ways to analyze PET data, including the standardization of results by labeling parts of the brain with coordinates rather than names and using coordinates that provide the flexibility required for different human brain sizes studied."

The most successful results with PET to date have involved fairly simple systems, such as those of the visual and motor cortex, where there is already a good, basic understanding of the physiology.

Most researchers agree that knowledge of the human brain must stem from human brain studies and not extrapolated from patterns exhibited by other species. Admittedly, a comprehension of how the brain processes the problems of language and the handling of deep emotion remain to be learned a number of years hence.

Single-Photon-Emission Computed Tomography (SPECT). This methodology makes up for a major shortcoming of PET, namely that SPECT is not required to be near a source of cyclotron radiation. With SPECT, radionuclides that emit gamma rays are administered by intravenous injection or inhalation. These radionuclides have longer half-lives than positron-emitting radionuclides and thus commercially available substances can be used. Although SPECT is less costly than PET, the spatial resolution of the images is more limited. In recent times, SPECT has been used widely to study cerebral blood flow, cerebral blood volume, and cerebral neurotransmitter receptors. Abnormalities in cerebral blood flow can be demonstrated, as found in stroke, migraine, epilepsy, and degenerative diseases, such as Alzheimer's, Pick's, and Huntington's disease.

Brain Mapping Network. In late 1990, neuroscientists launched a computerized database to incorporate the tremendous amounts of data that describe the structure and locations of functions in the brain, ranging from sites active in vision and speech to those that are engaged in anxiety and other emotions. Known as *BrainMap*, the project was conceived by Peter Fox and colleagues at Johns Hopkins University, who observe, "We hope to develop a system similar to the genome database." It is planned to present information on the network as numerical coordinates that describe the precise locations of functions or tasks in the brain. One objective of the database is that of impelling neuroscientists to describe their data in uniform terms.

Computational neuroscience, commenced in a serious way in the 1980s, is gaining increased attention in the early 1990s. The objective of computational neuroscience is to delineate the manner in which electrical and chemical signals are used in the brain as a means for representing and processing information. At an increasing rate, computer-created brain models are used to relate the microscopic level through the use of molecular and cellular techniques with the systems level as defined through the study of behavior. Some questions posed to computational neuroscience include: (1) What kind of computer is the brain? (2) How can realistic brain models be created, and what is the best technology for brain modeling? (3) How

does the brain detect and compute motion? (4) What are the principles of orientation selectivity in the visual cortex?

Sejnowski, Koch, and Churchland, researchers in this field, summarize a comprehensive paper on computational neuroscience with the observation: "At this stage in our understanding of the brain, it may be fruitful to concentrate on models that suggest new and promising lines of experimentation, at all levels of organization. In this spirit, a model should be considered a provisional framework for organizing possible ways of thinking about the nervous system." See reference listed.

The construction of mental models by readers or listeners of narrative material have been the center of recent studies by G.H. Bower and D.G. Morrow (Stanford University and Stanford Medical Center). The skill represented in building such models is, in essence, the basis of language comprehension. As observed by these researchers, "Cognitive psychologists and education specialists focus on research in reading comprehension, because it involves many components of intelligence, recognition of words, decoding them into meanings, combining meanings into statements, inferring connections among statements, holding in short-term memory earlier concepts while processing later discourse, inferring the writer's or speaker's intentions, schematization of the gist of a passage, and memory retrieval in answering questions about the passage. Thus, the study of comprehension has become for cognitive psychologists what the fruit fly became for geneticists, a means of investigating many issues."

In their paper (see reference listed), the researchers conclude, "The ability to construct and manipulate valid models of reality provides humans with our distinctive adaptive advantage; it must be considered one of the crowning achievements of the human intellect."

Neural Networks. In a review of neuroscience models and networks, M. Barinaga reviews the field, which dates back to the 1950s and 1960s. A breakthrough occurred in 1993 when T. Sejnowski (Johns Hopkins University) and G. Hinton (Carnegie-Mellon University) introduced the three-layer neural net. This proved to be a striking improvement over its predecessors. Barinaga observes, "In the three-layer net a middle layer of units connects the input and output layers. When the net is given an input, it sends signals through the hidden layer to produce an output. That output is checked against the "correct" output, and a learning algorithm is used to reduce error by strengthening or weakening connections in the net. The hidden layer retains the record of how the network distributed the task in the process."

Like other approaches, the three-layer network has its enthusiasts and its protagonists. With the appearance of more physiologically based models, stronger, more reliable predictions of brain activity can be expected. Most neuroscientists are looking to the current decade for large improvements in this science/art.

Neuronal Cell Development for Research

In years past, the number of nerve cells available for biochemical and physiological experiments has been limited by the comparatively small numbers of cells that can be obtained from an animal. A cell line for searchers has been difficult to achieve because mature neurons do not divide and will resist manipulation to a continuously dividing state. Several laboratories recently have developed a neuronal cell line by manipulating neurons in an early and vulnerable stage of development, that is, before they have matured.

Investigators at the California Institute of Technology have developed a method for purifying cells and "immortalizing" them with special retroviruses. In this process, several new and important findings were made. The cells do not respond to nerve growth factor (NGF) until they are first exposed to the fibroblast growth factor (FGF). The latter causes the cells to create NGF receptors. The influence of NGF permits their conversion to sympathetic neurons. When infant neurons are not influenced by FGF, they move to the adrenal gland where they become secretory cells.

Brain/Nervous System Disorders

Major abnormalities resulting in diseases and disorders of the brain and nervous system are described elsewhere in this Encyclopedia. Consult alphabetical index. An abridged list of these diseases is given in Table 2.

TABLE 2. DISEASES AND DISORDERS OF THE NERVOUS SYSTEM AND BRAIN

Muscle And Neuromuscular Junction	Degenerative And Hereditary Diseases	Metabolic And Nutritional Disorders
Muscular dystrophy	Alzheimer's disease	Encephalopathy
Toxic-metabolic myopathies	Arteriosclerotic dementia	Wernicke's encephalopathy
Glycogen storage disease (McArdle's disease)	Occult hydrocephalus	Infections
Myoglobinuria	Diseases of the basal ganglia	Acute pyogenic meningitis
Malignant hyperthermia	Huntington's disease	Chronic meningitis
Alcoholic myopathy	Essential tremor	Acute amebic meningitis and meningoencephalitis
Drug-induced myopathy	Dystonia	Parameningeal infections
Endocrine myopathy	Shy-Drager syndrome	Demyelinating Disease
Inflammatory muscle disease	Progressive supranuclear palsy	Multiple sclerosis
Polymyositis and dermatomyositis	Wilson's disease	Cerebrovascular Diseases
Myasthenia gravis	Gilles de la Tourette's syndrome	Cerebral transient ischemic attacks
Myasthenic (Eaton-Lambert) syndrome	Amyotrophic lateral sclerosis	Ischemic stroke
Peripheral Nervous System	Hereditary ataxias	Cerebral hemorrhage (hemorrhagic stroke)
Cranial mononeuropathy	Spinocerebellar degeneration	Subarachnoid hemorrhage
Bell's palsy	Joseph's disease	Hypertensive encephalopathy
Trigeminal neuralgia (tic douloureux)	Neurocutaneous disorders	Cerebral arteritis
Vestibular neuronitis	Stiff-man syndrome	Headache
Localized neuropathies	Mechanical And Traumatic Disorders	Classic migraine
Carpal tunnel syndrome	Spinal cord disorders	Common migraine
Ulnar palsy	Cervical disk disease	Basilar artery migraine
Brachial plexus neuropathy	Lumbar disk disease	Ophthalmoplegic migraine
Meralgia paresthetica	Claudication of the cauda equina	Hemiplegic migraine
Peroneal palsy	Cervical fracture-dislocation	Cluster headache
Toxic or metabolic neuropathy	Cervical spondylosis	Increased Intracranial pressure
Drug-induced	Head trauma	Epilepsy
Chemical and heavy-metal induced	Neoplastic Disorders	Sleep Disorders
Vitamin B12 deficiency	Brain tumor	Insomnia
Developmental Anomalies	Spinal cord tumor	Narcolepsy
Aqueductal stenosis		Sleep apnea syndromes
Arnold-Chiari malformation		
Syringomyelia		

Note: Several of these disorders are described in separate articles in this encyclopedia, or as parts of broader articles. Check alphabetical index.

CENTRAL FORCE. A force acting along the line joining two centers, as, for example, the electrostatic attraction between charges.

CENTRAL LIMIT THEOREM. The distribution of sample means usually approximates a normal distribution. The approximation becomes more accurate as the size of the sample increases. This is particularly remarkable in that the shape of the distribution of the population from which the sample was drawn has little influence over the shape of the distribution of sample means. The necessary and sufficient condition that sample means be distributed normally constitutes the central limit theorem of probability. We shall state a sufficient condition proved by Liapounoff, which is extremely general. Let $x_1, x_2, \ldots, x_n$ be independent variables with means zero, possessing absolute third moments. $\mu_3^{(1)}, \mu_3^{(2)}, \ldots, \mu_3^{(n)}$, respectively. (An absolute third moment is defined as the expected value $|x|^3$.)

Let σ_i^2 be the variance of x_i and

$$\sigma^2 = \sum_{i=1}^{n} \sigma_i^2$$

let

$$\alpha_3 = \sum_{i=1}^{n} \mu_3{}^{(i)}/\sigma^2$$

Then if $\lim_{n\to\infty} \alpha_3$ approaches zero the mean $\overline{x}$ approaches a normal distribution.

An example of a distribution that does not obey the central limit theorem is the Cauchy Distribution.

There are various generalizations of the theorem, e.g., by relaxing the conditions under which it holds, by extension to sums of correlated variables, and by extension to multivariate situations.

CENTRAL PROCESSING UNIT (CPU). See **Digital Computer Systems**.

CENTRAL WATER. See **Meteorology**.

CENTRECHINOIDEA *(Echinodermata, Echinoidea)*. Sea urchins with a central mouth about which are gills. The commoner sea urchins of North America belong in this group.

CENTRIFUGAL FORCE. A radially outward force experienced by an observer in a reference frame which is rotating at an angular velocity ω with respect to an inertial frame (cf. Coriolis Effects, 2). The centrifugal force is the reaction to the centripetal force necessary to hold the observer at a fixed point in the rotating frame, and thus has a magnitude equal to and a direction opposite to the centripetal force.

The centrifugal force involved in the motion of a vehicle around a curve makes desirable the "superelevation" or "banking" of the roadway at an angle dependent upon the curvature and the speed, in order that the wheels of the vehicle may push perpendicularly against the pavement or track. If the speed is v and the radius of the curve is r, then the roadbed should be inclined at an angle s given by the formula: $\tan s = v^2/gr$, where g is the acceleration of gravity. For example, if $v = 40$ feet (12.19 meters) per second and $r = 1000$ feet (304.8 meters) and the value of $g = 32.15$ feet (9.8 meters) per second per second, the formula gives $s = 2°51'$; which, on a standard-gage railroad track, would require the outer rail to be 2.8 inches (7.1 centimeters) above the inner.

CENTRIFUGING. A separation technique based upon the application of centrifugal force to a mixture or suspension of materials of closely similar densities. The smaller the difference in density, the greater is the force required. The equipment used (centrifuge) is a chamber revolving at high speed to impart a force up to 17,000 times that of gravity (much higher in the *ultracentrifuge*). The materials of higher density are thrown toward the outer portion of the chamber, while those of lower density are concentrated at or near the inner portion. A common cream separator is a type of centrifuge in which the flow is continuous. The centrifugal force throws the heavier milk into a different chamber from the lighter cream. Many hundreds of products, particularly in the chemical and food processing industries, require centrifugation at some stage in their manufacture. For example, important applications are found in the beet sugar and sugar cane industries, in the processing of corn (maize) products, in soybean processing, and in milk and dairy products manufacture.

Basic Principle of Centrifuging. The force acting on a particle within a centrifugal field is defined by Newton's fundamental force equation: $FM = ma$. Acceleration acting upon the particle, directed toward the center of rotation is $a = rw^2$. Therefore, the centrifugal force acting on the particle is $F = mrw^2$, or expressed as multiples of gravity,

$$F = 14.2 \times 10^{-6} DN^2 (D \text{ in inches})$$

$$= 5.59 \times 10^{-6} DN^2 (D \text{ in centimeters})$$

where m = mass of particle,g
a = acceleration, cm/s^2
r = radical distance of a particle in a centrifugal field from axis of rotation, cm
ω = angular velocity, rad/s
D = inner diameter of centrifugal bowl
N = bowl speed, rpm

A particle and a mixture introduced, confined, and rotated within a circular enclosure accelerates as it moves from a neutral center toward the maximum diameter (inner periphery) of the enclosure. Thus, if a mixture is introduced to the center of a 24-inch (61-centimeter) diameter solid-bowl centrifuge rotating at 1500 rpm, the particle will be caused to move at a speed of 32.2 feet (9.8 meters) per second at the center. At the maximum diameter, the particle will have a terminal velocity of 766.8×32.2 feet per second, or 24,690 feet (7525 meters) per second. Essentially, the separation occurs at $766.8 \times g$.

Industrial Designs. Industrial centrifuges are available in a variety of designs. Bowl sizes range from less than 0.5 to over 4 feet (15.2 to 122 centimeters) in diameter. Forces applied generally range from about 500 to 14,200 times the force of gravity. Operating temperatures range up to 260 °C or higher; pressures up to about 8.5 atmospheres. Liquid flow rates range from 5 to 500 gallons (19 to 1893 liters) per minute; solid rates from 0.2 to 68 metric tons per hour. Depending upon design, the range of size of particles that can be handled is from 1 micrometer to as large as 0.6 centimeter. Centrifuges often are equipped with filters to provide a highly clarified effluent. The majority of industrial centrifuges are designed for continuous operation, although batch designs are obtainable.

One of several types of industrial designs is shown in Fig. 1. This is a continuous horizontal, pusher (reciprocating) filter centrifuge. The feed is

continuously introduced through a stationary pipe. The solids settle to the screen surface and form a filter bed through which the liquid passes. The liquid continues through the basket and is discharged from the machine, while the solids, having formed a uniform filter-bed thickness in the cylinder basket, are assisted to discharge by a pusher ram. Washing of cake solids, following the initial dewatering, is a feature of this design.

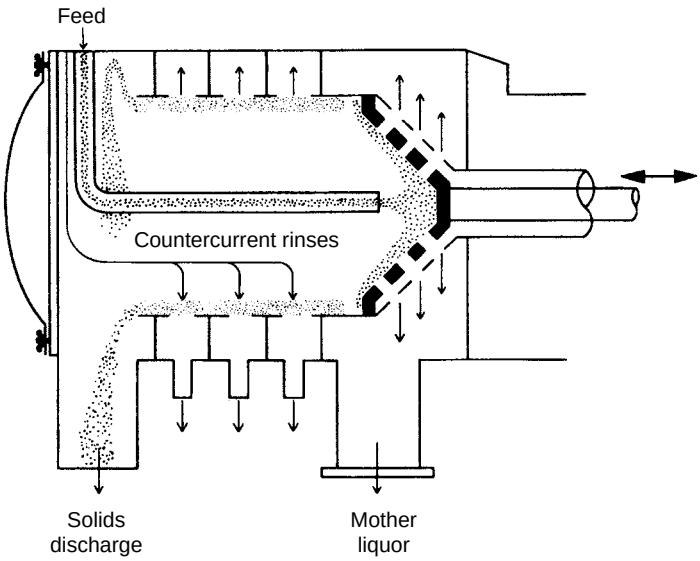

Fig. 1. Continuous horizontal, pusher (reciprocating) filter centrifuge. Double arrow at right indicates motion of ram.

Among other types are the gas centrifuges, which have been used for the separation of isotopes. In the concurrent type, one or more streams of gas enters at one end of the centrifuge and the partially separated isotopes are removed in two or more streams at the other end. In the countercurrent type, countercurrent circulation is established in a centrifuge either thermally or mechanically. By the circulation of the gas the radial concentration gradient is converted into an axial gradient. The evaporation type operates on volatile liquids, which evaporate within the apparatus. Two streams of vapor are removed from a point near the axis of the centrifuge, having been separated by diffusion through the centrifugal field.

Large industrial centrifuges can cause serious vibration problems. Some centrifuges as found, for example, in separating water from caustic potash slurries may accommodate loads of up to 1 ton. To avoid unduly vibrating an entire building that may house up to twelve of the large centrifuges, some means for damping the vibrations is required. Heavy-duty isolators must be installed. One solution is the use of multistranded steel wire rope. The ropes are coiled into helical assemblies. Under load, the wire rope helices assume an oval shape and deflect in any direction, providing isolation in compression, tension, shear, or roll. In most cases the helices provide up to 90% isolation at high frequencies and amplitudes.

Ultracentrifuge. Centrifuges which operate at very high speeds and which find applications in colloid chemistry and biochemical research are sometimes called *ultracentrifuges*. In research laboratories where proteins, polymers, and other substances with high molecular weights are studied, the ultracentrifuge is effectively used. The sedimentation of large molecules in a strong centrifugal field enables the determination of both average molecular weights and the distribution of molecular weights in various systems. When a solution containing polymer or other large molecules is centrifuged at forces up to 250,000 times gravity, the molecules begin to settle, leaving pure solvent above a boundary, which progressively moves toward the bottom of the cell. This boundary is a rather sharp gradient of concentrations for molecules of uniform size, such as globular proteins. For polydisperse systems, the boundary is diffuse, the lowest molecular weights lagging behind the larger molecules. An optical system can be provided for viewing this boundary, and a study as a function of time of centrifuging yields the rate of sedimentation for the single component, or for each of many components of a polydisperse system. These sedimentation rates may then be related to the corresponding molecular weights of the species present after the diffusion coefficients for each species are determined by independent experiments. Both the sedimentation and diffusion rates are affected by interactions between molecules, so that each must be studied as a function of concentration and extrapolated to infinite dilution, as is done for the colligative properties. The result of this detailed work is the distribution of molecular weights in the sample, which is available by few other methods. Extrapolation of diffusion coefficients to infinite dilution is difficult for high-molecular-weight linear polymers, and so alternate means are used to relate sedimentation constants to molecular weights in these important applications.

For research applications, ultracentrifuges may be equipped with microprocessors for programming, as well as automated handling of samples.

CENTRIOLE. See **Cell (Biology)**.

CENTRIPETAL ACCELERATION. 1. The acceleration toward the center to which any particle moving in a circular orbit is subject. This acceleration is equal to v^2/r, where v is the orbital velocity and r the radius. 2. More generally, that part of the radial component of the acceleration of a particle moving in any curved path which is equal to the magnitude of the radius vector from the instantaneous center of rotation multiplied by the square of the instantaneous angular velocity about that center. See also **Coriolis Effect**.

CENTRIPETAL FORCE. The force necessary to impart centripetal acceleration to a body. For a body of mass m moving about a fixed axis at a distance r and with an angular velocity ω, the centripetal force is $-m\omega^2 r = -mv^2/r$, where v is the linear velocity of the particle and where the negative sign indicates that the force is directed radially inward. Effects such as the rupture of a rotating body or the outward skidding of an automobile in rounding a corner are often discussed as effects of centrifugal force, but are better described as being due to the in sufficiency of the centripetal forces (elastic stresses or the frictional force of the wheels on the road) to maintain the masses at a constant distance from the center of rotation.

CENTRODE. The path of the instantaneous center of a plane figure having plane motion, that is, motion resulting when all points in the figure move in parallel fixed planes, is called the centrode. Any plane body having plane motion which is neither entirely rectilinear nor entirely rotative, but a combination of the two, may be considered at any instant as having rotary motion about a moving point called the instantaneous center of rotation. As shown in Fig. 1, the plane body AB has a motion such that the velocity of

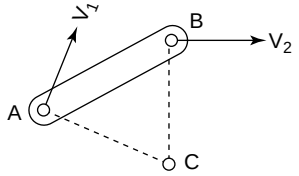

Fig. 1. Centrode.

A is V_1 while the velocity of B is V_2. At the instant corresponding to the position shown for AB, the body must be rotating about a point C, which is located at the intersection of the perpendiculars to V_1 and V_2 dropped from A and B respectively. C is the instantaneous center of rotation of AB and the centrode is the path traced by the point C while AB is in motion.

CENTROID. The centroid of a given geometrical figure (curve arc, portion of a plane or curved surface, or solid) is the point whose coordinates are the mean values of the coordinates of the points of the given figure; it is independent of the choice of axes. The centroid of a geometrical figure corresponds to the center of gravity (or center of mass) of a material body of similar form.

For a plane curve arc, the centroid is given by

$$\overline{x} = \frac{\int_a^b x\,ds}{L}, \overline{y} = \frac{\int_a^b y\,ds}{L}$$

$$ds = \sqrt{1 + \left(\frac{dy}{dx}\right)^2} \cdot dx = \sqrt{1 + \left(\frac{dx}{dy}\right)^2} \cdot dy$$

where L is the length of the arc, and ds is the length of an infinitesimal portion of the curve.

For a plane area, the centroid is given by

$$\overline{x} = \frac{\iint_A x\,dS}{A}, \overline{y} = \frac{\iint_A y\,dS}{A}$$

where A is the area of the given region, and dS is the area of an infinitesimal portion of the surface.

For a solid, the centroid is given by

$$\overline{x} = \frac{\iiint_V x\,dV}{V}, \overline{y} = \frac{\iiint_V y\,dV}{V}, \overline{z} = \frac{\iiint_V z\,dV}{V}$$

where V is the volume of the given region, and dV is the volume of an infinitesimal portion of the solid.

CENTROMERE. A localized region of the chromosome to which the microtubules of the spindle apparatus attach during mitosis. It has a cup-like shape and is composed of nonchromatin material. During the process of cell division, the chromosomes become duplicated in the late resting stage (interphase). The resulting two chromatids are held together by the centromere until, at the metaphase, the centromere divides and each daughter centromere progresses, with the aid of the spindle apparatus, to opposite poles of the cell. The daughter chromosomes are pulled along behind. See **Cell (Biology)**.

CENTROSOME. A clear zone surrounding one or two centrioles found in the cytoplasm near the nucleus of most animal cells. The centrosome is sometimes referred to as the microcentrum. See **Cell (Biology)**.

CENTURY PLANT. Of the family *Amaryllidaceae* (amaryllis family), genus *Agave*, the century plant, *Agave americana*, is a fleshy-leaved agave native of Mexico, and well-named because of its blooming habit. The plant has a very short, thick stem which bears a rosette of thick fleshy leaves, in which are stored food reserves. Each year the plant adds three or four leaves to the rosette. After a period varying from 5 to many years (perhaps a century) vegetative growth ceases and flowering occurs. A gigantic terminal flower bud is formed and grows rapidly. It bears many flowers. After the fruit has formed the whole plant dies. It is this habit of bearing flowers only after a prolonged period of vegetative growth that has given this plant the common name, century plant. It is widely grown in cultivation, and seldom flowers under such conditions. The plant propagates by means of suckers, which grow out from the base of the stem. See also **Agave**.

CEPHALOCHORDATA *(Chordata).* A subphylum containing a number of species of small marine animals called lancelets. From one of the included genera the name Amphioxus has become common in laboratories to designate any lancelet, although the animals so designated more commonly belong to the genus *Branchiostoma*.

The lancelets differ from the other groups of lower chordates in their fish-like form. They are small, usually from $1\frac{1}{2}$ inches (3.8 centimeters) to rather more than 2 inches (5.1 centimeters) long, and taper toward both ends; the body is laterally compressed. Like other members of the phylum they have a dorsal nerve cord, below it a stiffening longitudinal rod, the notochord, and a pharynx perforated by many slits. A depression called the vestibule leads to the mouth. It is surrounded by a circlet of slender cirri. Cilia about the mouth carry food particles into the alimentary tract where they are caught by the mucus in a ventral groove, the endostyle, carried forward, upward, and then back to the intestine, all by ciliary action.

The lancelets are important to the evolutionist in several ways. Since they swim actively in the tides and bury themselves in the sand at other times, taking their food like sessile animals, they illustrate possible ancestral conditions for the tunicates on the one hand and the fishes on the other. The peculiar food-concentrating mechanism described above is also important; it occurs in larval lampreys and provides one of the few well-marked evidences of relationship between the vertebrates and lower chordates.

CEPHALOPODA. A class of the phylum *Mollusca* containing the squids, cuttlefish, octopus or devilfish, and nautilus. The class is relatively small but it includes the most highly developed of unsegmented invertebrates and is of some economic importance. All of the species are marine.

These mollusks are distinguished by the following characteristics: (1) The head bears a pair of large eyes which are of the camera type like those of humans although they differ fundamentally in structure. (2) The mouth is surrounded by a group of tentacles provided with many cup-like suckers and sometimes with hooks. (3) The mantle cavity opens to the exterior by a broad entrance and by a slender tube, the funnel or siphon; by forcing jets of water from the cavity through the siphon the animal propels itself through the water in the opposite direction. (4) The foot is modified to form the siphon and possibly the tentacles. (5) The mouth is provided with a sharp beak superficially like that of a bird of prey. (6) Some species have an ink-sac from which a dark fluid is discharged for concealment. (7) The shell is internal or absent in most species. See Fig. 1.

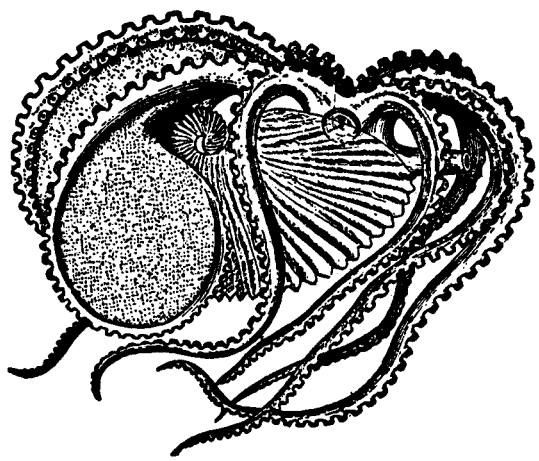

Fig. 1. Female *Argonauta argo*. (*Lull, "Organic Evolution," Macmillan.*)

Squids and cuttlefish are eaten by some peoples. The latter species furnishes the cuttlebone so familiar in bird cages and the true sepia pigment. Squids are of importance in North America chiefly as bait in the fisheries of the Atlantic Coast. The octopus has been credited with amazing feats of destruction at sea which are probably entirely imaginary. Giant squids are known to occur, with a total length of 50 feet (15 meters), and are more likely subjects of these tales, but there is no satisfactory evidence that even these creatures are greatly to be feared by humans.

The class is divided into two orders. The first was abundant in the past but is now almost extinct.

Order *Tetrabranchiata*. Shell external, spiral, and divided into a series of chambers of increasing size, in the last of which the animal lives. Once abundant, now limited to four known species in the genus *Nautilus*.

Order *Dibranchiata*. Shell internal or lacking and usually straight. The squids and cuttlefishes have ten tentacles, the octopus or devilfish and the argonaut or paper nautilus only eight. See also **Invertebrate Paleontology**.

CEPHEIDS. Variable, or pulsating, star types, so named for their earliest-studied prototype, Delta Cephei. This group of variable stars is divided into two subgroups: classical cepheids, which are yellow supergiants, rare in space, and high in luminosity with periods ranging generally from 1 to 50 days (most commonly around 5 days); and type II cepheids, whose light curves have broader maxima and are more nearly symmetrical than the former, and whose periods are mostly from 12 to 20 days. A number of these stars are visible to the naked eye (e.g., Polaris, δ Cephei, η Aquilae, ζ Germinorum, β Doradus), and an interesting project is to plot their light curves as a function of time.

A star type related to the cepheids is the RR Lyrae group of variables. These stars, often called cluster variables, were first found in globular clusters, but are now recognized in greater numbers outside the clusters. They are blue giants, far outnumbering the classical cepheids, but not visible to the naked eye. Their periods range from somewhat more than an hour to about one day.

The shapes of light curves for variable stars with periods of less than 50 days are remarkably similar. Shown in Fig. 1 is the mean light curve together with the mean velocity curve as a function of period for the classical cepheid, W. Sagittarii. This light curve is very typical in that the rise to maximum for almost all cepheids is rather rapid, followed by a more gradual decline to minimum. The descending portion of the curve often will show slight irregularities. The normal cepheid is usually a supergiant of spectral class F or G; it changes its spectral type slightly when going through its light variation, and is somewhat bluer at maximum than at minimum. Note that the radial velocity curve correlates with the light curve, indicating that the star is actually pulsating.

Another interesting point about these stars is that their absolute magnitudes increase as their periods grow longer, and the difference between maximum and minimum also increases.

Early development of an understanding of the cepheids is quite interesting. For many years, it was believed, because of the variations in radial velocity, that the objects were spectroscopic binaries. Shapley, Eddington, and others later showed that this is not a true explanation and proposed the alternative hypothesis that the stars are pulsating. These investigators reasoned that the star when approaching its minimum is relatively cool and is contracting under the influence of gravitational attraction. As the mass of gas contracts, the increased pressure in the interior produces a rise of temperature and eventually outward pressure due to high temperature overbalances the gravitational force and the star suddenly expands. The sudden expansion produces cooling until gravitation overbalances the outward force and contraction again takes place. It was reasoned that since at the time of expansion the outer surface will be approaching the observer and also the temperature will be higher than during the contracting stage, there is the expected correlation between brightness, spectral type, and radial velocity.

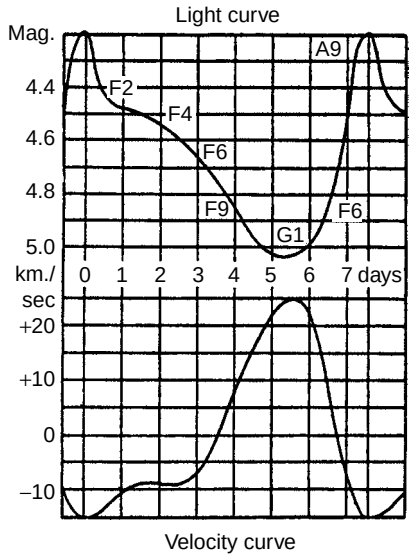

Fig. 1. Light and velocity curves of *W. Sagittarii*.

In the course of the study of typical Cepheids in the Small Magellanic Cloud, Leavitt (Harvard) found a direct correlation between the average magnitude of the Cepheids and the period of variation. Since all variables in the cloud are at approximately the same distance from earth, it appeared that the period of variation was directly correlated with intrinsic brightness or, in other words, with average absolute magnitude. Shapley, after an exhaustive study of numerous cepheids with known distances and hence known average absolute magnitudes, was able to show that the correlation between period and luminosity was apparently characteristic of all cepheids and, by plotting period against average absolute magnitude, he obtained what is commonly known as the period-luminosity curve. After this curve is established, it is possible to determine the absolute magnitude of any cepheid, no matter how distant, by simply determining the period. With the absolute magnitude and the apparent magnitude known, the calculation of the distance of the cepheid is a relatively easy task. See also **Period Luminosity Law**.

The period-luminosity relationship was extended to the cluster-type cepheids, this serving a valuable purpose in determining distances of globular clusters. Cepheid variables have been found in distant nebulae well beyond our own galaxy and thus can be used to establish distances to objects outside the galaxy. This led to the once commonly used phrase, "measuring rods of the universe."

Within the relatively recent past, astronomers have worked on the development of a new cosmic yardstick, so to speak. Radio astronomers have found that the neutral hydrogen gas that pervades a spiral galaxy emits at a wavelength of 21 centimeters. By using the width of the 21-centimeter line, a measure of the rotation of the galaxy is gained. It is further reasoned that the rotation speed is dependent upon the mass of the galaxy. Past studies have shown that for spiral galaxies mass and optical luminosity also go together — because mass and luminosity are both largely provided by stars. Thus, it is reasoned that the width of the 21-centimeter line should be of use in determining the galaxy's intrinsic brightness. By combining the intrinsic brightness from the line width, observed optical brightness can be used for distance calculations. In 1976, the concept was initially tested on nearby galaxies, the distances of which had been previously determined by other methods. Reasonably good correlation was found when brightness in blue light was measured. But the conclusion was drawn that reliable galaxy brightness could not be derived from 21-centimeter line widths alone. Later research showed that there is much better correlation between the 21-centimeter line and the infrared intrinsic brightness. Research in this area is continuing, with the target of ultimately pinpointing the Hubble constant. This constant is discussed in entries on **Cosmology**; and **Red Shift**. See also **Giant and Dwarf Stars**.

CEPHEUS. A constellation that is particularly interesting because it contains the remarkable variable star, δ Cephei. This star is the typical cepheid variable, one of a class that is most valuable in providing a measuring rod for probing the remote regions of space, because it obeys a relation called the period-luminosity law. (See map accompanying entry on **Constellations**.)

CERAMICS. Derived from the Greek word *keramos* ("burnt stuff"), ceramics comprise a wide variety of materials that constitute a major industry. The principal facets of the ceramic industry, in order of increasing value of annual production, are: (1) abrasives; (2) porcelain enamel coatings; (3) refractories; (4) whitewares; (5) structural clay products; (6) electronic and technical ceramic products; and (7) glass. Glass accounts for about 45% of all ceramics produced. See also **Glass**.

Porcelain enamels are used to protect and decorate steel and aluminum metals. Actually, they are glasses especially designed to have high thermal expansions to match the base metal and to mature (to become glassy) at temperatures low enough to prevent distortion of the underlying metal sheet. Glazes perform a similar function on ceramic substrates, again, as special glasses matching the thermal expansion of the base and maturing at the desired temperature. Although not relatively large in terms of production value, the preparation of ceramic composites is important and growing. This area covers a variety of combinations, such as sapphire, Al_2O_3, whiskers in metals, metal-bonded carbides used in the machine tool industry, and directionally solidified two-phase ceramic systems. In a system of this type, an oriented fibrous second phase is grown in a primary matrix phase to maximize in a selected direction various important characteristics, such as minimum long term, high-temperature creep. An example of use is in gas turbine rotor blades.

Conventional Ceramics (*Structurals*). The essential raw material is clay. Clay is essentially a hydrated compound of aluminum and silicon $H_2Al_2Si_2O_9$, containing more or less foreign matter such as (1) ferric oxide Fe_2O_3, which contributes the reddish color frequently associated with clay, (2) silica SiO_2 as sand, (3) calcium carbonate $CaCO_3$ as limestone. Since clay is formed by the decomposition of igneous rocks, followed by transportation of the fine particles by running water and later deposition of these particles by sedimentation when the flow of water diminishes in speed, the quality of clays shows a wide range. When clay is wet it is plastic and can be shaped according to the desire and skill of the operator. The shape is retained on drying, and subsequent heating produces a coherent, hard mass, which suffers in the process more or less shrinkage and deformation depending upon the composition of the raw materials, and the method and temperature of treatment. Common bricks are made of crude materials without careful regulation of the conditions of treatment.

Bricks and plain clay products possess an earthy surface and fracture, are porous, and the strength depends upon the materials and treatment. Porcelain, on the other hand, possesses a glasslike or vitreous surface and fracture, and is not porous. Porcelain is made by mixing with the clay some powdered feldspar mineral, potassium aluminosilicate ($KAlSi_3O_8$ approximately). At the temperature of firing, feldspar undergoes a gradual change from the crystalline to the glassy state, the rate depending upon the time of heating and the temperature to which it is subjected. The fusion point of feldspar is of the order of 1300 °C, whereas that of kaolin (pure clay) is of the order of 1700 °C. Subjection of the porcelain raw material to the latter temperature would result in the formation of a glass. But when the temperature used is below the melting point of the clay portion and about the melting point of the feldspar, the latter produces a glass cement which binds together the particles of the former. When ground quartz SiO_2 is added to the original clay mixture the shrinkage of the material in the processes of drying and firing is reduced, the resistance to deformation during firing is increased, and the temperature coefficient of expansion of the product is affected.

The range of clay, feldspar, and quartz, as to the ratios in the mixture and as to individual composition of each (see Tables 1 and 2), as well as the available range of temperature of firing makes possible the production of products of a wide variety of physical structure. There has been proposed an arbitrary line of demarcation, namely that the unglazed product, such as has been described, which absorbs not more than 1% of its weight upon and after immersion in water, shall be termed porcelain, otherwise it shall be called earthenware. Such a nonporous material as porcelain, which includes chinaware, is also distinctly translucent in thicknesses of a few millimeters, whereas earthenware is nontranslucent and somewhat porous.

TABLE 1

Raw Materials	Chinaware	Earthenware
Total clay, usually blended	46.5%	50.5%
Feldspar	15	13.5
Quartz	36	36
Dolomite	2.5	—
Porosity average	0.5	8

Materials that are to be glazed are dipped in a slip (the mixture of raw materials and water), dried, and refired. The glaze mixture is made up so that its fusion temperature is lower than that of the body of the ware, and the firing temperature is such that a surface of glass is formed over the body of the ware.

Designs and colors may be placed, as is commonly done, on the glaze and refired, or, as less commonly and more recently done with fine effect, placed directly on the body under the glaze, in which case the glaze when produced covers and protects both the body of the ware and the decoration.

The properties of ceramics depend mainly on how the atoms are arranged and the interatomic bonds they form. The most important bonding force in the crystalline phases in most ceramics is ionic bonding, the metallic atoms losing an outer electron to become positive ions; and the nonmetallic atoms gaining an outer electron to form a negative ion. Ionic crystals are brittle and hard, melt at high temperatures, and have low electrical conductivity at room temperature. Compounds of metals with oxygen ions that are largely ionic are MgO, Al_2O_3, and ZrO_2. Covalent bonding is also found in ceramic crystalline materials. In this case, a pair of electrons is shared by two atoms. Covalent crystals, such as diamond and silicon carbide, have high hardness, high melting points, and low electrical conductivities at low temperatures.

The basic building block for the silicate crystal structures is the silicon-oxygen tetrahedron with a silicon atom at the center and four oxygen atoms at the corners. The silicates are classed by the types of bonding existing between the tetrahedra in their crystal structures. In orthosilicates, the tetrahedra are independent of each other. These structures make good refractories because of their high melting points. This group includes the olivine minerals, garnets, zircon, kyanite, and mullite. When the tetrahedra are joined at only one corner (oxygen atom), they form pyrosilicates, which are rare. In metasilicates, the tetrahedra share two corners to form a variety of ring or chain structures. Minerals of this type include the pyroxines, such as spodumene, and the amphiboles, such as asbestos. Sharing three corners, the tetrahedra form disilicates, which exist as sheets or planes,

TABLE 2. ANALYSES OF CERTAIN CERAMIC RAW MATERIALS

	Silica	Alumina	Lime	Magnesia	Iron Oxides	Soda	Potash
	%	%	%	%	%	%	%
Kaolin	58	29	0.2	0.3	1	1	1
Fire clay	61	26	0.3	0.4	1	1	1

Feldspar	71	16	0.3	0.0	0.5	4	7
Quartz	100	—	—	—	—	—	—

forming such minerals as mica. In the various forms of silica, such as quartz and crystobalite, all four tetrahedron corners are shared.

Most ceramic shapes do not consist of one single crystal, but are composed of numerous crystals joined together to form polycrystalline structures. The characteristics of the grain boundaries between crystals can influence the strength, chemical stability, and electrical properties as much as do the crystalline structures within the individual grains.

Glass is a very important part of ceramics. The glass industry is the largest single element of the entire ceramic industry, and the glassy portions of many ceramic bodies are the bonds that hold many ceramics together. Probably the majority of the ceramics produced are a mixture of crystalline grains and a glassy phase. The glass frequently acts as the bond. This is the basis of the vitrified-grinding wheel industry and much of the structural and whiteware branches of the ceramics industry.

The rare-earth elements have found application in the ceramics field. In one example, a mixture of about 90% yttrium oxide powder and 10% thorium oxide powder is pressed into the desired shape and then sintered at about 2200 °C. This heat treatment removes the microscopically small pores from between the powder particles. The result is a single-phase, polycrystalline material with a grain size normally between 10 and 50 micrometers in diameter. Yttrium oxide has a cubic crystal structure, thus light is not scattered at grain boundaries. This property, combined with the absence of a second phase and pores, imparts exceptional transparency (with polishing) to visible and infrared light. The transmission cutoff in the ultraviolet range occurs at 0.24 micrometers and in the infrared range at about 9 micrometers. Although the index of refraction of the ceramic is high, about 1.91 at the sodium D line wavelength, the optical dispersion of the material is very low. See also **Rare-Earth Elements and Metals**.

High-Technology Ceramics. Development of these materials stems from the need for improved performance in terms of thermal, wear, and corrosion resistance, superior electrical insulation properties, high magnetic permeability, and, sometimes, unusual optical properties. Through precise control of composition, particle shape, and particle size distribution, some materials can be engineered and processed to provide specific properties that may be required of a an application for which readily available standard materials are inadequate. The demanding conditions of engines and turbines are frequently mentioned to illustrate applications where complete satisfaction with alloyed metals has not been achieved. In some instances, engineered ceramics can replace higher-cost materials, such as the use of cobalt, in jet aircraft engine applications. In addition to high-performance engines and machines, advanced ceramics are finding uses in the electronics industry for their electrical and optical behavior.

The ceramic materials most successfully applied to date are high-researching monoli purity oxides, nitrides, carbides, and borides in combination with silicon, tungsten, titanium, tantalum, zirconium, zinc, aluminum, and magnesium. Currently, the oxides dominate the market, commanding about 85% of the critical uses. The application of high-technology ceramics in aircraft and some automotive engines includes turbocharger rotors, rocker arms and cam followers, valves, valve guides, and valve seats, pistons, piston pins, piston rings, cylinder liners, and exhaust port liners.

In the United States, as early as 1987, a program known as "Ceramic Technology for Advanced Heat Engines" was established at Oak Ridge National Laboratory. Some of the research targets of this program included: (1) to develop more reliable monolithic ceramics, toughened ceramic composites, and ceramic coatings via improved and unique synthesis and fabrication technology; (2) to achieve reliable ceramic attachments by new and improved joining technology; (3) to understand better the physical and chemical mechanisms that control the friction and wear of ceramic materials and coatings under heat-engine operating conditions; and (4) to identify and explain the mechanisms that control the long-term mechanical reliability of structural ceramics in advanced-engine environments.

The program also addressed the need to develop tough ceramic-matrix composites (CMCs) with much greater resistance to brittle fracture. Early in the program, researchers found that the chemical structure that imparts superior thermal and mechanical properties to ceramics also results in negative attributes, particularly of brittleness, which easily can lead to catastrophic failure.

In addition to research monolithic parts, ceramic coatings also are being investigated. Although there are numerous problems to be solved, including very extensive testing of materials under standard operating conditions, most professionals in the field forecast that monolithic ceramics and ceramic coatings will be found in conventional automotive engines by the early 2000s. The full acceptance of ceramic parts in jet aircraft engines may not occur until well into the 2000s. For example, C.T. Sims (Rensselaer Polytechnic Institute) observed in mid-1991, "The chronicling of the imminent demise of superalloys in gas-turbine engines appears to have been premature. The lack of toughness in monolithic ceramics and CMCs remains a serious obstacle to their use in gas-turbine engines."

Manufacturers of ceramic components, often composites, must commence fabrication with exquisitely pure raw materials, most frequently in the form of powders. Some of the new ceramic powders include the lesser-known elements, such as niobium and hafnium. Ceramic powders fall into three fundamental classes — the carbides, the nitrides, and the oxides. The powders are synthesized by a number of means, including (1) carbothermal reduction; (2) solid-solid, solid-gas combustion; (3) vapor-phase synthesis; (4) laser synthesis; and (5) plasma synthesis. At the late-1980s state of the art, plasma synthesis, an efficient simple and continuous process, appears in the lead. However, because of some of its disadvantages, including high power demand, large capital and operating costs, health hazards, and sometimes low powder yields, among other negative factors, all of the other methods are also being intensively researched. As pointed out by Sheppard (April 1987), in plasma synthesis, the powders are formed in a vapor-phase reaction under a high-temperature gas (~10,000 K) generated by the plasma. Ultrafine (<100 micrometers), ultrapure powders, often in a metastable high-temperature phase, are produced by rapid quenching of the hot gases. No milling or grinding is usually required. By comparison, the RF-inductively-coupled plasma requires no electrodes and has the ability to inject the reactants axially. The dc plasma, formed by a high current flow between two electrodes, has high thermal efficiency, and higher plasma temperatures, among other factors.

Some of the ceramic powders now being researched or made in quantity by plasma synthesis are indicated in Table 3.

Ceramic materials also are being used in a limited fashion by the chemical process industries for such applications as high-temperature (1,100 °C) heat exchangers, as absorption and distillation column packing, catalyst supports, and high-temperature refractory linings.

Ceramic-Fiber Reinforced Metal-Matrix Composites (MMCs). These engineered materials provide good strength at high temperatures, good structural rigidity and dimensional stability, light weight, and good fabricability. The incorporation of ceramic fibers in these materials greatly increases their endurance at high temperatures.

- Graphite fibers have been incorporated with aluminum, magnesium, lead, and copper for use in satellite, missile, and helicopter structures; storage battery plates, and electrical contacts and bearings.
- Boron fibers have been used in connection with aluminum, magnesium, and titanium for such applications as compressor blades and structural supports, antenna structures, and jet-engine fan blades.
- Borsic fibers have been used with aluminum and titanium for jet-engine fan blades and high-temperature structures.
- Alumina fibers have been incorporated with aluminum, lead, and magnesium for superconductor restraints in fusion power reactors, storage battery plates, and helicopter transmission structures.
- Silicon carbide fibers have been used with aluminum, titanium, and cobalt-based superalloys for high-temperature structures and engine components.

Molybdenum and tungsten fibers also have been used with superalloys for a variety of applications.

A process known as *squeeze casting* (solidification of liquid metal under pressure) contributes to producing defect-free castings with improved metallurgical properties. See also **Casting**.

Preforms for squeeze-cast composites are comprised of ceramic fibers, such as Al_2O_3 and SiO_2, which are bound into near-net (finally desired dimensions) shapes.

Some researchers have found that the reinforcement of ceramics with microscopic "whiskers" as opposed to continuous fibers, increases fracture toughness, even though the basic material nominally remains brittle. It has been reported that the mechanisms by which whiskers toughen the composite include both whisker bridging and whisker pullout within the region immediately beyond the tip of a crack (fracture). Toughness appears to be affected by the volume fraction of whiskers, elastic properties of the matrix, relative fraction energy of the fiber/matrix interface, and whisker diameter and strength.

TABLE 3. SOME CERAMIC POWDERS PREPARED BY PLASMA SYNTHESIS

Ceramic Compound	Starting Materials	Type of Plasma Used
CARBIDES		
SiC	CH_3SiCl_3	RF/Arc

MgO	$Mg(NO_3)_2$(aq)	Rf
ZrO_2, ZrO_2/Al_2O_3	$Zr(NO_3)_2$(aq) + $Al(NO_3)_3$(aq)	RF
ZrO_2/SiO_2	$Zr(NO_3)_2$(aq) + Silicone Oil	RF

Information Source: Los Alamos National Laboratory, New Mexico.

As observed by D. Johnson and J. Stiegler, "Polymer-precursor routes for fabricating ceramics offer one potential means of producing reliable, cost-effective ceramics. Pyrolysis of polymeric metalloorganic compounds can be used to produce a wide variety of ceramic materials." Silicon carbide and silicon oxycarbide fibers have been produced and sol gel methods have been used to prepare fine oxide ceramic powders, such as spherical alumina, as well as porous and fully dense monolithic forms.

D. Johnson and J. Stiegler also observe, "Polysilazines, which contain the (-Si-N) unit, typify the type of product that can be expected to result from this merging of ceramic science with organic- and inorganic-preparation chemistry."

Liquid-Ceramic Process. A process for producing ceramic or ceramic-matrix-composite (CMC) parts via a liquid route, instead of the conventional power method, was announced in mid-1992. Silicon nitride, for example, is produced by reacting a silicon-based liquid with ammonia, removing byproducts through supercritical fluid extraction, and then heat-treating. Carbide ceramics, such as silicon carbide, also can be made by using a hydrocarbon as one of the reactants. Developers of the process claim that the procedure is less damaging to reinforcing fibers for CMC applications. Other advantages include better adaptability of the process to mass production, considerably lower costs than traditional powder processing, and the manufacture of more complex shapes.

As described by A.J. Klein and T.M. Sullivan, "The Sullivan process uses supercritical fluid extraction to remove carbon and halide impurities from liquid ceramic that has been reacted with ammonia or another reactant under supercritical temperatures and pressures. Supercritical temperatures and pressures are those above the critical point, or the point where two phases (gas and liquid) of a material are continually approximating each other, and become identical to form one phase. In the process, inexpensive raw materials are converted under pressure to amorphous ceramics by reaction, distillation, fluid extraction, and densification. First, by-products of the reacted liquid ceramic are extracted in the supercritical fluid. The fluid then is decompressed and cooled in a separator to precipitate solids. Gases are trapped or condensed and then are recycled. Slight changes in temperature and pressure in the critical region cause large changes in solvent density and dissolving power. The supercritical fluid extraction process has wide flexibility for extractive separation by varying temperature, pressure, choice of solvent used, and entrainers (additives). Otherwise insoluble polymers may dissolve in supercritical fluids to an extent that there may be two to seven orders of magnitude in excess of that predicted by the ideal gas law.

In one application (production of aluminum beverage can lids), a monolithic silicon nitride punch has demonstrated a useful life greater than ten times that of a cemented carbide tool.

CEREBRAL EMBOLISM. See **Cerebrovascular Diseases**; and **Central and Peripheral Nervous Systems**.

CEREBRAL GANGLION. 1. The simple brain of many invertebrates. 2. Either member of the anterior pair of ganglia in the molluscan nervous system. 3. The upper posterior component of the brain of cephalopod mollusks.

CEREBRAL PALSY. The common name for a group of disorders resulting from brain injury, usually manifested by some type of paralysis and incoordination. The term normally denotes a condition in which the patient has lost some degree of muscular control. There is a wide range in the degree to which paralysis may be present. Conditions are caused by damage in one or more of three main areas of the brain that regulate muscular activity: (1) the *motor cortex*, damage to which results in stiffness of the muscles (*spastic paralysis*); (2) *basal ganglia*, a group of nerve cells in the brain which normally restrain certain types of muscle activity, thus injury in this area permits unplanned movements to occur. They are of two main types — slow, squirming, twisting movements that spread from the smaller joints to the larger ones without pattern (*athetosis*), more common in the arms than in the face and legs; and tremor, characterized by rhythmic motions which may range from slight shaking to violent jerking; and (3) the *cerebellar* area of the brain which controls muscle coordination as well as balance, injury of which causes the ataxic type of cerebral palsy, characterized by clumsiness and lack of balance. See also **Central and Peripheral Nervous Systems**.

There are numerous causes of cerebral palsy. Prior to birth, the brain may not fully develop. Injury or disease of the mother during pregnancy and antagonistic blood factors are other causes. Damage to the brain may result at birth because of delivery difficulties. In the case of a premature baby with soft bones, there may be insufficient protection to shield the brain from harmful pressures. Bleeding in the brain after birth may cause destruction of cells. Breathing difficulties at the time of birth may prevent sufficient oxygen from getting into the blood and hence supplying the brain. Nerve cells, which are easily destroyed by lack of oxygen, may suffer.

After birth, the baby with cerebral palsy may appear and act normally. Presence of blueness, twitching, or convulsions, however, should be regarded with suspicion. Sometimes it is difficult to make a definite diagnosis until the second 6 months of life. If watched closely, parents may detect signs as early as the first 2 or 3 months. The baby may not move much, or the legs may seem unusually stiff. Failure to follow the normal rate of babyhood accomplishments is important. Thus, a child who cannot grasp an object at 3 months, or turn over at 5 months, or sit alone at 7 months, may be showing the first signs of cerebral palsy.

The *spastic* type of cerebral palsy is the most common (approximately 65% of all cases). The child's stiff, tense muscles do not remain quiet and relaxed when not in use, as normal muscles do. They tighten up even more as the child tries to move, or if he is excited or frightened. The posture of spastic children is characteristic. The legs turn in, bending at the hips and knees, and the heels are off the ground. The arms are bent at the elbows and wrists, while the fingers are clenched. The child has trouble speaking and swallowing. The child is shy, prefers to be alone, and is generally afraid.

In the *athetoid* type of child (19% of all cases), unwanted motions begin when the child starts a planned motion. In reaching for a ball, the arm may wave about so that the hand never comes near its goal. The aimless activity affects the muscles of the throat, face, and tongue, and seriously hampers speech and swallowing. This type of child is fearless, lovable, and patient.

The *ataxic* form (about 8% of all cases) is characterized by clumsy-looking children who have a sense of balance and try to keep from falling, but they find it difficult to walk on a narrow base. Muscle coordination is lost and they have great trouble with skillful acts, such as writing and throwing a ball. Speech and swallowing are fairly normal.

Where the entire brain suffers, *rigidity* (4% of all cases) results and is often associated with severe mental deficiency. The body is rigidly arched backward, and the head is thrown back. The victims relax some in sleep. In the *tremor* type (2% of all cases), the child has control of his muscles until he starts to do something or becomes excited. Then, the vibrations become worse and interfere with the use of his hands. In severe cases, the movements are present even when the child is quiet and at rest.

Mental deficiency is seen with all types of cerebral palsy and may be mild or severe, but only one-third of affected children are below the acceptable educational levels. Ataxic or spastic children are somewhat more apt to be deficient mentally.

Treatment is slow, long, and constant. Parents should realize that the aim of treatment is not to restore to normalcy, but to make the child useful to himself and society, and therefore happier. Speech and swallowing defects are the most urgent to overcome. Muscle training is the most valuable way of treating these children, and a way in which intelligent, cooperative parents can be immensely helpful. This training is done by a physiotherapist, but many of their routines can be learned by parents and repeated at home. The child must find a sympathetic, encouraging environment in which he or she is accepted by others and given opportunity for relationships with others.

CEREBROSPINAL FLUID. This fluid (CSF) is a clear watery liquid that surrounds the brain and spinal cord and fills the four cavities or ventricles of the brain. See also **Central and Peripheral Nervous Systems**. The bulk of the fluid is thought to originate in filamentous structures, the choroid plexuses, which are situated on the walls of the ventricles. The fluid flows out of the brain through openings in the roof of the fourth ventricle to circulate over the brain and around the spinal cord in the subarachnoid space. This area is simply the space between the membrane (pia mater) directly adjacent to the nervous tissue and the membrane (arachnoid) attached to the tough outer covering of the brain (dura mater). The liquid leaves the subarachnoid spaces to enter the blood by flowing through canals in the arachnoid villi, which open into large venous channels. There are similar structures related to veins in the arachnoid membrane covering the spinal cord. These spatial relationships are shown in Fig. 1.

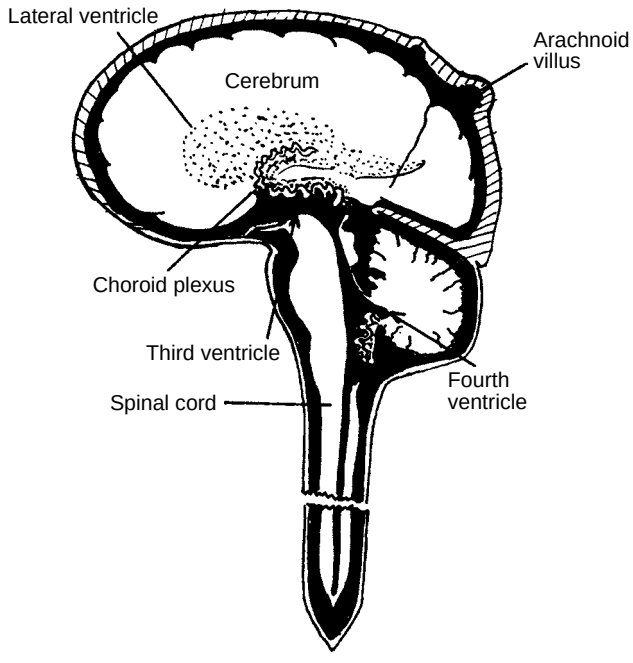

Fig. 1. Median section of the nervous system, showing the relation of the cerebrospinal fluid (black) to the brain and spinal cord. The two lateral ventricles are not visible, but their shape is denoted by the stippled area.

In humans, the entire volume of CSF is between 120 and 150 cubic centimeters, about 30 cc of which is in the ventricles. The rate of formation is difficult to establish, as it appears to depend upon the normal degree of absorption through the arachnoid villi. More than a liter may be formed in a day if drainage is brought about by artificial means, or by spontaneous

pathological processes. Ordinarily, daily production is estimated to be from one to three times the total volume.

In addition to protecting the brain and spinal cord from mechanical shock, the CSF functions to maintain the intracranial pressure at a constant level. Thus, whenever the volume of brain tissue is altered because of differences in the volume of blood in the brain, or after surgical manipulation, the CSF volume is adjusted accordingly. No proven nutritive function and no unique biochemical action on the nervous tissue it bathes can be attributed to this fluid.

When the meninges or membranes covering the brain become infected, the protein concentration of the CSF may increase enormously and the largest protein molecules of the plasma are then found in the CSF. These disappear and the protein concentration returns to normal when the patient recovers. See also **Meningitis**.

The maintenance of such a large differential in protein concentration between the plasma and CSF indicates that a highly selective membrane exists between the blood and the CSF. In fact, the equilibration of substance between the blood and CSF does not occur with the same rapidity that it does between the blood and extracellular spaces of other body tissues. This impediment to rapid equilibration of substances between the blood and the CSF has been termed the blood-CSF barrier, although no anatomical structure can be discerned on which to explain its existence. It appears to reside in the nature of the cells of the choroid plexuses and the cells lining the surface of the brain.

CEREBROVASCULAR DISEASES. These diseases by definition involve the vascular (blood vessel) system of the brain. Like vascular diseases that occur elsewhere in the body, a major cause is atherosclerosis, a process that damages the arteries and veins and which is described in some detail in the entry on **Arteries and Veins**. The principal cerebrovascular diseases are: (1) cerebral transient ischemic attacks (TIA); (2) cerebral thrombosis; (3) cerebral embolism; and (4) cerebral hemorrhage. Other cerebrovascular diseases include hypersensitive encephalopathy and cerebral arteritis.

Annually in the United States, approximately 750,000 new cases of stroke are presented. All age groups are represented, but the percentage is higher among the elderly. Stroke fatalities rank third, behind heart disease and cancer, among all causes of adult death and account for about 150,000 deaths annually. It is estimated that almost half of patients hospitalized for neurologic care have cerebrovascular disease. The residual care requirements of these diseases is often quite considerable. It was found in the Framingham study, conducted several years ago, that 31% of stroke survivors need some kind of assistance in self-care; 20% require assistance in ambulation; 71% have decreased vocational function at a mean time some seven years after their stroke. After stroke, 16% of patients remain institutionalized.

In addition to atherosclerosis, a major contributor to stroke, other high risk factors include hypertension, age, heart disease and, in the opinion of some authorities, the use of oral contraceptives. On the positive side, statistically stroke has declined nearly 50% during the past 30 years, particularly in elderly persons. Much of the credit for this decline is attributed to antihypertensive therapy. The rate for subarachnoid hemorrhage (between a membrane covering the brain and the brain itself) has shown very little decline during this same time period.

Metabolic Rate of the Brain. The brain cannot survive long when deprived of glucose and oxygen and normally the metabolic rate of the brain is very high by comparison with other body organs. The brain consumes 25% of the body's total requirements for oxygen and 70% of the glucose. Research has shown that, within the brain, the rate of blood flow to a given area is related to the metabolic requirements of that area. In acute cerebrovascular disease, it has been found that a match does not always exist between blood flow and metabolic activity. To protect against the excesses of either hypertension or hypotension, a means of *autoregulation* is incorporated in the brain. This protective system helps to provide against ischemia as well as excessive pressures that may cause hemorrhage. This mechanism is not well understood, but it has been established that in focal cerebral ischemia from stroke, there is dysfunction of the autoregulation system. The degree to which this dysfunction occurs has a bearing upon the extent of recovery from ischemia.

Cerebral Transient Ischemia Attacks *(TIA).* In essence, these are minor or silent strokes, which may develop suddenly and persist from a few minutes to a whole day. Caused by circulatory disturbances (carotid or vertebrobasilar arterial systems) in the brain, TIAs usually are not observed until the seventh decade of life. It is suggested that these attacks may arise from microemboli that rapidly fragment and thus pose no further threat. Such emboli may come from a number of sources.

Where the ophthalamic artery is involved, there may be a transient blackout of vision (up to several minutes). Some patients have described this episode as "the drawing down of a curtain." After the attack, there will be no neurological evidence of its occurrence. Mild symptoms may accompany such a TIA — numbness in the hands, short-term fuzziness of thinking, possibly some difficulty in speaking. Rarely are there disturbances of consciousness. Such attacks may occur only once or infrequently, or there may be several in a given day. The patient should consider a TIA as a warning and report such episodes to the physician. Depending upon patient, exact symptoms, and past history, the physician may decide to institute therapy to forestall the onset of a major stroke. For example, anticoagulation therapy may be indicated. See **Anticoagulants**. Some physicians also have found that daily doses of aspirin are effective.

It has been established that about one-third of persons who experience TIAs ultimately have a completed stroke; another one-third may continue to experience additional TIAs; for the other third, a TIA may be an isolated experience.

When the vertebrobasilar artery syndrome is involved in a TIA, the symptoms will differ. Diplopia (double vision), dizziness, nausea, vomiting, speaking difficulty, and weakness of limbs may be present.

Cerebral Thrombosis. This condition may develop suddenly or slowly. Any of the cerebral arteries may be involved, but most frequently the site of intracranial vascular thrombosis will be in the middle cerebral artery. Small areas of infarction (*lacunar sites*) also may occur where there is an occlusion in the branch of a major cerebral artery. Cerebral thrombosis frequently leads to infarction with irreversible death of brain tissue. To some extent, the damage due to dead tissue may be resolved by a full clearing of edema, and perhaps by functional reorganization of the brain, including new synapse formations. See also **Central and Peripheral Nervous Systems**. The course and degree of recovery from stroke are highly variable and for the first several weeks after the episode, difficult to forecast. Treatment is generally supportive, including provision for adequate intakes by the patient of air and glucose to the brain. Thus, intravenous and nasogastric tube feeding are frequently indicated. Hypertension if severe should be treated promptly. Inasmuch as recovery is usually long and drawn out, early attention must be given to the patient's comfort and general health. Normal functions may be affected by paralysis accompanying the stroke, notably to the urinary and digestive system. Condom or catheter drainage may be provided. The patient will be turned frequently. Some physicians prefer that water mattresses be used. In an evolving stroke, many physicians use anticoagulants, but not usually in a completed stroke. Very important to the stroke patient is early commencement of physical therapy.

Cerebral Embolism. Emboli may reach the cerebrovascular system. These emboli may be blood clots, atheromatous substances (from damaged blood vessels), tumor cells, fats, foreign bodies, air, and nitrogen bubbles, among others, but in cerebral embolism, blood clots, usually originating in a diseased heart, are by far the most common. Blood clots account for 10 to 15% of all cerebrovascular accidents.

Stroke from an embolism may develop within a few seconds. Other symptoms parallel those of cerebral thrombosis. Tissue damage is highly dependent upon the final site of the embolism. If the cerebrospinal fluid is

clear, some specialists use anticoagulant therapy with heparin during the acute phase of embolism. Once the patient has stabilized, the physician will attempt to determine the source of emboli and promptly initiate preventive measures against further emboli. Supportive measures and physical therapy parallel those for cerebral thrombosis.

Cerebral Hemorrhage. This condition is quite different from the similarities shown by cerebral thrombosis and cerebral embolism. In cerebral hemorrhage, bleeding into the brain tissue occurs.

In a *parenchymatous hemorrhage*, rupture may occur in small, penetrating arterioles located deep within the brain. Bleeding will result in the formation of a hematoma (massive clot of extravasated blood). This will occupy space and thus displace brain structures. Often one or two hours may be required for a cerebral hemorrhage to evolve to this stage. During this time, there may be vacillating states of consciousness, almost always accompanied by severe headache and, frequently, vomiting. Deviation of the eyes may occur. Stupor and coma are not uncommon.

An intracranial hemorrhage frequently produces a bloody cerebrospinal fluid, along with increased pressure. Lumbar puncture may be indicated. Computerized axial tomography and cerebral arteriography provide more definite diagnosis when required.

Massive intracerebral hemorrhage is fatal during the acute phase in about 80% of cases. But if the hematomas are small, essentially full recovery is possible. Surgery is sometimes indicated.

In *primary subarachnoid hemorrhage* (bleeding into the cerebrospinal fluid), ruptured aneurysms are a frequent cause. Such hemorrhages also may arise from primary bleeding disorders, leukemia, overaggressive anticoagulation therapy, hemorrhagic encephalitis, and hemorrhage from tumors. Although aneurysms are prone to rupture in the middle decades of life, rupture can occur at any age. In a number of cases, there are premonitory symptoms, such as recurrent headache (during period just prior to hemorrhage) and stiff neck. However, most hemorrhages of this type occur quite suddenly, commencing with a violent headache, quickly progressing to confusion, agitation, collapse, and coma. Diagnosis is confirmed by finding increased pressure and a lot of blood in the spinal fluid. As soon as the patient's condition permits, angiography will be ordered. Neurosurgery will be weighed carefully. This early consideration of surgery is important because renewed bleeding may commence during the second week after the initial hemorrhage. A number of operative procedures have been developed and frequently prove successful.

During the early critical period of this condition, full supportive measures must be taken, with around-the-clock nursing care. Absolute bed rest is essential, with no patient self-care permitted during the critical period. Efforts may be made to induce hypotension (low blood pressure). Even with good progress, hospitalization for about 6 weeks is usually considered minimal. The patient will be advised not to resume normal activities for about 3 months.

Hypertensive Encephalopathy. This condition is believed to be caused by a spasm in a cerebral blood vessel, which, in turn, precipitates a sudden increase of systemic blood pressure. The syndrome is recognized by the severity of the quickly developing symptoms-confusion, delirium, twitching muscles, and convulsions ultimately leading to stupor or coma. Sometimes, an increasingly severe headache will be a prelude. These are early morning headaches regionalized in the back of the head. Examination will show an elevation of diastolic blood pressure.

Treatment requires rapid lowering of blood pressure, with the intravenous administration of drugs, such as diazoxide or nitroprusside frequently indicated. Dexamethasone may be administered intravenously to relieve intracranial pressure as the result of cerebral edema. Convulsions may be treated with phenytoin.

Giant Cell Arteritis. In this disease, there is mononuclear and giant cell infiltration of the arterial wall, causing fibrous proliferation of elastic tissue. Blindness is a frequent accompaniment of the disease when left untreated. This disease is rarely seen in persons less than 50 years of age. Early symptoms are quite nonspecific and include headache, low-grade fever, loss of appetite and weight, fatigue, and depression, but may not be sufficiently annoying for a person to seek the counsel of a physician. Unfortunately, the disease may progress to the point where the patient has lost the sight of one eye prior to seeing a physician. Upon examination, the presence of tender nodular swelling of arteries in the scalp may be noted. Temporal artery biopsy is required to confirm giant cell arteritis. Treatment with prednisone is commenced immediately and its effect on the symptoms will be noted within a few days. Since recurrences are common in this disease, prednisone may be continued for an indefinite period. Early diagnosis can prevent blindness.

ČERENKOV RADIATION. This is a feeble radiation in the visible spectrum, which occurs when a fast charged particle traverses a dielectric medium at a velocity exceeding the velocity of light in the medium. It is thus a shock-wave phenomenon, the optical analog of a sonic boom. The particle runs away from its own electromagnetic field. The radiation arises from the local and transient polarization of the medium close to the track of the particle. With reference to Fig. 1(a), consider an arbitrary element S of the medium to one side of the track AB of a fast electron, the track defining the z-axis. At a particular instant of time, when the electron is at, say, e_1, the local polarization vector P_1 will be directed along Se_1', to a point e_1' slightly behind e_1 owing to the retarded fields. As the particle goes by, the vector P_2 will turn over and, when the electron reaches e_2, will be directed to a point e_2'. The variation of P with time may be resolved into radial and axial components P_ρ and P_z, as shown in Fig. 1(b). Owing to cylindrical symmetry, this polarization, viewed at a point distant from the particle, appears as an elementary dipole lying along the z-axis, Fig. 1(c). As the particle plunges through the medium, radiation arises from the coherent growth and decay of this sequence of elementary dipoles.

Two essential features of the radiation become at once apparent. First, since it is only the P_z component that is important, the field variation (Fig. 1(b)) is that of a double δ-function. Thus, from Fourier analysis, if the circular frequency ω, we will expect a spectrum of the form $\omega \cdot d\omega$, i.e., radiation which is bluer than that from an equi-energy spectrum. Secondly, since the radiating element is an axial dipole, the angular distribution, for this element alone, will be of the form $\sin^2\theta$ (Fig. 1(c)). It is important to realize that the radiation arises from the medium itself, not directly from the particle. Since the medium is stationary, the intensity and angular distributions do not contain the relativistic factor (mc^2/E); in this respect, Čerenkov radiation is essentially different from Bremsstrahlung or synchrotron radiation. (See also **Bremsstrahlung**.) The foregoing description applies only to one element along the track. The

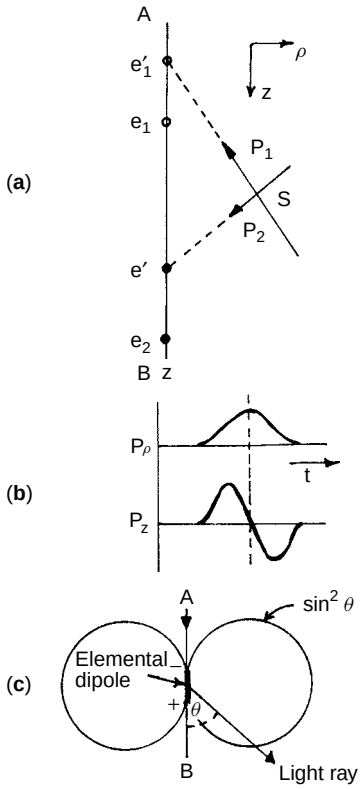

Fig. 1. Track of particle in formation of Cerenkov radiation.

presence of other charged particles would add to the effect. The effect is greater when the index of refraction of the medium is large.

The phenomenon has found considerable application in the fields of high-energy nuclear physics and cosmic ray research; in almost all practical Čerenkov counters, the light is detected by means of a photomultiplier. The unique directional and threshold properties of the radiation may be used in a number of different ways. For example, by velocity selection, it is possible to distinguish between particles of different mass having the same energy, and it is also possible to measure particle velocities directly by measuring θ. Light flashes from the night sky associated with cosmic ray showers have been attributed to the effect, and microwaves have been produced by the Cerenkov process.

CERIUM. [CAS: 7440-45-1] Chemical element, symbol Ce, at. no. 58, at. wt. 140.12, first in the Lanthanide Series in the periodic table, mp 798 °C, bp 3433 °C, density 6.770 g/cm^3 (20 °C). Elemental cerium has a face-centered cubic crystal structure at 25 °C. Cerium is the most abundant element of the rare-earth group and is 28th in ranking of the naturally occurring elements in the earth's crust. The element is a silver-gray metal which oxidizes readily at room temperature, particularly in moist air, to form the oxide CeO_2, which is of a pale yellowish-green color. Above 300 °C, the element may ignite and burn with a bright red glow. Of the nineteen isotopes of cerium, only four occur in nature, ^{136}Ce, ^{138}Ce, ^{140}Ce, and ^{142}Ce. The thermal neutron-absorption cross section of the element is low. The element has a low toxicity rating. Electronic configuration is $1s^22s^22p^63s^23p^63d^{10}4s^24p^64d^{10}4f^15s^25p^65d^16s^2$. Ionic radius Ce^{3+} 1.034 Å, Ce^{4+} 0.92 Å Metallic radius 1.825 Å. First ionization potential 5.47 eV; second 10.85 eV. Other important physical properties of cerium are given under **Rare-Earth Elements and Metals**. See also **Chemical Elements**.

Cerium was first identified by M.H. Klaproth in 1803 and, independently, in the same year by J.J. Berzelius and W. Hisinger. The element occurs in four source minerals, allanite, bastnasite, cerite, and monazite. Bastnasite, which is a rare-earth fluorocarbonate, is found in southern California. Monazite, a phosphate that contains thorium and the light lanthanides, is distributed widely throughout the world. See also **Bastnasite**; and **Monazite**. Cerium is recovered from the minerals through an extractive process using H_2SO_4, followed by precipitation with oxalic acid, which separates the light lanthanides from thorium, yttrium, and the heavy lanthanides. Cerium metal is produced from its salts, such as CeF_3 or $CeCl_3$, by thermal reduction in a tantalum or molybdenum crucible. Alternative processes include the electrolysis of $CeCl_3$ or CeO_2. The latter compounds are soluble in a complex molten halide flux. The Ce^{3+} is reduced to metal at a molybdenum electrode. The process is carried out at from 800 to 1,000 °C.

A major use for CeO_2 is in decolorizing soda-lime container glass. The compound also is used for polishing gemstones and glass, notably precision optical glasses. Cerium is particularly useful in glass that is subject to α-, γ-, and x-radiation, and the impingement of light and electrons because the cerium prevents discoloration that may arise from the presence of Fe(II) by oxidizing the Fe(II) as it is formed to Fe(III). This is an important factor in color television tubes. Cerium dioxide also is used in cathodes, capacitors, phosphors, ceramic coatings, refractory oxides, semiconductors, and photochromic glasses. The compound also is used as a catalyst and as an opacifying agent in porcelain enamels. Because of its low nuclear cross section, CeO_2 may be applied as a diluent in oxide nuclear fuels.

Cerium metal finds wide application in mischmetal, which is a rare-earth metal comprised of 50% Ce, 25% La, 18% Nd, 5% Pr, and 2% other rare earths. This alloy is used in shell linings for military projectiles, as an alloying agent for improving the malleability of ductile iron, and in lighter "flints" where the alloy is compounded with a 30% iron alloy. The pyrophoric and incendiary nature of cerium are evident when cerium-base alloys are machined. Mischmetal also improves the creep resistance of magnesium alloys, the resistance to oxidation of nickel alloys, the hardness of copper alloys, and the strength of aluminum alloys. Both cerium metal and mischmetal are used as getters to remove traces of oxygen in vacuum tubes and equipment. When alloyed with cobalt, cerium is gaining importance as a magnet material. $CeCo_5$, as a permanent magnet material, has properties that exceed those of the alnicos and ferrites. Mixed rare-earth oxides and fluorides containing up to 50% cerium are used as cores for carbon arcs which, for illuminating purposes, have much greater intensity and color balance. The mixed oxides with cerium also are used as catalysts (petroleum cracking and chemical oxidation reactions) and in a variety of waterproofing agents, fungicides, and polishing materials.

Note: This entry is based upon a prior article furnished by K.A. Gschneidner, Jr., Director, and B. Evans, Assistant Chemist, Rare-Earth Information Center, Energy and Mineral Resources Research Institute, Iowa State University, Ames, Iowa.

CERMET. See **Chromium**; and **Nuclear Power Technology**.

CERTAINTY FACTOR. The extent to which a statement is considered reliable. This is a subjective factor, as opposed to probability, which is a mathematical likelihood of occurrence, based on previous experience. For example, a forecaster may state that there is a 50% probability of rain, and assign a certainty factor of 95% to that statement. There are several methods of combining certainty factors to arrive at an overall certainty. The most common of these is the Dempster–Shafer rule. The theory was developed by Arthur P. Dempster and Glenn Shafer.

Shafer, G.: *A Mathematical Theory of Evidence*, Princeton University Press, Princeton, NJ, 1976.

CERUMEN. The waxy secretion that collects in the external ear.

CERUSSITE. The mineral cerussite, lead carbonate, $PbCO_3$, is orthorhombic with tabular, prismatic and pyramidal crystals, with twinned forms very common. If not in crystal aggregates it may occur in granular or compact masses. Cerussite is very brittle with a conchoidal fracture; hardness, 3–3.5; specific gravity, 6.55 (a heavy mineral); luster, adamantine but may be vitreous to resinous, pearly or even submetallic. Its color is variable, white to gray, grayish-black or blue or green, transparent to translucent.

Cerussite is of secondary origin, being found associated with other lead minerals, and is widely distributed. There are many European and American localities. Fine crystals have been obtained from Phoenixville, Pennsylvania; Joplin, Missouri; Leadville, Colorado; Pima County, Arizona, and Dona Ana County, New Mexico. It is an ore of lead, and frequently carries values of silver. Derived from the Latin cerussa, white lead.

CERVIX. Any narrow or neck-like portion of an organ. The term is usually used in reference to the narrow end of the uterus that projects into the vagina. See also **Cancer and Oncology**; and **Gonads**.

CESAREAN SECTION. Surgical removal of the fetus from the uterus by means of an incision through the abdominal walls. The procedure is used: when there is deformity and narrowing of the bony pelvis, which does not permit delivery through the vaginal route; where a pelvic tumor blocks the birth canal; in cases where there would be difficult breech deliveries; and in certain patients with conditions that make labor dangerous to the safety of the mother.

CESIUM. [CAS: 7440-46-2] Chemical element, symbol Cs, at. no. 55, at. wt. 132.905, periodic table group 1, mp 28.40 °C, bp 669 °C, density 1.88 g/cm^3 (20 °C). Elemental cesium has a body-centered cubic crystal structure. Cesium is a silver-white, very soft metal, one of the softest of all metals. The element tarnishes instantly on exposure to air, soon igniting spontaneously with flame to form the oxide. Generally, the element is preserved under kerosene. Cesium reacts vigorously with H_2O, forming cesium hydroxide and hydrogen gas. The element first was identified by Bunsen and Kirchhoff in 1860 through spectroscopic observations. Cesium occurs in nature as the ^{133}Cs isotope. There are 15 radioactive isotopes ^{125}Cs through ^{132}Cs and ^{134}Cs through ^{139}Cs. The half-life of ^{137}Cs is 33 years. This isotope is used as a source of gamma radiation, particularly in radiography and therapy. See also **Radioactivity**. First ionization potential, 3.89 eV; second, 23.4 eV. Oxidation potential $Cs \rightarrow Cs^+ + e^-$, 3.02 V. Other important physical characteristics of cesium are given under **Chemical Elements**.

The main source of cesium is carnallite $KCl \cdot MgCl_2 \cdot 6H_2O$ which contains a small percentage of cesium compounds. See also **Carnallite**. Cesium also occurs in pollucite (cesium aluminosilicate, 35% Cs_2O) and lepidolite (lithium aluminosilicate). See also **Lepidolite**; and **Pollucite**. In early processes, cesium metal was obtained by the reduction of cesium salts, such as the hydroxide or chloride. In current practice, the metal is produced by electrolyzing the cyanide. The latter compound usually is fused cesium barium cyanide mixture.

The uses for cesium and its compounds are limited. Cesium is used in photoelectric devices because of its high sensitivity to light, finding applications in television, motion picture, radar, and instrumentation equipment. Cesium also has been used in luminescent tubes and screens. Certain processes for the manufacture of synthetic resins, such as chloroprene, use cesium as a catalyst. Some interest has been indicated in cesium as a fuel for ion-propulsion engines of low thrust for spacecraft. Like sodium, cesium also has been considered as a heat-transfer medium for special applications. The function of cesium in time measurement is important. As officially defined in 1967 by the International Bureau of Weights and Measures, the atomic second is equivalent to 9,192, 631,770 oscillations of the atom of ^{133}Cs. This value expresses the ephemeris time (ET) second as closely as practical in terms of an atomic standard. To derive this value, scientists at Great Britain's National Physical Laboratory and the United States Naval Observatory used a dual-rate moon-position camera and a cesium-beam clock.

Cesium forms several solid solutions with rubidium. These alloys are used as *getters* for eliminating residual gases from vacuum tubes and systems. Because of their extreme reactivity in air, the alloys are difficult to apply. For easier handling, cesium can be alloyed with calcium, barium, or strontium. The ternary alloys of cesium, aluminum, and barium or strontium are employed in photoelectric cells. Cesium alloyed with antimony, silver, bismuth, and gold also displays photoelectric properties.

Chemistry and Compounds: Cesium is more electropositive than rubidium (or the lower alkali metals) as is consistent with its position in group 1.

Because of the ease of removal of its single 6s electron (3.89 eV) and the difficulty of removing a second electron (23.4 eV) cesium is monovalent in its compounds, which are ionic.

In its solutions in liquid NH_3, cesium is like the other alkali metals, a powerful reducing agent, so that in such solutions, titrations of cesium polysulfide with cesium are made by electrometric methods. The solubility of cesium salts in liquid NH_3 increases markedly with the radius of an anion (the chloride, CsCl, 0.0227 moles per kg, the bromide, CsBr, 0.215 moles per kg, and the iodide, CsI, 5.84 moles per kg), though the values are less than for the corresponding rubidium compounds.

As reported by Knittle and Jeanloz (1984), cesium iodide, a simple ionic salt at low pressures, undergoes a second-order transformation at 40 gigapascals (400 kilobars) from the cubic B2 (cesium chloride-type) structure to the body-centered tetragonal structure. Also, the energy gap between valence and conduction bands decreases from 6.4 eV at zero pressure to about 1.7 eV at 60 gigapascals, transforming cesium iodide from a highly ionic compound to a semiconductor. The structural transition increases the rate at which the band gap closes, and an extrapolation suggests that cesium iodide becomes metallic near (or somewhat above) 100 gigapascals. It is noted that similar changes in bonding character are apt to occur in other alkali halides at pressures exceeding 100 gigapascals.

As in the case of the other alkali metals, cesium forms compounds generally with the inorganic and organic anions. For a general discussion of these compounds (see also **Sodium**) because the sodium compounds differ principally in their greater extent of hydration and greater number of hydrates. However, cesium coordinates with large organic molecules, such as salicylaldehyde, even though it does not with H_2O.

One respect in which cesium (and rubidium) are outstanding among the alkali metals is the readiness with which it forms alums. Cesium alums are known for all of the trivalent cations that form alums, Al^{3+}, Cr^{3+}, Fe^{3+}, Mn^{3+}, V^{3+}, Ti^{3+}, Co^{3+}, Ga^{3+}, Rh^{3+}, Ir^{3+}, and In^{3+}.

As in the case of potassium and rubidium, cesium forms a superoxide on reaction of the metal with oxygen. The compound is orange in color and paramagnetic because it contains the O_2^- ion with an odd electron in an antibonding orbital, and has the formula CsO_2. On heating, this compound loses oxygen to form black Cs_2O_3, which contains both CsO_2 and Cs_2O_2 (peroxide), which is the product of further heating. A series of suboxides of cesium is known, Cs_7O, Cs_4O (uncertain), Cs_7O_2, Cs_3O and Cs_2O. Moreover the normal oxide, Cs_2O, can be prepared by heating cesium nitrite with metallic cesium. It reacts explosively with oxygen to form CsO_2.

Cesium hydroxide, CsOH, is the strongest of the five alkali metal hydroxides, as would be expected from its position in the periodic table (francium hydroxide, when prepared, would be expected to be stronger). For the same reason, it has the lowest lattice energy of the five (135.6 kcal per mole).

The most numerous organic compounds of cesium are the oxygen-connected ones, such as the salts of organic acids, and alkoxy and aryloxy compounds (alcoholates, phenates, etc.). Among the carbon-connected compounds, an ethyl cesium, CsC_2H_5, and a phenyl cesium, CsC_6H_5, have been reported.

Later studies by investigators (Alberts et al., 1979) have shown that ^{137}Cs introduced into a watershed is attached to soil particles, which are removed by erosion and runoff. Some of the eroded soil particles comprise the sediments of the catchment basins in the watersheds and act as "sinks" for ^{137}Cs. Other investigators have reported an almost irreversible fixation of this element in clay interlattice sites in freshwater environments, and, that it is unlikely that this nuclide will be removed from these sediments under normal environmental conditions other than by exposure to solutions of high ionic strength, such as may occur in estuarine environments. Studies of ^{137}Cs have been important because the element can be introduced into a water system from a leak in a nuclear fuel element. These findings are reported in some detail by Alberts et al. in *Science*, **203**, 649–651 (1979).

It has been estimated that the most serious long-term threat to health and the environment as the result of the Chernobyl (former U.S.S.R) nuclear power plant disaster (1986) may come from radioactive cesium, which has a half-life of 33 years. Exposure to cesium-137 could increase the death rate from cancer in western Russia by a maximum of 0.4% over the next 70 years. That would equate with almost 40,000 excess deaths.

CESTODA *(Cestoidea).* The tapeworms. A class of the phylum Platyhelminthes. The tapeworms, like other members of the phylum, are flat-bodied. The body consists of two regions, a head or scolex usually bearing hooks, suckers, or both, and a strobila which, in all but the simplest species, is formed of a series of segments called proglottids. Tapeworms are parasitic in vertebrates.

In addition to the characteristics mentioned, tapeworms are distinguished by a complex life cycle. The adults live in the intestine of the host, absorbing food through the wall of the body since they have no alimentary tract, and produce a long succession of proglottids, which break off as they mature and pass out with the feces of the host, break off and remain in the intestine, or mature while still attached to the worm. They are reproductive bodies containing the organs of both sexes, rarely those of only one. The fertilized egg becomes a simple embryo with six hooks called the onchosphere. In this stage it is taken into the alimentary tract of a new host, migrates into the blood vessels, and, after drifting along the bloodstream, lodges in some part of the body and develops into another form, usually vesicular, called the bladder worm. In this stage it remains inactive unless the tissue containing it is eaten by another animal, in which case it attaches itself to the intestinal wall of the new host and develops into an adult tapeworm.

Tapeworms are among the important parasites of humans. Some of these species live in hogs and cattle and become established in humans as the result of eating imperfectly cooked meat and one of the most dangerous species is found in the dog during its adult stage and in domestic animals and humans in the bladder worm stage. The elimination of tapeworms from the human body requires the careful attention of a physician.

The tapeworms are classified as follows:

Subclass *Cestodaria*.Parasitic in fishes as adults and in annelid worms and mollusks in the early stages. No distinct scolex and no segments.
- Order *Amphilinidea*. Species of leaf-like form.
- Order *Gyrocotylidea*. Leaf-like, with a projecting organ of attachment at the posterior end.

Subclass *Cestodes*. Usually segmented. Proglottids with organs of both sexes.
- Order *Tetraphyllidea*. Scolex without retractile projections (proboscides), with four suckers or bothridia. Parasitic in cold-blooded vertebrates.
- Order *Tetrarhynchidea*. Scolex with proboscides. Parasitic in selachian fish.
- Order *Pseudophyllidea*. No proboscides; only two suckers or bothridia. In vertebrates of all classes.
- Order *Cyclophyllidea*. Four suckers and usually hooks. Body elongate, with distinct segments, often numerous. Principally in warm-blooded vertebrates.

CETANE NUMBER. See **Petroleum**.

CETUS (the whale). An equatorial constellation that lies south of Pisces.

CHABAZITE. The mineral chabazite is a member of that group of hydrous silicates, the zeolites, and corresponds to the formula $CaAl_2Si_4O_{12} \cdot 6H_2O$ with sodium sometimes replacing a part of the calcium. Potassium, barium and strontium may be present in very small amounts. Chabazite is hexagonal, usually in rhombohedrons that tend to resemble cubes. It has a rhombohedral cleavage; is brittle; hardness 4–5; specific gravity 2.05–2.10; luster vitreous; color white to flesh-red; streak white; translucent to transparent. Chabazite is found in the amygdaloidal cavities of basalts often associated with other zeolites. It is occasionally found in such crystalline rocks as syenites, gneisses and schists. Chabazite is a rather common zeolite, being found in many localities in Europe. In the United States it occurs in the Triassic traps of New Jersey and Maryland. The Triassic lavas of Nova Scotia have yielded fine specimens. The name chabazite is derived from the Greek word meaning a precious stone.

CHADWICK, JAMES (1891–1974). Chadwick was a distinguished English physicist. After receiving a Master's, he went to Germany to work with Hans Geiger. New research here showed that beta particles possess a range of energies up to some maximum value. During World War I he was interned in the Zivilgefangenenlager, Ruhleben. After the war, he was released and returned to England. He worked with Rutherford at the Cavendish Laboratory, Cambridge, on the bombardment of elements with alpha particles. He discovered the neutron, a particle in the nucleus of an atom that carries no electric charge. He received the Nobel Prize in 1935 for Physics. His work was a tool for investigating the atom and also led to the production of a variety of new radioisotopes.

See also **Neutron**.

J. M. I.

CHAETOGNATHA. The arrowworms, a group of small marine animals sometimes included in the phylum *Annelida* but now more often regarded as a separate phylum.

Arrowworms are usually elongate transparent animals. They have two or three pairs of horizontal fins, one forming a caudal fin at the end of the body. The head bears a pair of eyes and a group of spine-like jaws that give the name to the phylum. The alimentary tract runs through the body as a straight tube to an anus near the caudal end. The body cavity is divided into three chambers by two transverse septa. Although the phylum includes only about 30 species, arrowworms are found from the surface to great depths and in all of the oceans.

CHAETOPODA. A division of the annelid worms including the forms that have setae set in pockets in the integument. The coelom is well developed and is at least partially divided into metameric chambers, and the external segmentation of the body is also metameric. Most of the marine annelids such as the lobworm and clam worm and the earthworms and fresh-water annelids are included here. The leeches and a few more primitive worms make up the rest of the phylum.

By some authorities this division is called a class and is divided into two orders:

Order *Polychaeta*. Free-swimming and sedentary worms, mostly marine, with lobed appendages (parapodia) and many setae, and usually a head with sensory organs. This group is sometimes regarded as a class and is then divided into two orders, the *Errantia* with similar body segments, most species free-swimming or burrowing, and the *Sedentaria* with specialized body regions, living in tubes in the bottom of the ocean, or between the tides.

Order *Oligochaeta*. Fresh-water and terrestrial worms with few setae and with neither parapodia nor sensory appendages. The earthworms are common examples. Sometimes ranked as a class.

CHAFER *(Insecta, Coleoptera).* A name applied to certain plant-eating beetles, including the rose chafer of the United States. The adults of this species are sometimes a troublesome pest on small fruits, especially grapes. They damage the fruit itself. Spraying with control chemicals is recommended.

CHAGAS DISEASE (American Trypanosomiasis). The geographic distribution of American trypanosomiasis, known as Chagas Disease, effects the Americas from the southern United States to southern Argentina, and in poor, rural areas of Central and South America. Chronic Chagas disease is a major health problem in many Latin American countries. With increased population movements, the possibility of transmission by blood transfusion has become more substantial in the United States. Although only an estimated 1% of infected individuals contract the disease, poverty and poor housing exacerbate it. There is a particularly high incidence of the disease in children. The protozoan parasite, *Trypanosoma cruzi*, causes Chagas disease, a zoonotic disease that can be transmitted to humans by triatomine bugs, commonly called assassin or kissing bugs because of their predilection for biting the face. See also **Assassin Bug**; and **Kissing Bug**. Nonhuman reservoirs include domesticated animals such as cats, dogs, and pigs, as well as wild animals, eg, rats, bats, foxes, raccoons, opossums, and monkeys. These reservoirs can infect the vector, the night-feeding, blood-sucking triatomid bug. This insect, after biting a person usually on the face, defecates near the location of the wound. The life cycle is illustrated in Fig. 1. Parasites from the insect feces may either enter the human host at the point of the bite and/or by fecal contamination of

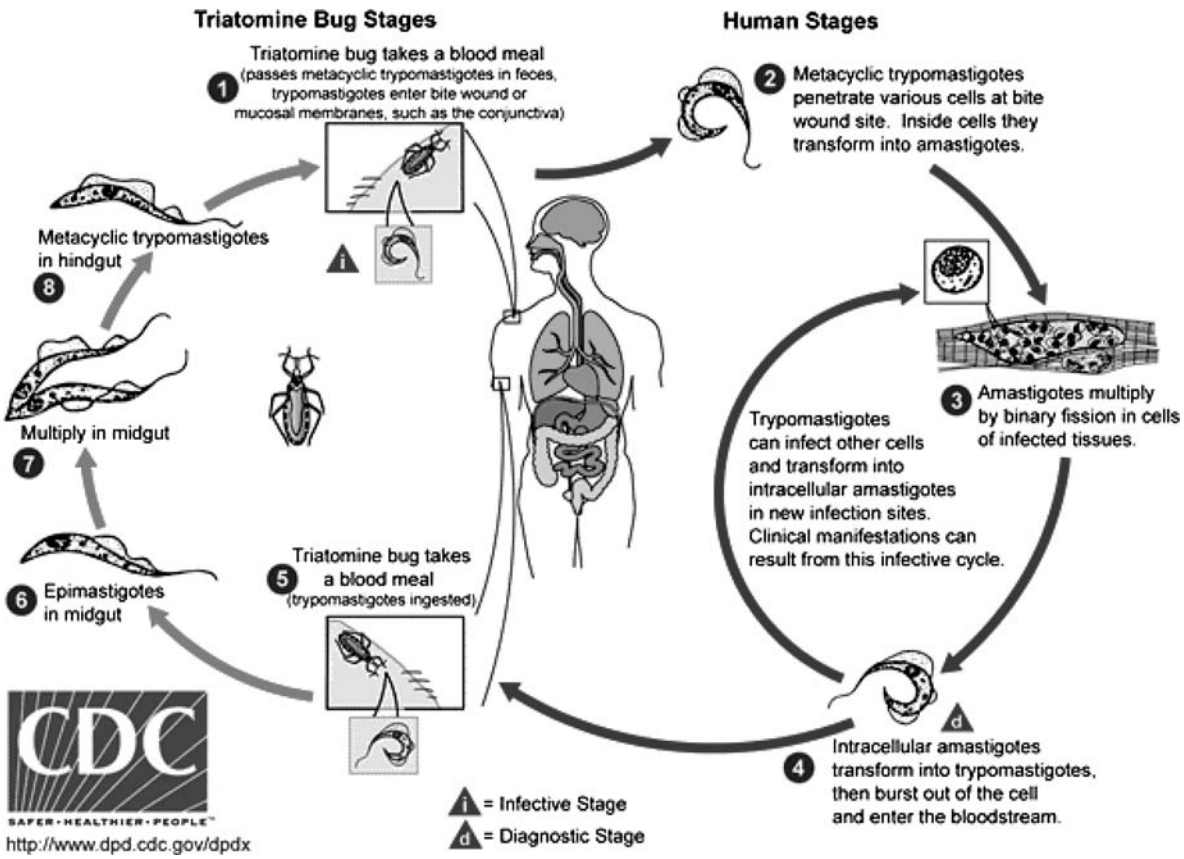

Fig. 1. An infected triatomine insect vector (or "kissing" bug) takes a blood meal and releases trypomastigotes in its feces near the site of the bite wound. Trypomastigotes enter the host through the wound or through intact mucosal membranes, such as the conjunctiva 1. Common triatomine vector species for trypanosomiasis belong to the genera *Triatoma*, *Rhodinius*, and *Panstrongylus*. Inside the host, the trypomastigotes invade cells, where they differentiate into intracellular amastigotes 2. The amastigotes multiply by binary fission 3 and differentiate into trypomastigotes, and then are released into the circulation as bloodstream trypomastigotes 4. Trypomastigotes infect cells from a variety of tissues and transform into intracellular amastigotes in new infection sites. Clinical manifestations can result from this infective cycle. The bloodstream trypomastigotes do not replicate (different from the African trypanosomes). Replication resumes only when the parasites enter another cell or are ingested by another vector. The "kissing" bug becomes infected by feeding on human or animal blood that contains circulating parasites 5. The ingested trypomastigotes transform into epimastigotes in the vector's midgut 6. The parasites multiply and differentiate in the midgut 7 and differentiate into infective metacyclic trypomastigotes in the hindgut 8. *Trypanosoma cruzi* can also be transmitted through blood transfusions, organ transplantation, transplacentally, and in laboratory accidents.

mucus membranes, usually those of the mouth or eyes. This causes a skin lesion (called a primary *chagoma*) that consists of a small, reddish, slightly painful nodule. One of the eyelids may become swollen. The injected trypanosomes enter many kinds of cells of the host where they multiply and become amastigotes. They then differentiate into trypomastigotes that circulate in the bloodstream and are distributed to all parts of the body. They do not replicate until they enter another cell or are ingested by another blood-sucking insect vector.

Two clinical forms of Chagas disease are recognized. The acute form develops after an incubation period of 5 to 15 days, principally in children, being seen primarily as an indurated lesion termed a chagoma which appears at the inoculation site. After about two weeks, the trypanosome makes its appearance in the blood stream as a motile, flagellum-bearing, spindle-like organism about 20 micrometers long (tryptomastigote) and then multiplies as a smaller intracellular parasite (amastigote) in the cells of the reticuloendothelial system. The acute stage of the disease usually lasts about 20 to 30 days and evokes fever, malaise, splenomegaly, hepatomegaly, and a non-pitting edema. Romaña's sign—a unilateral edema of the eyelid—may be seen at this point. In severe cases, a fatal myocarditis or meningoencephalitis may develop. The acute phase is usually self-limiting; patients become asymptomatic and parasites can no longer be demonstrated in the blood stream.

The chronic form of Chagas disease may become manifest either after an acute infection or after a clinically, asymptomatic, inapparent infection. It usually presents in the second or third decade of life and pursues its course over subsequent years. The organ most frequently involved is the heart, which develops biventricular hypertrophy and a mononuclear cell infiltrative myocarditis. Where the gastrointestinal tract becomes involved, dilation of the esophagus (megaesophagus) or colon (megacolon) may be seen because of the loss of automatic ganglia within the viscus walls.

Diagnosis is by microscopic examination of blood films or biopsies of lymph nodes or bone marrow; total leukocyte counts often exceed 18,000/mm^3, of which 70 to 90% are lymphocytes, and parasites are seen. Blood containing trypanosomes is highly infectious and should be handled with care.

Prognosis is poor, especially in children. Optimal therapy remains to be established. The 8-aminoquinolines are of some use in controlling the blood borne stage and Nifurtimox eliminates the parasitemia, but side effects are frequent.

Some progress is being made in South and Central America toward improving mud structures (with lots of cracks and crevices that provide entry of the insect vectors) with less penetrable construction materials. Also, persons who live under poverty conditions are being made aware of the relationship between the invasive insects and the illness that may follow.

It has been estimated that between 16 and 18 million people worldwide have been infected with *T. cruzi* and that another 90 million may be at risk of infection. Of those infected, from 30 to 40% may develop some form of cardiac involvement. Because of heavy immigration into the United States by persons from Central and South America, it is estimated that some 100,000 persons now residing in the United States may have been infected at one time or another with *T. cruzi*. Of these, several thousand are likely to develop Chagas heart disease. Some medical professionals are concerned that, because the disease is so easy to misdiagnose, patients

with Chagas heart disease may be overlooked and thus treated over long periods for other factors that commonly cause cardiac problems.

Hagar and Rahimtoola (University of Southern California Medical Center) undertook a retrospective case review of patients who had entered the aforementioned institution and who had a positive seriologic test for *T. cruzi*. The study covered a period from 1974 through 1990. Conclusions of the study: "In the United States, Chagas heart disease commonly mimics coronary artery disease or idiopathic dilated cardiomyopathy. The prognosis is poor for patients with heart failure or left ventricular aneurysm or dysfunction. The disease may be underdiagnosed in the United States."

The nitrofuran nifurtimox (**1**, [CAS: 23256-30-6] $C_{10}H_{13}N_3O_5S$) is the most effective drug against *T. cruzi*, being cidal against the trypomastigote and amastigote forms. It is active against both the extra- and intracellular form of the parasite. In combination with corticosteroids it has prevented myocardial inflammation and destroyed the parasites within the heart. Side effects of the drug tend to be mild and include nausea, vomiting, insomnia, nervous excitation, vertigo, and skin rashes. Cardiac symptoms are treated symptomatically. Benznidazole (**2**, [CAS: 22994-85-0] $C_{12}H_{12}N_4O_3$, *N*-benzyl-2-nitro-1 imidazoleacetamide, RO 7-1051), an alternative drug, can prevent the spread of the parasites from one tissue to another although relapses are common. Primaquine (**3**, [CAS: 63-45-6] $C_{15}H_{21}N_3O{\cdot}2H_3O_4P$) can destroy the extracellular trypanosomes in the blood, but is not effective against the intracellular forms of the parasite.

CHAIN. A flexible connector composed of metal links, used for hoisting or for power transmission. *Coil chain* is used for hoisting and haulage, and consists of oblong links of circular sections, usually of welded wrought iron or steel. Coil chain with a stud or bridge across the center of the coil is preferred to plain coil chain in some instances, since the studs tend to prevent stretching and kinking.

Chain used for power transmission is shown in Fig. 1. *Detachable link chain* is used for low-speed and light-load power transmission, and for conveyors and elevators of moderate capacity and length. The links can be easily detached and replaced, as illustrated. *Pintle chain* is from two to four times as strong as detachable link chain and can be used with the same sprockets. Both types of chain are usually made up of malleable iron unmachined links. They can be supplied with integral pin, plate, or scraper attachments.

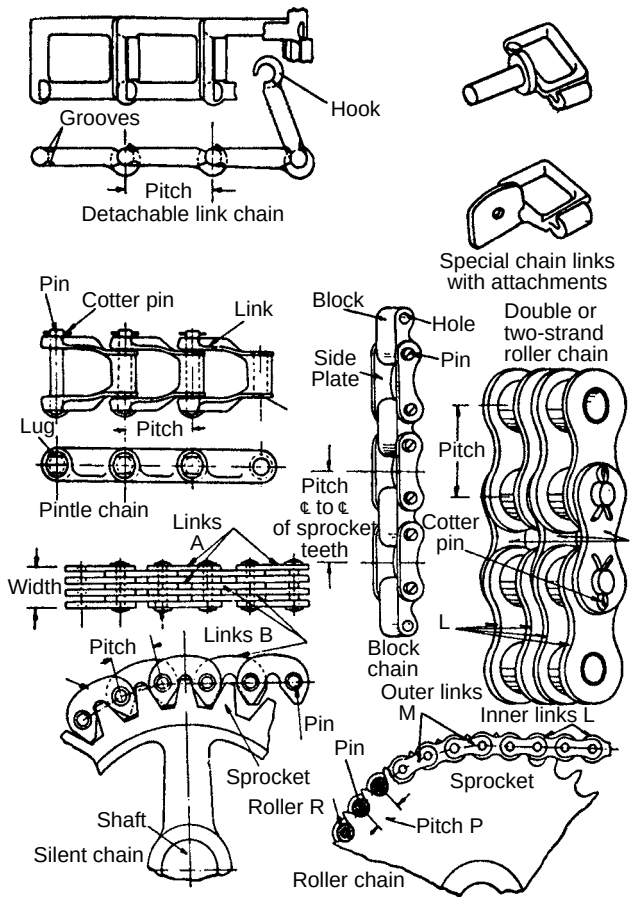

Fig. 1. Power transmission chain configuration.

Steel block, roller, and silent chains are used where an exact speed ratio is desired and the center distance of the shafts is too large for gearing. *Block chain* is used for comparatively slow speeds and consists of blocks linked together by connecting links and pins. *Roller chain* consists of alternate links *L* and *M* held by connecting pins, which are fastened by cotters. The pins also serve to carry the rollers, which bear on the sprocket teeth. Roller chain can transmit more power than block chain and can operate

at chain velocities up to 1200 feet (366 meters) per minute. For power requirements too great for single chains, double-, triple-, or quadruple-strand roller chains may be employed.

Silent chain is composed of alternate flat steel links *A* and *B* connected by pins. The links have straight faces in contact with the sprocket, and rotate slightly on the pins as the chain bends around the sprocket. Silent chain is used for heavy loads at speeds up to 1600 feet (488 meters) or more per minute. The silent chain is not actually quiet in operation but is much less noisy than other types of chain in use at the time of its adoption.

The speed ratio of a power chain depends upon the numbers of teeth in the driving and driven sprocket wheels; velocity ratios up to 7:1 are satisfactorily employed. Short-center drives with high ratios are usually more economical if fine-pitch chain is employed, while narrow large-pitch chain is cheaper for low-ratio long-center drives.

CHAIN BLOCK. Chains and sheaves may be employed in combination to produce an unusually powerful lifting mechanism. The best of these is the differential chain block, the action of which is explained in connection with Fig. 1. The mechanism consists of two sheaves, *A* and *B*, *A* being a double sheave having diameters *R* and *r*. It will be shown that the multiplying power of this mechanism depends upon the ratio of these diameters. If they are equal, the pull *P* will not move the weight, and the efficiency of the mechanism will be 0%, but the theoretical mechanical advantage is infinity. A slight difference in radii will produce a very large lifting effort, although the efficiency may still be very low. The sheaves are made with link pockets so that the chain fits nicely into the circumference, and is restrained from slipping. Furthermore, the chain is endless, and the mechanism is self-locking by virtue of the friction intentionally allowed on the journals.

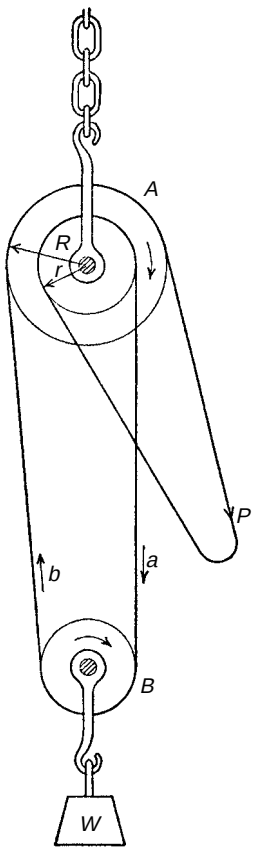

Fig. 1. Chain block hoist.

In explanation of the chain block, if the pull *P* revolves sheave *A* one revolution, the vertical chain at *a* is lowered through a distance to $2\pi r$, while the side *b* is raised the distance $2\pi R$. The net vertical displacement of the sheave *B* is $\pi(R - r)$ upward. With no friction considered, the work of lifting *W* through this distance must be equal to the work done by the pull *P* moving through $2\pi R$. Solving this equation for advantage W/P:

$$\frac{W}{P} = \frac{2R}{R - r}$$

Applying the mechanical efficiency *e* to this equation, the actual mechanical advantage is

$$\frac{W}{P} = \frac{2Re}{R - r}$$

These chain blocks are built in different sizes for hoisting loads from $\frac{1}{4}$ ton to 3 or 4 tons, by hand. On account of the self-locking feature depending on friction, the average mechanical efficiency of this device is only about 30%.

CHAIN, ERNST BORIS (1906–1979)). Ernst Chain was a German (naturalized as a British subject in 1939) biochemist who in 1945 shared the Nobel Prize for Medicine with Howard Florey and Alexander Fleming for his contribution to the development of penicillin.

Ernst Chain was born in Berlin of a Russian father and German mother. They were both Jewish. His father was a chemist who ran a successful chemical factory in a suburb of Berlin. This aroused Ernst's interest in chemistry and he pursued studies in chemistry and physiology at the Friedrich-Wilhelm University. His interest in chemistry was shared with a passion for music, which he retained all his life.

In 1933, having obtained a DPhil on the optical specificity of esterases, he left for England in search of a position. Hitler had come to power on 30 January of that year, and Chain's Jewish origins and left-wing opinions may have made it appear dangerous for him to remain in Germany. His father had died in 1919, and his family's financial situation was precarious. He did his best to assist his mother and sister, who stayed behind in Berlin, but were to die in a concentration camp during the war.

In 1935, he was asked to come and work with Howard Florey, who had been appointed to the Chair of Pathology at the Sir William Dunn School of Pathology in Oxford. Chain's main interest lay in the study of enzymes, and he collaborated with several members of the School on a variety of topics, including lysozyme, an enzyme with an antibacterial action that Alexander Fleming had found to be present in mucus secretions. This research was to lead Florey and Chain to study the antibacterial action of a mould, which had also been discovered by Fleming: penicillin. See also **Fleming, Sir Alexander (1881–1955)**; and **Florey, Howard Walter (1898–1968)**.

A small grant from the Medical Research Council, and further support from the Rockefeller Foundation, enabled the penicillin project to take off in 1939. After Norman Heatley, a biochemist experienced in micro-methods, had successfully begun the small-scale production of penicillin in the laboratory, Chain was able to concentrate on the purification and chemistry of penicillin. By then, he had been joined by Edward Abraham from the Dyson Perrins laboratory, and in 1942 they succeeded in producing partly purified penicillin for early clinical trials. A study of the different degradation products of penicillin led them to propose a β-lactam ring structure for the molecule, which was eventually confirmed by crystallographic analysis by Dorothy Crowfoot (Hodgkin). Chain also played an active role in a large collaborative scheme to synthesize penicillin. Although nothing came of it at the time, he became involved in the isolation of the penicillin nucleus in the 1950s, when he was consultant for the pharmaceutical company Beechams. This research led to the semi synthetic penicillin's that proved useful in the fight against penicillin-resistant bacteria. See also **Antibiotics: Penicillins and Others**; and **Hodgkin, Dorothy Mary Crowfoot (1910–1994)**.

Chain's temperamental outbursts, and sometimes difficult personality, led to friction between him and some of his colleagues, in particular Heatley and Florey. Perhaps because of this, in 1948 he left Oxford for Rome, where he played an important part in the development of the biotechnology industry. He returned to England in 1964, to take up the Chair of Biochemistry at Imperial College, London.

VIVIANE M. QUIRKE, The Queen's College, Oxford, UK

CHAIN RADAR BEACON. A radar beacon with a very fast recovery time. This recovery time provides the possibility of simultaneously interrogating and tracking the beacon by as many radars as required so long as they are phased, synchronized, or the sum total pulse recurrence

frequency does not exceed the maximum pulse recurrence frequency characteristics of the beacon.

CHAIN REACTION (Free Radical). See **Free Radical**.

CHALCANTHITE. This mineral of triclinic crystallization is found only as a rare secondary mineral in the oxidized zones of sulfide copper ores within arid regions. It is a hydrous copper sulfate, $CuSO_4 \cdot 5H_2O$, and is a most unstable mineral in moist atmosphere environments, altering readily to a powder-blue dust. The mineral possesses a vitreous luster of deep azure-blue color, ranging from transparent to translucent. Chalcanthite is found in abundance only in Chuquicamata and other arid regions of Chile where it is an important copper ore.

CHALCEDONY. One of the cryptocrystalline varieties of the mineral quartz, having a waxy luster. It may be semitransparent or translucent and is usually white to gray or grayish-blue or some shade of brown, sometimes nearly black. Light colored clear red chalcedony is known as carnelian; deep reddish brown as sardonyx; a green variety colored by nickel oxide is called chrysoprase. Prase is a dull green. Plasma is a bright to emerald-green chalcedony sometimes found with small spots of jasper resembling blood drops; it is then referred to as blood stone or heliotrope.

Chalcedony and agate are essentially porous, which permits their being dyed various colors by artificial means. Red color is produced by iron nitrate solution; nickel nitrate produces vivid green color; ammonium bichromate produces blue-green; and ferrocyanide salts a vivid blue. The black onyx used extensively in rings is a product of soaking chalcedony in sugar solutions and later in sulfuric acid.

The term chalcedony is derived from the Greek name Chalkedon, a town in the Middle East.

CHALCID WASP *(Insecta, Hymenoptera).* Very small insects of thousands of species, many of which are parasites on other insects and thus may be used for biologically controlling a number of damaging insect species. The tiny wasps are frequently of a shiny, metallic luster in appearance, with very simple wings showing a single vein. Only a few of the species feed on plants, notably the *fig wasp* (*Blastophaga psenes*), described below, which nevertheless is essential for the fertilization of Smyrna fig. The chalcid wasps are parasitic during their larval life, resulting from adult chalcids depositing eggs in a host. Host species are attacked by these parasites in all stages of metamorphosis, including the egg phase. A few species are important pests in wheat, but the chief economic importance of the group lies in the destruction of other pests by the parasitic species. The species *Trichogramma minutum* attacks more than 150 species of other insects and is raised in the millions for use as a natural parasite against the sugarcane borer and the Angoumous grain moth. The species *Aphycus helvolus* is a parasite and thus an effective control against the black scale insects (a severe pest of citrus). The species *Aphelinis mali* is a parasite of the damaging woolly apple aphid. The *Coccophagus gurneyi* species is a parasite of the citrophilus mealybug. And the species *Pteromalus puparum* is a parasite of the imported cabbageworm. The parasitic chalcid wasps of some species, in turn, live in and destroy other beneficial parasites, but in the overall, their net economic effect on food production is considered positive.

The chalcid wasps are distributed widely throughout the United States.

Fig wasp (*Blastophaga psenes*, Linnaeus). A minute, shining, amber-brown wasp that is nearly indispensable to Calimyrna fig production because of its role in pollination or caprification.[1] No other insect successfully pollinates commercial varieties of figs. Thus, fig varieties that require pollination develop no fruit unless this wasp is present. Before caprifigs containing *Blastophaga* wasps were introduced into California from Algeria in 1899, attempts to produce Smyrna-type figs on a commercial scale had been unsuccessful.

The remarkable arrangement whereby the male fruits of various species of fig provide food and shelter for the larvae of these small wasps is one of the more complex relationships between a plant and an insect to be found in nature. The caprifig (male) tree supports a population of these wasps throughout the year. It bears three crops of caprifigs, one in winter, another in spring, and a third in summer and fall.

The spring crop of caprifigs produces an average of about 500 female wasps and about 30 wingless males per fig. This crop of caprifigs has a barrier of pollen-bearing flowers around the opening or eye. A cycle of wasp development begins with the laying of eggs in the gallflowers of a caprifig. The wasps develop to maturity inside these flowers. As the females escape through the eye, they become dusted with pollen. During the first half of June, the female wasps fly to other caprifigs and also to edible figs produced by female trees. In the caprifigs, the insects' cycle is repeated, but the attempts by females to lay eggs in the galls of edible figs result only in pollination and setting of the fruit.

One disadvantage in the visits of these wasps to edible figs is that they carry into the figs the spores of a mold, *Fusarium moniliforme*, that results in a disease (*endosepsis*) that cause spoilage. The insects also carry a bacterium, *Serratia plymuthica*, that causes disease, and a yeast, *Candida gulliermondii*, var. *carpophilia*.

[1] Experiments by University of California scientists have shown that a hormone spray applied to the fruit and foliage at the proper time will cause the fruit to set without pollination, but the method has not been adopted because the resulting quality of the fruit appears to be inferior. Further research is required.

CHALCOCITE. This mineral is cuprous sulfide, Cu_2S, crystallizing in the orthorhombic system, often in pseudohexagonal forms. Above a temperature of 91 °C, chalcocite changes into an isometric form. It has conchoidal fracture; hardness, 2.5–3; specific gravity, 5.5–5.8; metallic luster; color, dark gray to blackish-gray, frequently with bluish-green tarnish. Chalcocite is of widespread occurrence and a valuable copper ore. It seems in some cases to be definitely secondary in origin, in other cases primary. It may have been formed from bornite by the action of alkaline solutions. It sometimes carries valuable amounts of silver.

Among the many European localities might be mentioned Cornwall, England, the Ural Mountains, and Rumania. It occurs also in the Congo, South West Africa, Peru, Mexico, and Alaska. In the United States it is found at Bristol, Connecticut, in fine crystals, Montana, Tennessee, Arizona, Nevada, and California.

The word *chalcocite* is derived from the Greek word meaning "copper." Chalcocite also is known as *copper glance*.

CHALCOPYRITE. The mineral chalcopyrite (also known as copper pyrites) is a sulfide of copper and iron corresponding to the formula $CuFeS_2$. Its tetragonal crystals are often complex with repeated twinning; massive chalcopyrite is common. It has an uneven fracture; is brittle; hardness, 3.5–4; specific gravity, 4.1–4.3; luster, metallic; color, brass-yellow, may be iridescent from tarnish; streak, greenish-black; opaque. Chalcopyrite is the most common copper-bearing mineral known and it is the most important ore of copper. It is a primary mineral in many igneous rocks and from it a host of secondary copper minerals have been derived.

Among the many localities where fine specimens of this mineral have been obtained might be mentioned: Freiburg, Saxony; Alsace; Rio Tinto, Spain; Cornwall, England; Australia; Chile, Peru, and Bolivia, South America; and in the United States, Ellenville, New York; Chester County, Pennsylvania; Joplin, Missouri; Gilpin County, Colorado; Arizona, Montana, Utah, Nevada, California, New Mexico and Tennessee. In Canada there are notable deposits of chalcopyrite in the Provinces of British Columbia, Ontario, and Quebec. The name *chalcopyrite* is derived from the Greek word meaning "copper," and the word *pyrites*.

CHALK. Chalk is a soft, porous limestone of white, grayish-white or buff color made up of the minute shells of foraminifera and fragments of cocospheres. It occurs extensively in England and France and less so in the United States.

Chalk consists almost entirely of calcite, formed principally by shallow-water accumulation of (1) calcareous tests of floating microorganisms and (2) comminuted remains of calcareous algae. The most widely distributed chalks are of Cretaceous age, as exemplified by the cliffs on both sides of the English Channel. Although an unaltered deposit, chalk masses may contain nodules of chert and pyrite.

CHALLENGING MINI-SATELLITE PAYLOAR FOR GEO-SCIENTIFIC RESEARCH AND APPLICATIONS PROGRAM (Champ). See **Space Science Missions: Earth**.

CHAMBER PRESSURE (symbol P_c). The pressure of gases within the combustion chamber of a rocket engine.

CHAMBER VOLUME (symbol V_c). The volume of the rocket combustion chamber including the convergent portion of the nozzle up to the throat.

CHAMELEON *(Reptilia, Sauria).* Any member of several genera of lizard-like reptiles of very peculiar form, occurring in Africa, the Oriental region, and about the Mediterranean. They are arboreal species with grasping feet, a crested head, and a long extensile tongue with a clubbed sticky tip used to catch insects. They are able to change color readily. The most common genus is *Chamaeleon*.

The little lizard sold at street fairs is not a true chameleon, but is more closely related to the iguanas.

See also **Agamids**; and tabular summary, Classification of Lizards, in entry on **Lizards**.

CHAMOMILE. The flowers of an annual herbaceous plant (*Matricaria chamomilla* L.) of the *Compositae* family, upon steam distillation, yield a viscous liquid of an intensely blue coloration and characteristic odor and taste. The principal constituents are chamazulene, sesquiterpene alcohols, and caprinic acid and ester. Flavorings, available as infusions, tinctures, or soft and dried fluid extract, are used in various foods, such as beverages, ice creams, candies, baked goods, and chewing gum for imparting a bitter-tonic flavor with a characteristic aroma. Traditionally the product has been most popular in Europe, where it is considered a mild sedative and digestive.

CHAMPAGNE. According to the strictest ethics of the world of wines, Champagne means French Champagne, made in the Champagne wine-producing district of France, located about 70 miles (112 kilometers) east of Paris and northwest of the Burgundy district. Although Champagne is known everywhere, it is interesting to note that less than 1% of the total wine production in France is Champagne. Champagne, usually white, sometimes pink, but never red, is a sparkling wine due to residual carbonation in the bottle. Two varieties of grapes are used in its production — the black grape, Pinot Noir, from which fine red Burgundies also are made; and the white grape, Chardonnay, which also is used for making excellent white Burgundies and Chablis. The juice of the Pinot Noir, is white, although the skin is dark. Thus great care must be used to insure that the skins are not in long contact with the pulp and juice. When there is limited contact, a pink juice (*must*) may result. In making the truly fine Champagnes, there is much hand-sorting of grapes prior to crushing. All bruised and rotten grapes are removed. A Champagne made from all-white juice (*blanc de blanc*) is available. Grapes for Champagne are pressed (in France, the same amount is always used, namely 4 tons or 4000 kilos), and the juice runs into tubs that hold 450 gallons (1703 liters). The slightly pinkish cast to the fresh juice (Pinot Noir) will diminish considerably during subsequent fermentation, fining, and filtration. The French use the term *cuvée* to describe the juice of the first pressing. As is true of pressing grapes for any kind of wine, the first-run juice contains less tannin and coloring pigments picked up from skins; it also contains the greatest concentration of sugar.

Fermentation of the first juices (450 gallons) proceeds for 2 to 3 days, a process carried out in glass-lined or concrete vats in the modern winery, whereas in traditional wineries, the must is "racked off" into oak casks that contain a little less than 50 gallons. Although the initial fermentation lasts but a few days, fermentation at a lesser rate persists for about 2 months. The appearance of a clear wine is an indication to the winemaker that fermentation has virtually ceased. Although it would be the desire of the winemaker that all batches be of the very highest quality, there is not absolute uniformity in dealing with a naturally derived product. Thus, at this juncture in processing, there is blending. The blended wines are called the winemaking firm's Cuvée. The blend is tested for residual sugar. If low, a predetermined amount of *liqueur de tirage* (pure cane sugar dissolved in Champagne wine) will be added. This is a critical operation because too much sugar will cause the bottle to burst and too little will detract from the sparkling qualities of the product.

Bottles are filled and corked, using a strong steel clamp to hold the cork in place. A second fermentation occurs in the bottle, producing carbonic acid gas and building up a pressure of 6 atmospheres or slightly less. The length of time the wine is retained in this configuration varies from one maker to the next and may range from about 1.5 to 5 years. At the end of this period, the bottles are removed and shaken, after which they are placed in titled racks known as *pupitres*. It is now necessary to remove the deposit of sediment resulting from the second fermentation caused by adding the *liqueur de tirage*. This sediment removal is called *remuage* in French. Usually the bottle is shaken and turned in its rack by just a few degrees each day (up to 24 such shakings and turnings). This results in a relatively uniform deposition of sediment against the cork, a condition important prior to disgorging. In California, remuage is sometimes called *riddling*.

Removal of the deposit is called *disgorgement*. In modern facilities, a freezing machine is used. Bottles, in an upside-down configuration, are exposed to a low temperature to a distance of about 2 inches (5 centimeters) along the neck to form an ice plug perhaps 0.5-inch (12–13 millimeters) thick. Within this plug will be embedded the sediment which it is desired to remove. In disgorging the plug, an operator will loosen the clamp and open the bottle in essentially the usual fashion, pointing it upward and at an angle. Once the plug is blown out, it is necessary to allow some of the wine to flow out, but not too much. After the bottle is inspected for traces of deposits, it is then ready for dosage.

Cane sugar dissolved in mature wine or old brand (*liqueur d'expedition*) is added to the bottle. It is at this time that the final sweetness of the Champagne is determined, ranging from *Brut* (considered drier than extra dry and not containing over a 2% dosage); to *Demi-Sac* (half-dry, a term no longer used very much). Usually the dosage is comprised of 3 parts cane sugar and 2 parts old wine. Rock candy is sometimes used, and in some cases a small amount of special brand (espirit de Cognac, double-distilled, 140 proof) is added in the dosage. The final cork is then placed in the neck of the bottle and clamped. The bottle is then shaken thoroughly to mix the wine with its dosage, after which the Champagne is again stored. This period may range from essentially zero time up to 10 years, again depending upon the policy of the producer. Vintage Champagne continues to improve for about 10 years, after which it loses its quality, including sparkle. Many authorities believe that a good Champagne should be consumed between 6 months and 6 years after disgorgement.

A number of countries have agreed to recognize that Champagne is an appellation (name) of origin and it is the property of the originators in France. In the United States, Champagne may be used to identify a product if made essentially in accordance with the process just outlined, even though the product may be red. There are no restrictions as regards variety of grapes used. It should be noted that a number of producers in the United States are attempting to produce a quality product, one comparable in many respects to the original. It should also be pointed out that a good sparkling wine can be made by other processes. See also **Wine**.

CHANDRASEKHAR, SUBRAHMANYAN (1910–1995). Pronounced: su/bra/mon'/yon chandra /say/kar. Chandra immigrated in 1937 from India to the United States, where he joined the faculty of the University of Chicago, a position he remained at until his death August 21, 1995. He and his wife became American citizens in 1953.

Trained as a physicist at Presidency College, in Madras, India and at the University of Cambridge, in England, he was one of the first scientists to combine the disciplines of physics and astronomy. Early in his career he demonstrated that there is an upper limit — now called the Chandrasekhar limit — to the mass of a white dwarf star. See also **Neutron Stars**. A white dwarf is the last stage in the evolution of a star such as the sun. When the nuclear energy source in the center of a star such as the sun is exhausted, it collapses to form a white dwarf. This discovery is basic to much of modern astrophysics, since it shows that stars much more massive than the sun must either explode or form black holes. See also **Black Hole**; and **Giant and Dwarf Stars**.

Chandra was a popular teacher who guided over fifty students to their Ph.D. His research explored nearly all branches of theoretical astrophysics and he published ten books, each covering a different topic, including one on the relationship between art and science. For 19 years, he served as editor of the *Astrophysical Journal* and turned it into a world-class publication. In 1983, Chandra was awarded the Nobel Prize for Physics, for his theoretical studies of the physical processes important to the structure and evolution of stars.

NASA's premier X-ray observatory was named the Chandra X-ray Observatory in honor of the late Indian-American Nobel laureate, known to the world as Chandra (which means, "moon" or "luminous" in Sanskrit). See also **Chandra X-Ray Observatory**.

CHANDRA X-RAY OBSERVATORY. The Chandra X-Ray Observatory (originally called the Advanced X-ray Astrophysics Facility—AXAF) is the X-ray component of NASA's Great Observatories which also includes the recently decommissioned Compton Gamma Ray Observatory (CGRO), the Hubble Space Telescope (HST), and the Spitzer Space Telescope (SST). The Chandra X-ray Observatory (hereafter CXO) is sensitive to X rays in the energy range from below 0.1 to above 10.0 keV, corresponding to wavelengths from 12 to 0.12 nanometers. The relationships among the various parts of the electromagnetic spectrum, sorted by characteristic temperature and the corresponding wavelength, are illustrated in Fig. 1. Chandra's performance advantage over other X-ray observatories is analogous to that of the Hubble Space Telescope over ground-based observatories.

Chandra is a NASA facility that provides scientific data to the international astronomical community in response to proposals for its use. Data becomes public one year after the observation. The Observatory is the product of the efforts of many commercial, academic, and government organizations in the United States and Europe. NASA's Marshall Space Flight Center (MSFC) manages the Project and provides Project Science; TRW Space and Electronics Group served as prime contractor responsible for providing the spacecraft, the telescope, and assembling and testing the observatory; the Smithsonian Astrophysical Observatory (SAO) provides technical support and is responsible for ground operations.

In 1895, the German physicist, Wilhelm Roentgen, discovered what he thought was a new form of radiation. He called it X radiation to summarize its properties. The radiation could pass through many materials that easily absorb visible light and could free electrons from atoms. We now know that X rays are nothing more than light (electromagnetic radiation) but at high quantum energies.

Light has been given many names: radio waves, microwaves, infrared, visible, ultraviolet, X-rays, and gamma radiation are all different forms. Radio waves are composed of low-energy particles of light (photons). Optical photons—the only photons perceived by the human eye—are a million times more energetic than the typical radio photon, whereas the energies of X-ray photons range from hundreds to thousands of times higher than those of optical photons. Very low temperature systems (hundreds of degrees below 0°C) produce low-energy radio and microwave photons, whereas cool bodies like our own (about 30°C) produce infrared radiation. Very high temperatures (millions of degrees Celsius) are one way of producing X-rays.

X-ray astronomy is an extremely important field because it has been found that all categories of astronomical objects (or a subset thereof), from comets to quasars, emit X-rays. Thus learning how and why these objects produce X-rays are fundamental to our understanding of the way astronomical systems work. This, together with the large amounts of energy required to produce X-rays, makes their study interesting and exciting. A second reason that the field is so important is that the vast bulk of the matter in the Universe that we can directly observe through the electromagnetic radiation that it emits is in the very hot (temperatures of millions of degrees) X-ray emitting gas that fills the space between galaxies in clusters of galaxies (Fig. 2), the largest collections of matter in the Universe. The CXO is the prime method of gaining new information about the X-ray emission seen in the Universe.

The field of X-ray astronomy began with the discovery in 1948 that the Sun is a source of X rays. The experiment performed by scientists at the Naval Research Laboratories used photographic film mounted in a V-2 sounding rocket. Earth's atmosphere absorbs X rays, and so experiments must be performed above it. The first X-rays from a source other than the Sun were detected in 1962 by R. Giacconi and B. Rossi using a Geiger counter in a sounding rocket. For this, and subsequent pioneering efforts including fostering the development of the Chandra X-ray Observatory, Giacconi was awarded half of the Nobel prize for physics in 2002.

Most of the early X-ray astronomy experiments used gas-filled X-ray detectors, either Geiger or proportional counters. Locating the X-ray sources in the sky used mechanical collimation to restrict the field of view to at best about 0.5° (the apparent size of the Sun and the Moon). This crude accuracy made identification of the X-ray sources with objects seen in either the visible or the radio difficult. One notable exception in this early era was an experiment by H. Friedman and colleagues at the Naval Research Laboratories that used lunar occultation to show that the nebula associated with the X-ray pulsar in the Crab Nebula was extended.

X-ray astronomy began to make huge strides due to the development of focusing X-ray optics that could concentrate large amounts of X rays into small areas and form an image. The first X-ray astronomy satellite fully devoted to extrasolar X-ray imaging was NASA's second High Energy Astronomy Observatory, it was referred to as the Einstein Observatory in the scientific community, and it was launched in 1979. The prototype of the Chandra X-ray Observatory, the Einstein observatory had the first large-area grazing incidence X-ray optics and featured an angular resolution of about 10 seconds of arc, although only a small fraction of the X rays reflected by the telescope was within this central core due to scattering caused by the roughness of the reflecting surfaces.

The next major advance in X-ray focusing was the German/USA/UK mission Rosat (1990–1998; see, e.g., Truemper, 1983). It was equipped with an imaging X-ray telescope of about 4 seconds of arc angular resolution and three interchangeable imaging X-ray detectors, and it made numerous contributions.

The Observatory and Its Instrumentation

In 1977, NASA/MSFC and SAO began the study leading to the definition of the then named Advanced X-Ray Astrophysics Facility mission. This study, in turn, had been initiated as a result of an unsolicited proposal submitted to NASA in 1976 by Prof. R. Giacconi (Harvard University and SAO) and Dr. H. Tananbaum (SAO). Several significant events took place during the intervening years, including the highest recommendation by the National Academy of Sciences Astronomy Survey Committee, selection of the instruments, selection of the prime contractor, demonstration of the ability to build the optics, restructuring of the mission, selecting the name of the mission in honor of the Nobel Prize winner, Subramanyan Chandrasekhar, and the launch.

Chandra was launched July 23, 1999 by the Space Shuttle *Columbia*. The Commander was Col. Eileen Collins, the first female commander of a Shuttle flight. With a second rocket system, the Inertial Upper Stage (IUS) attached, the Chandra was both the largest and heaviest payload ever deployed from a Space Shuttle. Once deployed, and after separating from the IUS, the Chandra flight system is 13.8-m (43.5-ft) long by 4.2-m (14-ft) diameter, with a 19.5-m (64-ft) solar-panel wingspan. With extensive use of graphite–epoxy structures, the mass of the Chandra flight system is light for its size at 4,800 kg (10,600 pounds).

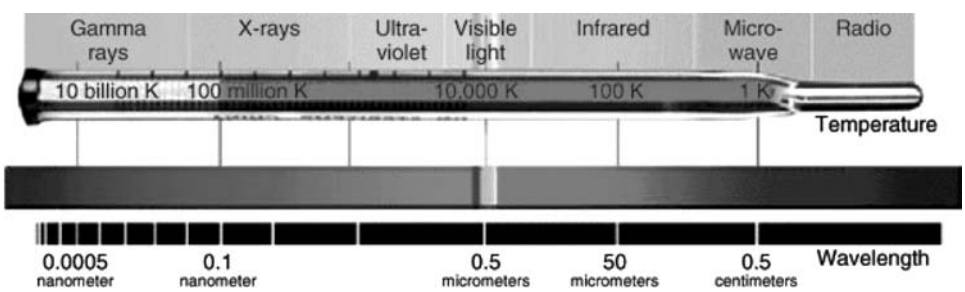

Fig. 1. The electromagnetic spectrum as a function of temperature and wavelength.

Following the Shuttle launch and release from the cargo bay, the IUS performed two firings and separated from the Observatory. Finally, after five firings of Chandra's internal propulsion system the last of which took place 15 days after launch — the Observatory was placed in its highly elliptical orbit. This orbit has an apogee of 140,000 km (1/3 of the way to the moon) and a perigee of 10,000 km. The inclination to the equator is 28.5°. The satellite is above the radiation belts for more than 75% of the 63.5-hour orbital period.

The specified design life of the mission is 5 years; however, the only perishable (gas for maneuvering) is sized to allow operation for more than 10 years. The orbit will be stable for decades.

The first x-rays focused by the telescope were observed on August 12, 1999. Figure 3 shows that image of a young (320 year old) remnant of an exploding star, a supernova remnant, in the constellation Cassiopeia. The Chandra image included a new discovery the bright visible point near the center of the image was the first detection of the compact star (probably a neutron star) created during the implosion of the more massive progenitor. Discoveries of new astronomical features in Chandra images have been the rule, not the exception.

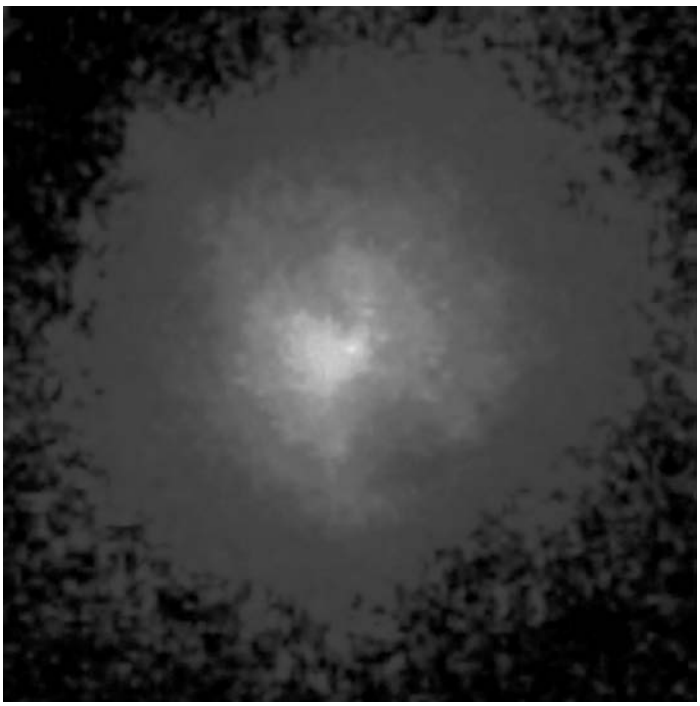

Fig. 2. The Chandra X-ray image of Hydra A, a galaxy cluster 840 million light years from Earth, shows strands (blue/pink) of 35–40 million degree Celsius gas embedded in a large cloud of equally hot gas (blue) that is several million light years across. A bright white wedge of hot multimillion degree Celsius gas is seen pushing into the heart of the cluster. (*Courtesy of: NASA/Chandra X-ray Center/Smithsonian Astrophysical Observatory.*)

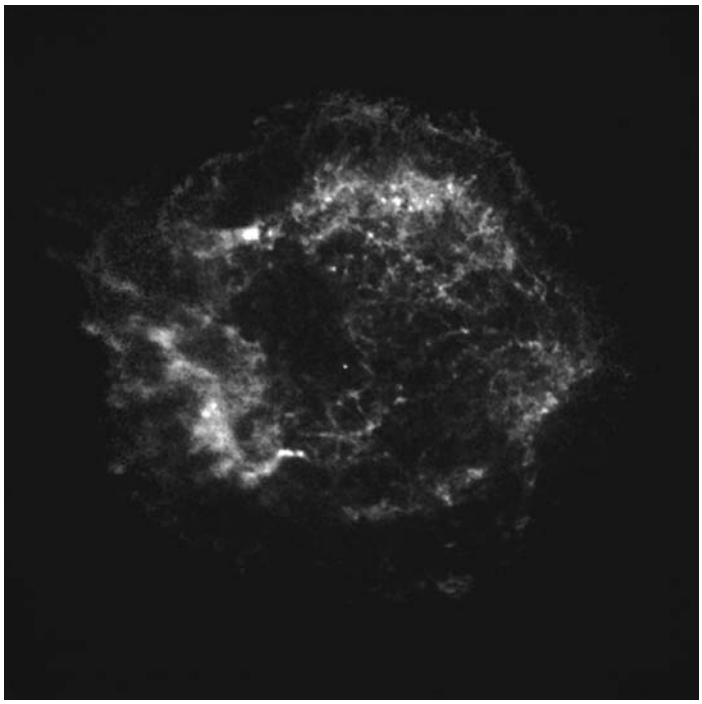

Fig. 3. Chandra image of the supernova remnant Casseopeia-A. It is 10 light years across and 10,000 light years from Earth. (*NASA/CXC/SAO*).

The Chandra optics and detectors provide, for the first time, sub-arcsecond imaging, sub-arcsecond spectrometric imaging, and together with the transmission gratings, high-resolution x-ray spectroscopy. With these capabilities, a wide variety of high-energy phenomena in a broad range of astronomical objects are being observed. X-rays result from highly energetic processes. There are thermal processes in plasmas with temperatures of millions of degrees or nonthermal processes, such as synchrotron emission or scattering from very hot or relativistic electrons.

The details of the Observatory are illustrated in Figure 4. The spacecraft is standard except for its lightweight construction and provides pointing control, power, command and data management, thermal control, and other such services to the scientific payload. The principal elements of the payload are the x-ray telescope, the scientific instruments, and the aspect system used to determine where on the sky the observatory was pointed.

The telescope is made of four concentric, precision-figured, superpolished Wolter-1 x-ray telescopes, similar to the Einstein Observatory, but of much higher quality, larger diameter, and longer focal length. The Wolter-1 design uses a paraboloid of revolution followed by a hyperboloid of revolution. Two reflections minimize coma. The 4-mirror-pair grazing-incidence optics are constructed of Zerodur, a glassy ceramic chosen for its high thermal stability. The optics are coated with iridium, chosen for high reflectivity at the x-ray energies of interest 0.08–10.0-keV (15–0.12 nm).

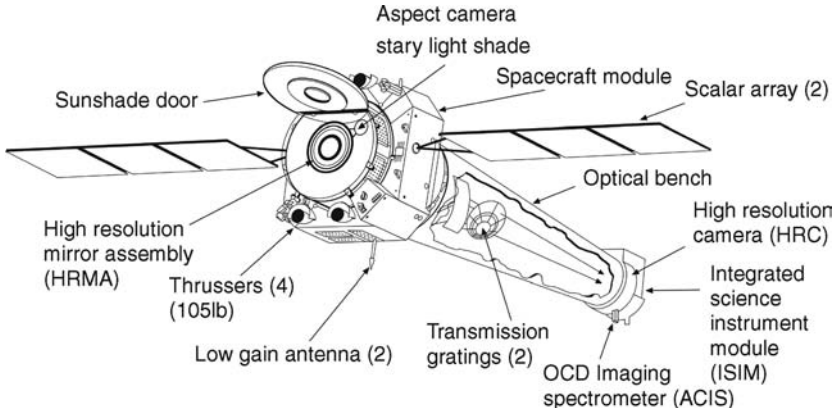

Fig. 4. The Chandra X-Ray Observatory. (*NASA/CXC/SAO*). http://chandra.harvard.edu/resources/illustrations/craftOutlineLabel.html Artwork Source.

The aspect camera system includes a visible-light telescope and CCD camera attached to the telescope. A fiducial-light transfer system is used to project lights attached to the focal-plane instruments onto the aspect. Thus, the aspect camera simultaneously determines both where the observatory was pointing and the location of the x-ray detectors relative to the positions of known stars.

The science instrument module includes mechanisms for focusing and translating Chandra's focal-plane instruments. Translation is required as the instruments cannot realistically share the telescope's focus.

Just behind the telescope are two objective transmission gratings. They are the Low-Energy Transmission Grating (LETG), which is optimized for longer x-ray wavelengths, and the High-Energy Transmission Grating (HETG), which is optimized for shorter wavelengths. Positioning mechanisms may insert either grating into the converging beam to disperse the x-radiation onto the focal plane producing high-resolution spectra read-out by one of the detectors. The gratings allow for measurements with spectral resolving power of $\lambda/\Delta\lambda = E/\Delta E > 500$ for wavelengths of >0.4 nm (energies <3 keV).

The Space Research Institute of the Netherlands and the Max-Planck-Institut fur Extraterrestrische Physik designed and fabricated the LETG. The assembly is made of 540 grating facets with gold bars of 991-nm period. The LETG provides high-resolution spectroscopy from 0.08 to 2 keV (15 to 0.6 nm).

The Massachusetts Institute of Technology (MIT) designed and fabricated the High-Energy Transmission Grating (HETG). The HETG uses two types of grating facets. The Medium-Energy Gratings (MEG), when inserted, are placed behind the telescope's two outermost shells, and the High-Energy Gratings (HEG), are placed behind the 2 innermost shells. The HEG and MEG are oriented at slightly different dispersion directions. With polyimide-supported gold bars of 400-nm and 200-nm periods, the HETG provides high-resolution spectroscopy from 0.4 to 4 keV (MEG, 3 to 0.3 nm) and from 0.8 to 8 keV (HEG, 1.5 to 0.15 nm).

Chandra's two focal-plane science instruments are the High Resolution Camera (HRC) and the Advanced CCD Imaging Spectrometer (ACIS).

SAO designed and fabricated the HRC. One of the HRC detectors is made of a 10-cm-square microchannel plate, and provides high-resolution imaging over a 31-arcmin-square field of view. A second detector, comprising three rectangular segments (3-cm $\times$ 10-cm each) mounted end-to-end along the grating dispersion direction, serves as the primary read-out detector for the LETG. Both of the HRC detectors are coated with a cesium–iodide photocathode and have thin aluminized polyimide shields to prevent contamination by ions and ultraviolet light.

The Pennsylvania State University MIT built the ACIS with charge-coupled devices (CCDs) fabricated by MIT's Lincoln Laboratory. As with the HRC, there are two detector systems. One is made of a 2×2 array of CCDs, and provides high-resolution spectrometric imaging over a 17-arcmin-square field of view. The other, a 6×1 array mounted along the grating dispersion direction, serves as the primary read-out detector for the HETG. Two types of CCDs were used: eight front-illuminated (FI) and two back-illuminated (BI). The latter CCDs have higher efficiency at lower energies than the FI devices, but were much more difficult to fabricate. One BI was placed at the on-axis focal position of the 6×1 array. Thus this particular CCD also provides high-resolution spectrometric imaging extending to lower energies, but over a smaller (8-arcmin-square) field than the 2×2 array. Both ACIS detector systems have thin aluminized polyimide filters to minimize contamination by visible light.

The Observatory's point spread function, as measured during ground calibration, had a full width at half-maximum less than 0.5 arcsec and a half-power diameter less than 1 arcsec. The prediction for the on-orbit encircled-energy fraction was that a 1-arcsec-diameter circle would enclose at least half the flux from a point source. The relatively mild dependence on energy, resulting from diffractive scattering by surface microroughness, attested to the excellent superpolished finish of the Chandra optics, less than about 3 Å rms. The ground measurements were, of course, taken under environmental conditions quite different than those encountered on-orbit. Most notably the effects of gravity on the optics and the finite distance and the size of the various x-ray sources used were unique to the ground calibration. On the other hand, on the ground there was no Observatory motion to deal with. On-orbit the performance includes the spatial resolution of the flight detectors and any uncertainties in the aspect solution. The on-orbit performance met expectations.

Scientific Results

X rays are produced by highly energetic processes — thermal processes in plasmas at temperatures of millions of degrees — or non thermal processes, such as synchrotron emission (realized when charge particles are accelerated by magnetic fields) or scattering of visible light or radio waves from very hot electrons. Consequently, X-ray sources are frequently exotic: supernova explosions and remnants, whose explosion shocks the ambient interstellar medium or a pulsar, a rotating neutron star, powers the emission; disks of accreting nearby material or jets around stellar-mass neutron stars or black holes; accretion disks or jets around massive black holes in the nucleus of galaxies; hot gas in galaxies and in clusters of galaxies that traces the gravitational field and can be used to determine the mass. These are all examples of sites of, and methods for, producing X-rays. Here we give several examples of observations by the CXO that illustrate its capability for investigating these processes and objects.

Chandra's capability for high-resolution imaging enables detailed high-resolution studies of the structure of extended X-ray sources, including supernova remnants (see Fig. 5), astrophysical jets (Fig. 6), and hot gas in galaxies and clusters of galaxies (Fig. 2). The additional capability for spectrometric imaging allows studies of structure, not only in X-ray intensity, but also in temperature and in chemical composition. Through these observations, astronomers are addressing several of the most exciting topics in contemporary astrophysics; e.g., galaxy mergers, dark matter, and the cosmological distance scale.

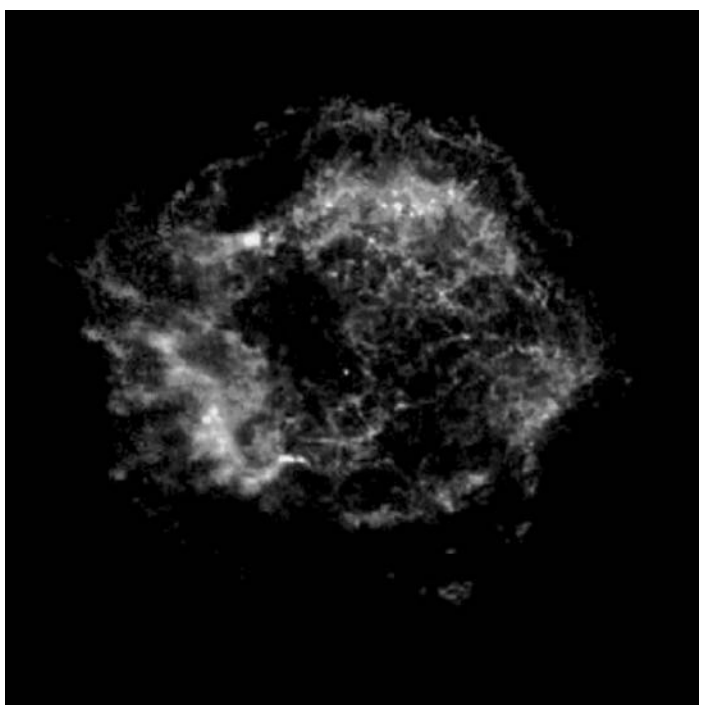

Fig. 5. Chandra image of the supernova remnant Cassiopeia-A based on about three-quarters of an hour of data. The point source at the center, previously undetected, simply leaps out of the Chandra image (*courtesy of NASA/Chandra X-ray Center*).

In addition to mapping the structure of extended sources, the high angular resolution permits studies of ensembles of discrete sources, which would otherwise be impossible. An example comes is the Chandra observation of the center of Andromeda (M31). See Fig. 7. The image shows what used to be considered as the emission associated with the black hole at the center of the galaxy now resolved into several objects. A most interesting consequence was that the emission from the central black hole is unexpectedly and surprisingly faint. Chandra observations are being used to isolate individual stars in clusters and star-forming regions and X-ray binaries in nearby normal galaxies. Furthermore, high-angular-resolution observations with Chandra are obtaining deep-field exposures likely to resolve most of the extragalactic cosmic x-ray background into faint, discrete sources.

Equally important to the imaging science is Chandra's unique contributions to high-resolution dispersive spectroscopy. As the capability for

Fig. 6. This Chandra image, 24 arc seconds on a side, shows details in the powerful jet shooting from the quasar 3C273, providing an X-ray view into the area between 3C273's core and the beginning of the jet (*courtesy NASA/Chandra X-ray Center/Smithsonian Astrophysical Observatory/Marshall et al.,* 2001).

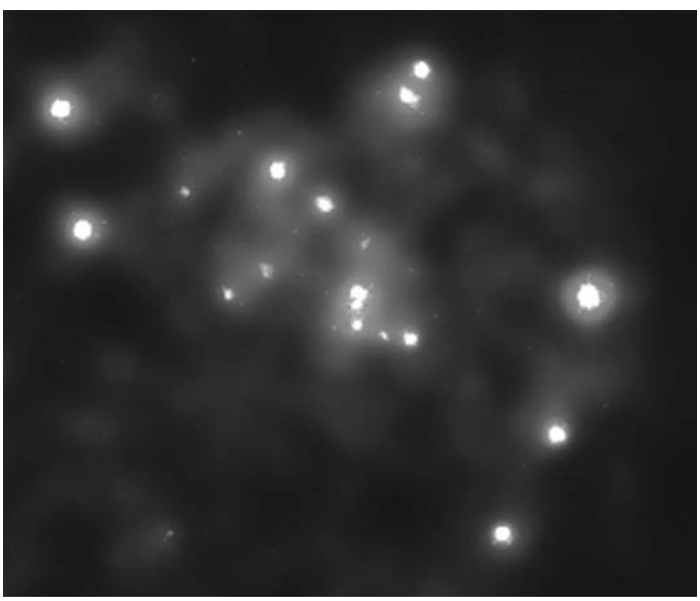

Fig. 7. Chandra image of the center of Andromeda (M31). The central region is resolved into five distinct sources, the faintest and coolest of which is shown at the center and is associated with the black hole at the center of the galaxy. (*NASA/CXC/SAO*).

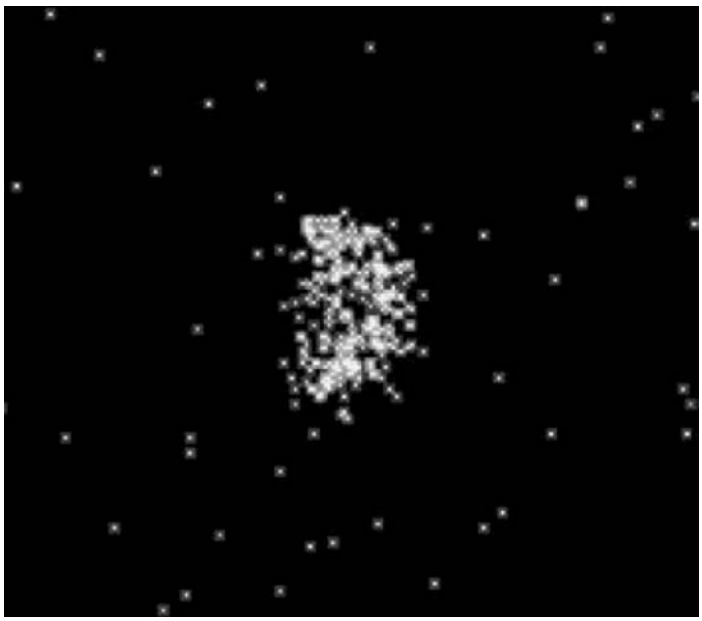

Fig. 8. Chandra image, the first X-ray image ever of Venus, shows a half crescent due to the relative orientation of the Sun, Earth, and the planet — the Sun is to the right. X-rays from Venus are produced by fluorescent radiation from oxygen and other atoms in the atmosphere about 130 kilometers above the surface (*courtesy of NASA/Max Planck Institute for Extraterrestrial Physics/Dennerl et al.,* 2002).

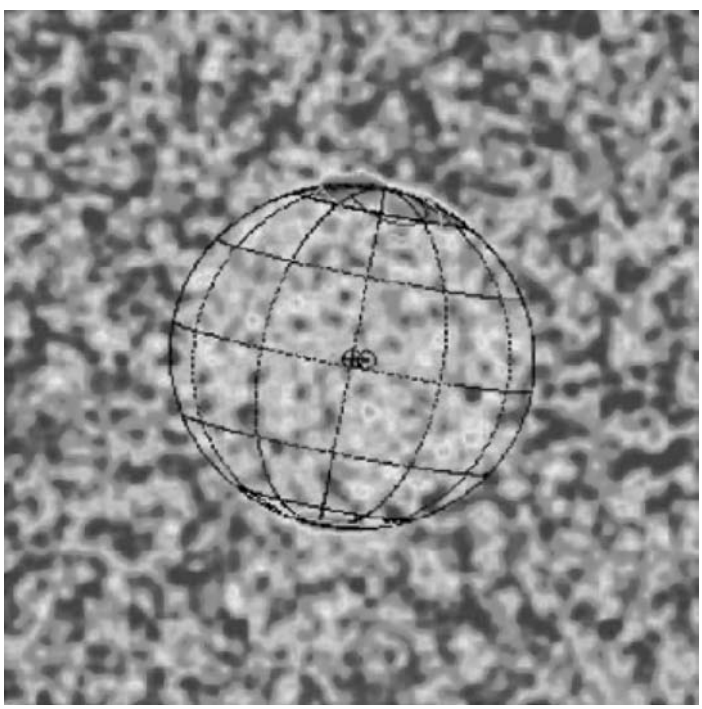

Fig. 9. Chandra image of X-ray emission from Jupiter. The red colors indicate the highest intensity. The bulk of the emission takes place near the magnetic poles (*courtesy of NASA/Marshall Space Flight Center/Gladstone et al.,* 2002).

visible-light spectroscopy begat the field of astrophysics about a century ago, high-resolution X-ray spectroscopy contributes profoundly to the understanding of the physical processes in cosmic X-ray sources. High-resolution X-ray spectroscopy is the essential tool for diagnosing conditions in hot plasmas. It provides information for determining temperature, density, elemental abundance, and the ionization stage of x-ray emitting plasma. The high spectral resolution of Chandra isolates individual lines from the myriad of spectral lines, which would overlap at lower resolution. It enables the determination of flow and turbulent velocities through measurement of Doppler shifts and line-widths.

Comets and Planets. Besides the Sun, which is too bright to be observed safely by the Observatory, other known X-ray sources in our solar system include Earth, the Moon, Venus, Jupiter and some of its moons, and comets. The X-rays from the Moon, Venus and, to a certain extent, Earth are due to the fluorescence of solar X-rays that strike the atmosphere. The discovery image of X-ray emission from Venus (Fig. 8) by Chandra shows a half crescent due to the relative orientation of the Sun, Earth, and Venus. Solar X-rays are absorbed in the Venusian atmosphere above the surface of the planet that knock electrons out of the inner parts of atoms and excite the atoms to a higher energy level. The atoms almost immediately return to their lower energy state and emit a characteristic or "fluorescent" X-ray. Similarly, ultraviolet light produces the visible light of fluorescent lamps. The origin of the X-ray emission from Jupiter (Fig. 9) is more complex

and not completely understood. Important ingredients are the presence of a magnetic field and rotation of the planet. Studies using Chandra should help provide a better understanding of the physical processes involved.
